of two separate plates put artificially together, we may conceive, that at any place where a solid body might be shorn across, the particles of the body, or the grains of which it is composed, fit into the interstices of each other; and the two parts into which the body may be divided or shorn are held firmly together by the cohesion of the particles over the whole surface where the division takes place (Fig. 90). In order to effect a separation by pressing the body in opposite directions, as with shears, we should have to overcome the cohesion, and the resistance which the asperities present to the slip across the rough surface of separation. The actual amount of cohesive attraction and the resistance from asperity, must mainly depend upon the peculiar nature of the material acted on; but the relative amount of resistance which two pieces of the same material of different dimensions present, seems to depend simply upon the number of particles separated; that is to say, on the area of the section or quantity of surface separated. Thus, to separate crosswise, a piece of iron 2 inches square, we should expect to apply four times as much force as would be required to separate a piece of the same iron 1 inch square, because the piece 2 inches square has an area of section, or a surface of separation, four times as great as the piece 1 inch square. But, farther, if we suppose the separation to be effected by means of shears (Fig. 91), so arranged that the 2-inch piece is placed twice as far from the pivot or fulcrum of the lever, of which the shears form the arms, as the 1-inch piece, we should have to apply double the force to divide the 2-inch piece, on account of the disadvantage of leverage; and, on the whole, in such a case we should require eight times the force to divide the 2-inch piece that we require for the 1-inch piece. If now, instead of shearing across a square bar, we apply this principle to the fracture of a cylindrical bar or shaft, by torsion, the centre of the shaft becomes the fulcrum of the lever, which we may assume to be one foot long; and each portion of the sectional area of the shaft resists separation with a force proportional to its area, and to its leverage or distance from the centre C (Fig. 92). If we take any small square of the section, such as A, and suppose a ring traced inclosing it, it is clear that the resistance of every part of that ring of particles, of the same magnitude as A, offers the same resistance, because it has the same leverage, or is equally distant from the centre; and that, therefore, the total resistance of the ring is as its area multiplied by its leverage A C. But if the ring be very narrow, its area is nearly its circumference multiplied by its breadth, and its circumference is as its radius A C; therefore its resistance is as its breadth multiplied by its radius twice, or the square of its radius.

Fig. 91.

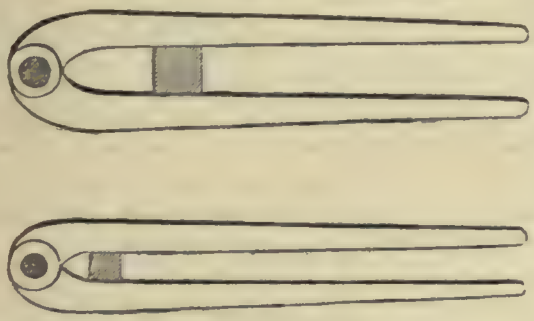

Fig. 92.

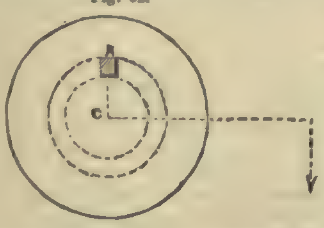
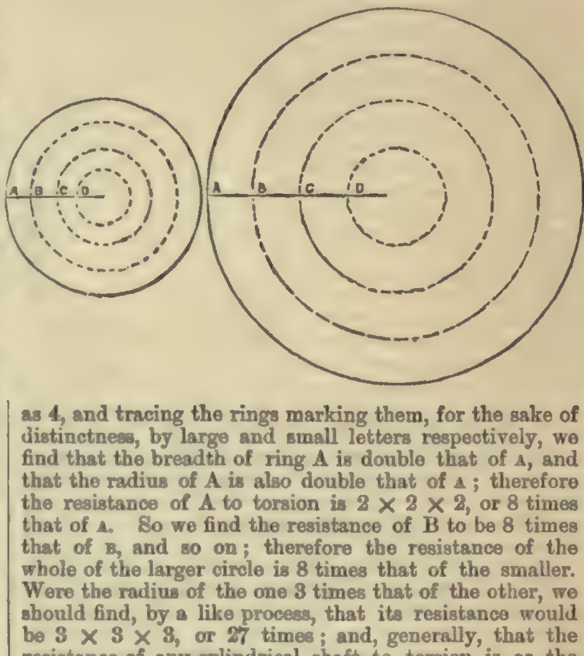


Were we to suppose, then, the whole circle divided into numerous narrow rings of equal breadth, the resistance of the whole to separation by torsion would be the sum of the resistances of all the rings, the resistance of each being as its breadth multiplied by the square of its radius. Now, if we compare a circle of one radius, such as 12 ins., with another, such as 6 ins. (Fig. 93), dividing each radius into an equal number of parts, such as 4, and tracing the rings marking them, for the sake of distinctness, by large and small letters respectively, we find that the breadth of ring A is double that of a, and that the radius of A is also double that of a; therefore the resistance of A to torsion is 2 × 2 × 2, or 8 times that of a. So we find the resistance of B to be 8 times that of b, and so on; therefore the resistance of the whole of the larger circle is 8 times that of the smaller. Were the radius of the one 3 times that of the other, we should find, by a like process, that its resistance would be 3 × 3 × 3, or 27 times; and, generally, that the resistance of any cylindrical shaft to torsion is as the cube of its radius, or of its diameter (which is the double of its radius).

Fig. 93.



This general proposition is almost self-evident; for if we admit that the resistance of any part of the circular section is as its area multiplied by the leverage at which it acts, the resistance of the whole circular section must be as its area multiplied by the mean or average leverage, of all its parts. The areas of circles are as the squares of their diameters, and in every circle, the mean leverage is proportional to the diameter; therefore the resistance to torsion is as the area or square of the diameter multiplied by the diameter—that is to say, as the cube of the diameter.

The reasoning we have used is founded on the assumption that the effect of excessive torsion is to divide or shear a shaft across at some place where the material is accidentally weaker than elsewhere. But in shafts of uniform strength throughout their length, and of fibrous texture, this is by no means the effect of destructive torsion. In a wrought-iron shaft, for instance, the fibres are made to twist, so that, in some cases, the outer surface presents the screw-form of a cord or rope; and ultimately they separate and present a fracture where parts seem to have been dragged out of their place by this twisting action. In producing such a twist of fibres, there must be a considerable elongation, particularly of the outer fibres; for it is longer round the thread of a screw than in a direct line from one end of a bar to the other; and the greater the diameter of the thread, or the farther it is from the centre, the longer is its course. If, then, we confine our attention to any set of fibres similarly situated, in two bars of different diameters subjected to torsion, we see, in the first place, that in the larger bar the number of fibres in the portion of the section referred to, is greater than the number in a similar portion of the smaller bar, in proportion as the square of the one diameter, or total area of the larger, exceeds that of the smaller. Again, in the larger bar the leverage of the set of fibres to resist the screw elongation, or the amount of the elongation which they have to undergo, exceeds that of the smaller, in proportion as the one diameter exceeds the other. Therefore, upon the whole, we must conclude, as before, that the resistance of the larger to torsion, is to that of the smaller, as the cube of the one diameter is to that of the other.

The same principles of reasoning apply equally to other than circular forms of section. The torsive strengths of square bars follow the same law; as do those of any other forms, provided they be similar, or have all their corresponding parts proportional. In comparing bars of circular with those of square section of equal diameter (Fig. 94), we readily see that the torsive strength of the square must exceed the other, not only on account of the square having the larger area, and, therefore, the greater number of fibres, or points of cohesion, but, also, because the additional area is situated at places farther from the centre, and, therefore, resisting with more leverage than any parts of the circular section. On the other hand, we observe, that while all the fibres of the circular section are supported against being forced aside by those around them, the fibres in the angles of the square section are not so supported, and may be expected to yield more readily to the twisting force. Upon the whole, it has been found that the torsive strength of the square section is about one-fourth greater than that of the circular. As the distance of any fibre from the centre contributes much to its resisting power, it may be advantageous to remove some of the material of a shaft from the inside, where it is of little value to resist torsion, and place it on the outside, where it acts with greatly increased leverage. On this principle, hollow or tubular shafts present the advantage of economising material, and securing strength with lightness; for each of the fibres in the ring section of a tube has so much greater leverage than those towards the centre of a shaft, that their number, and consequently the sectional area of the ring, may be considerably diminished without lessening the torsive strength.

Fig. 94.

From a number of experiments, made with a view of ascertaining the torsive strength of different materials, we are enabled to compile a table, from which the strength of a shaft of given materials and dimensions may be calculated; or, conversely, the dimensions may be computed of a shaft destined to sustain a given torsive strain.

Table of torsive strengths of cylindrical shafts 1 *inch in diameter; weights acting at* 1 *foot leverage.*

Name of material.	Permanent load.	Name of material.	Permanent load.
Brass	150 lbs.	Lead	34 lbs.
Copper	135 ,,	Steel (blister)	560 ,,
Gun-metal	170 ,,	Steel (cast)	590 ,,
Iron (wrought, English)	335 ,,	Steel (shear)	570 ,,
Iron (wrought, Swedish)	390 ,,	Tin	47 ,,
Iron (cast)	330 ,,		

The table, col. 2, gives the weight in pounds placed at the end of a lever 1 foot long, which a cylindrical shaft, 1 inch in diameter, will permanently sustain without injury; and the following rules embody the methods of computing the torsive strengths of other shafts, according to their diameter.

I. Given the diameter of a cylindrical shaft, and the length of lever at which the twisting weight acts, to find what weight it will permanently sustain.

Rule.—Multiply the number in the table three times by the diameter (in inches), and divide by the length of lever (in feet).

Example 1.—Required the strain that can be applied at the end of a lever 2 feet long to turn a cast-iron shaft 4 inches in diameter.

$$\frac{330 \times 4 \times 4 \times 4}{2} = 10{,}560 \text{ lbs., nearly } 4\tfrac{3}{4} \text{ tons.}$$

Example 2.—A rope passes round a pulley 3 feet in diameter, fixed to a gun-metal spindle 2½ inches in diameter; required the weight that may be attached to the rope.

Since the diameter of the pulley is 3 feet, the leverage of the weight is 1½ ft.; and

$$\frac{170 \times 2\tfrac{1}{2} \times 2\tfrac{1}{2} \times 2\tfrac{1}{2}}{1\tfrac{1}{2}} = 1{,}771 \text{ lbs., or nearly 16 cwt.}$$

II. When the shaft has a square section.

Rule.—Add ¼th to the weight.

Example.—Required the weight that may be hung to a lever 5 feet long, fixed to a wrought-iron (English) square shaft 2 inches broad.

$$\frac{335 \times 2 \times 2 \times 2}{5} = 536 \text{ lbs.}$$

$$\text{Add } \tfrac{1}{4} = 134 \text{ ,,}$$

$$670 \text{ lbs., nearly 6 cwt.}$$

III. Given the weight and lever, to find the diameter of a cylindrical shaft.

Rule.—Multiply the weight (in lbs.) by the length of lever (in feet), divide by the number in the table, and extract the cube root for the diameter (in inches).

Example 4.—A cast-steel spindle has to withstand the torsion of 5 tons at the end of a lever 8 feet long: required its diameter.

$$5 \text{ tons} = 11{,}200 \text{ lbs., and } \frac{11{,}200 \times 8}{590} = 152 \text{ nearly.}$$

The cube root of 152 is about 5⅜ inches.

IV. When the shaft is square.

Rule.—Multiply the weight by the lever, divide by the tabular number, deduct ⅕th of the result, and extract the cube root.

Example 5.—A square shaft of English wrought-iron has to sustain 6 cwt. at the end of a lever 5 feet long: required the breadth.

$$\frac{6 \text{ cwt.} = 672 \text{ lbs.} \times 5}{335} = 10$$

$$\text{Deduct } \tfrac{1}{5}\text{th} = \ 2$$

$$8, \text{ cube root 2 inches.}$$

The table and rules apply only to cases where a simple regular strain is applied. When shafts or spindles are intended to convey motion to machinery, they are generally subjected to great irregularities of torsive strain; and though they may only convey upon the whole a certain power, yet at different periods of their revolution they may be subjected to strains ranging from nothing up to many times the average strain due to the power they convey. If we consider for a moment the conditions under which the crank-shaft of a steam-engine rotates, we shall see the great variation of strain to which it is exposed. At two points of each revolution, what are technically called the *dead-centres*, the steam power has no effect to turn the shaft round; but, on the contrary, the momentum stored up in the fly-wheel turns the shaft, and through it gives movement to the parts of the engine. At two other points, when the connecting-rod of the engine is acting in the most favourable position, the shaft receives a torsive strain through the crank, greater than the total pressure of the steam on the piston; and the amount of this strain depends on the total steam-pressure on the piston, the obliquity of the connecting-rod, and the length of the crank. But all machinery is besides subject to accidental irregularities of strain. For instance, in the engines of a steam-vessel propelled by paddle-wheels, sometimes in a heavy sea, while the engines and paddles are moving at full speed, a wave strikes one paddle and suddenly immerses it to a great depth in water, so as at once to retard its rotation. The shock thus communicated to the engine, through the shaft which drives the paddle, is enormous, and occasionally more than 100 times the average force passing through the shaft. It is, therefore, essential to make all shafts intended to communicate power, of much greater strength than what is due to the mere average strain passing through them. The power that is communicated through any shaft is generally reckoned in horse-power; and as power consists of two elements—pressure or weight moved, and the velocity or speed with which it is moved—it is necessary to ascertain not only the assumed power passing through a shaft, but also the speed with which that shaft rotates, or the number of revolutions it makes in a given time, such as a minute, before we can compute the strain to which it is subjected, and the dimensions of which it should be made. The more quickly a shaft rotates in communicating a certain power, the less is the torsive strain to which it is subjected, for power is pressure or strain multiplied by velocity; and if, to produce a certain power, the velocity be increased, the strain must be proportionally diminished. The shafts of engines, and machinery connected with them, are generally made of wrought or cast-iron. As wrought-iron is more flexible and tenacious than cast-iron, it is less subject to fracture by sudden variations of strain, and is therefore preferable to cast-iron for shafts, and may be made considerably lighter. Again, the shafts which communicate the first effort of the power from the steam-pressure to the fly-wheel, are subjected to much greater variations of strain, than those which communicate the power afterwards from the fly-wheel shaft to other machinery. It is, therefore, advisable to give the first shafts, or prime movers as they are called, greater strength than is necessary for second movers. Practical men generally make the prime movers about twice as strong as the second movers; and the following rules embody the modes of computing dimensions of shafts for conveying given power at given velocities.

I. For wrought-iron prime movers, given the horse-power, and the number of revolutions per minute, to ascertain the diameter.

Rule.—Divide the power by the velocity, extract the cube root of the quotient, and multiply by 7, for the diameter in inches.

Example 1.—Required the diameter of a wrought-iron prime-moving shaft for 100 horse-power, making 20 revolutions per minute.

$\frac{100}{20}=5$, cube root 1·7 inches, and $7 \times 1·7=11·9$, nearly 12 inches.

II. For cast-iron prime movers.

Rule.—Divide the power by the velocity, and take 7½ times the cube root of the quotient.

Example 2.—Required the diameter of a cast-iron prime-moving shaft for 50 horse-power at 25 revolutions per minute.

$\frac{50}{25}=2$, cube root $1·26 \times 7\frac{1}{2}=9·45$ or 9½ inches.

III. For wrought-iron second movers.

Rule.—Divide the power by the velocity, and take 5½ times the cube root of the quotient.

Example 3.—Required the diameter of a wrought-iron second mover for 40 horse-power at 15 revolutions per minute.

$\frac{40}{15}=2·6$, cube root $1·4 \times 5\frac{1}{2}=7·7$ or 7¾ inches.

IV. For cast-iron second movers.

Rule.—Divide power by velocity, and take 6 times the cube root of the quotient.

Example 4.—Required the diameter of a cast-iron second mover for 22 horse-power at 36 revolutions per minute.

$\frac{22}{36}=0·6$, cube root $0·87 \times 6=5·22$ or 5¼ inches.

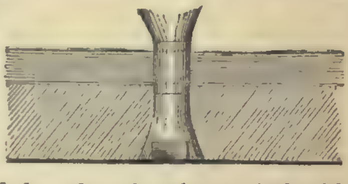
For shafts under very regular strain, and distantly connected with the prime mover, the multipliers may be for wrought-iron 5, and for cast-iron 5½.

The dimensions computed by the above rules are those of the weakest part of the shafts. When shafts are of great length, or have great weights, such as fly-wheels, and the like, fixed upon them, they are subject to the deflection due to transverse strain. This deflection in a revolving shaft is an important element of weakness, for it continually changes in direction as the one side or other of the shaft is uppermost, and thus subjects the material to all the degradation of alternate strains in opposite directions. In breaking a piece of wire, it is not unusual to bend it backwards and forwards until its tenacity is quite destroyed. The same kind of action occurs in a shaft too light for its length, or for the weight it bears, and gradually lessens its tenacity, and deprives the fibres of their continuous texture. The very best material employed in shafting undergoes a peculiar change in its molecular constitution, after having been long kept in revolution. The iron becomes quite short and crystalline, although at first fibrous and tenacious, and will often break off as short as cast-iron in a shaft which has been working for some years. This result is very common in railway axles, which are exposed to great vibration; and extreme cold has a similar tendency. For such cases the strengths should be made considerably in excess of what they are computed to be. In this, as in numerous other instances, experience must be the guide of the practical mechanic in the absence of set rules.

5. CLIPPING OR SHEARING STRAIN.—The strain which a body undergoes when it is divided across by means of shears, or any instrument consisting of two blades that pass one another like those of a scissors or shears, is of a kind very distinct from any of the other strains which we have discussed. Under *tensive* strain, the fibres are torn asunder by a force in the direction of their length; under *compressive* strain they are forced out of their place, and have their lateral cohesion destroyed; under *transverse* strain they are subjected partly to compression and partly to extension; under *torsive* strain they are extended in a screw or spiral direction; but under the *clipping* strain the particles are forced across each other, as we have described in endeavouring to investigate torsive strain on the principle of shearing.

Besides actual clipping by instruments for the purpose, there are various circumstances under which materials may be exposed to a strain of a similar character. In punching holes in a plate of metal, a similar action takes place. The punch (Fig. 95) is a piece of steel, the end of which is made of the size and shape of the hole to be punched, the edges being keen and not rounded off; the matrix is a block of steel, or iron faced with steel, having a hole such as is to be punched, with edges also keen. The punch and the matrix are so adjusted that the former shall pass exactly into the latter; and a plate of metal being placed on the matrix while the punch is up, has a hole pierced in it by its descent—the piece of metal being punched or pressed down into the hole of the matrix. When the edges of the punch and matrix are keen, and they accurately fit each other,

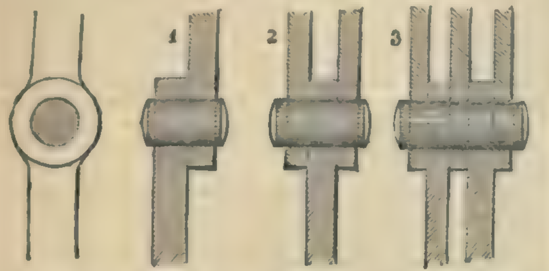
Fig. 95.



the metal of the plate is shorn cleanly round the circumference of the hole; and the force required to effect the operation, appears to be the same as would be required to shear a plate of the same material and thickness as that punched, over a length equal to that of the circumference of the hole.

Another example of shearing strain occurring in practice, is that to which the pins uniting the limbs of a chain are subject (Fig. 96). 1. If the joint consist of single limbs united by a pin, a strain applied to the limb longitudinally tends to shear the pin across at one place.

Fig. 96.



2. If the links be double and single alternately, the pin is exposed to be shorn at two places. 3. Where the links are three and two alternately, the shearing must take place at four places; and, generally, whatever be the number of links embracing each other at both sides, the number of places at which the pin must be shorn is double the smaller number of links. We naturally conclude that, if a certain power be required to shear a pin at one place, it would require double the force to shear it at two, triple at three, and so on, an additional force being required for each additional separation of the substance made. Practically, this is found to be true. Carrying the same reasoning to the consideration of the strains required for shearing pins of different sizes, we conclude that if we double the area of section—that is, the surface where the separation is effected or the number of fibres shorn—we have to double the force necessary to shear it. We, therefore, conclude that the strength to resist shearing, or the force required to shear, is proportional to the area of the body shorn at the place where the separation is effected: and here, also, our reasoning is borne out by experiment. A pin of iron 2 inches in diameter, requires 4 times the force to shear it that a pin 1 inch in diameter requires, because the area of the circle 2 inches is 4 times, or 2 × 2 times, the area of a circle 1 inch in diameter.

It is not uncommon, in machinery, to couple two rods A and B in the manner indicated in Fig. 97. The ends of the rods being turned truly cylindrical, and a socket C bored to fit on them, the ends are inserted in the socket, and keys D and E are driven into slits cut through the socket and the rods. On a great longitudinal strain being applied to the rods, so as to pull them out of the socket, fracture may occur in one of the following ways:—

1. Either of the rods, or the socket itself, may give way under the effort of direct tension; and if so, they must yield at the weakest place, which is manifestly where the keys pass through them, part of their sectional area being occupied by the keys, which add nothing to the cohesive strength.

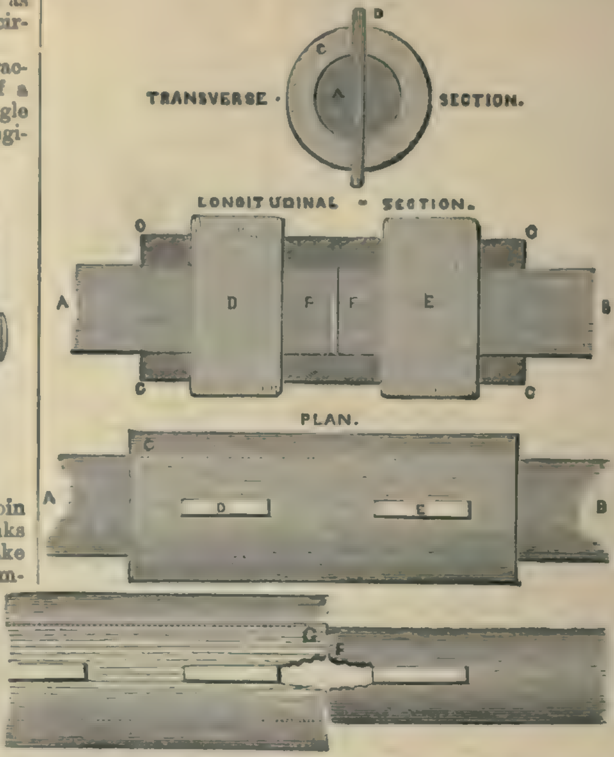
2. Either of the keys may be shorn across at the two places where they leave the socket, and enter the rods.

3. Either of the rods may have the material between the key and its end drawn out, so as to leave an opening F, the material forced out being punched or shorn, at both sides by the strain on the key.

4. Either end of the socket may have the material at G drawn out in a similar way.

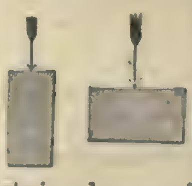
Now, if the material be of the same quality throughout, the strength to resist fracture in the 2nd, 3rd, and 4th ways may be equalised, because they are all shearing strains of the same kind, and we have only to make the several areas of the parts that would be shorn, all equal; that is to say, the sectional area of each key D and E should be equal to that of the end part F of each rod, because the shearing would separate two surfaces in either case; and the area of the part G of the socket need be only half that, because four surfaces would be separated. But we have as yet established no relation between the strength to resist tensive strain and that to resist shearing, and cannot, therefore, without further information, compute the proportional strength of the effective transverse sections of the rods and socket where the keys pass through them. The truth is, that very few experiments have been made upon the strength of materials to resist a shearing strain. Such as have been made with malleable iron, seem to show that it is precisely equal to the strength to resist tension. We believe that with other materials this law may be very safely assumed as correct. As the tensive strength is also proportional to the area of section, the areas to resist equal tensive and shearing strains should be equal. Accordingly, we should make the transverse sections of the rods and socket such, that the area of each part, on either side of the key, shall be equal to the transverse section of the key; for the key would be shorn at two places, and the rod or socket would be pulled asunder at the two places on either side of the key. On examining the figure, it will at once suggest itself that the keys should be made narrow and broad (measuring the breadth in the direction of the rods lengthways), so as to trench as little as possible upon the sectional area of the socket and rods.

Fig. 97.



Although for round or square pins, or bars, the law that the strength to resist shearing, is very nearly the same as the cohesive strength, yet there is little doubt that by increasing the depth of a bar exposed to be shorn, the breadth being diminished so as to retain the same area, the strength is materially increased. If we placed a bar of iron having 2 ins. × 1 in. of sectional area under a shearing strain edgeways, it would certainly resist more than when placed sideways. We are not aware, however, that experiments have been made to a sufficient extent to warrant us in laying down any law as to this.

Fig. 98.



In practice, no material error will arise from the assumption of the simple law we have already stated; and if strengths to resist shearing be calculated according to it, let the mechanic, as far as he can, contrive to bring the shearing strain against the greatest depth, and he will certainly be safe against fracture from this cause.

In punching a hole in metal, the surface of the separation produced, is the circumference of the hole, multiplied by the thickness or depth; and the resisting force should be equivalent to the tensive strength of a bar of the same material, having a sectional area equal to the surface of separation. Thus, in estimating the force required to punch a circular hole, 1 inch in diameter, through a plate of malleable iron ¾ths of an inch thick, we should reckon the circumference of a circle 1 inch in diameter is 3·1416 inches; multiplying by the thickness, ¾ths of an inch, we have the area of the surface of separation, 2·3562; and therefore the strength to resist the punching, is that of a bar of iron having a sectional area of 2·3562 square inches to resist fracture by tensive strain. The weight required to tear asunder a bar of iron 1 square inch in sectional area, is found, by experiment, to be about 26 tons; and the weight to tear asunder 2·3562 square inches would, therefore, be about 61 tons, which we reckon as the force required for punching the hole such as we have described.

The subject of shearing strain is, upon the whole, somewhat obscure. The experiments have been few, and made rather with a view to the solution of other questions than the determination of a law as to this strain. We would therefore caution the practical man against placing too much dependence on any computations made in respect of it. Where he is in doubt, and has no case practically carried out to which he may refer, it is far better that he should make experiments for himself; or, in the absence of data which he might deduce from them, at least he should make his work rather in excess of strength than otherwise. Great evils may often result from the execution of work, where the dimensions are too closely approximated to the results of calculation as to strains and strength. These evils are of an uncertain character—they may occur unexpectedly, under circumstances that may aggravate the mischief they cause; great expense may be incurred, limbs may be broken, life may be endangered or destroyed, and all because material has been grudgingly employed or disproportionally applied. But when strength is given in excess, to any structure intended to be permanent, the first evil, that of additional cost, is the only one—i tis known as to amount, is undergone, and appears not again—and the artificer has the satisfaction of thinking, that if difficulties or dangers arise during the use of the work he has contrived and formed, it must be from adventitious causes for which he cannot be held blameable.

Indeed, the whole subject of strength of materials is in an unsatisfactory state. Every new experiment made, every new work completed, adds somewhat to our practical knowledge in this department of mechanics. But so long as the materials we use vary in quality, are wanting in uniformity, and are subject to the changes which moisture, temperature, and other circumstances impose upon them, so long must we remain incapable of estimating correctly their strengths for any particular purposes, and so long must we be prepared to make large allowances for all such variations, and for contingencies which do not always readily suggest themselves.

CHAPTER IV.

SOURCES OF MECHANICAL POWER.

Contents.—MUSCULAR FORCE—WIND, DIRECT, OBLIQUE—WINDMILLS, SAILS, GOVERNORS—WATERWHEELS, UNDERSHOT, OVERSHOT, BREAST, AND COMBINED—DAMS AND LEADS—TURBINES—HYDRAULIC RAM—WEIGHT—FALLING BODIES—SPRINGS—HYDRAULIC LIFT AND CRANE—HEAT AND ELECTRICITY.

THE principal sources of power may be classed under five heads.

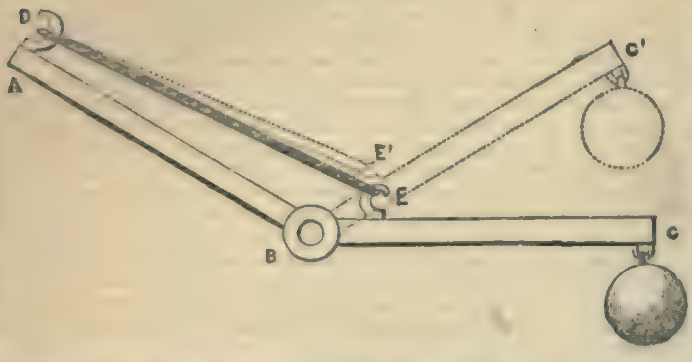
1. Muscular force of men and animals.
2. Natural movements of air.
3. Natural movement of water.
4. Weight and elasticity of bodies.
5. Heat, electricity, magnetism, and chemical action.

1. MUSCULAR POWER OF MEN AND ANIMALS.—It is not our province to discuss the mode in which the muscles of men and animals are put in action. This is a question which belongs to the physiologist. Suffice it to say, that the mechanism of animal structure is of that most perfect kind, which characterises all the works of Him who designed and executed it. The simple effort of *will*, or whatever that particular mental faculty be called, appears to communicate itself through the nerves which pervade the whole animal frame like a network of electric wires, and to operate immediately on the muscular tissue. The muscles, so far as we understand their nature, appear to have no innate force of their own, but are merely organised instruments put in action by the influence transmitted to them by the nerves, just as the index of an electric telegraph is perfectly inert until it is deflected, one way or other, by the subtile magnetic influence transmitted to it through the electric wire. Notwithstanding the immense variety of movements of which the different parts of the animal frame are capable, the action of the muscles, which effect those movements, is of one kind only—contraction in length, accompanied by expansion in diameter.

The eyes are caused to rotate in their sockets, and their focus as optical instruments can be varied; the lips, the tongue, the throat, and the jaws are moved so as to give voice to musical notes and articulate language; the shoulders, arms, wrists, hands, and fingers are put in motion so as to enable man to lift heavy weights, or to manipulate with consummate delicacy; the back, body, the legs and feet, are moved so that man may walk, run, or leap, row, or perform feats of strength and agility. And yet every one of these motions is effected by the longitudinal contractions of muscles under the nervous influence of volition. The frame-work of this exquisite machinery is the skeleton, consisting of numerous bones joined together. The form, length, strength, and situation of every bone have been devised with most minute care to suit its particular object. Each bone plays the part of a beam, and has attached to it a tendon or strong cord near its joint or fulcrum. This tendon is the end or continuation of a bundle of fleshy fibres, which constitute a muscle, fixed at the opposite end to some other part of the frame-work; and as these fibres contract in length under the nervous influence, the tendon or cord is pulled, and the bone or lever caused to move round its joint or fulcrum.

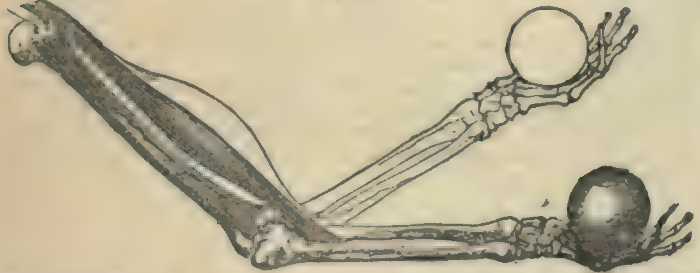
We may suppose A B (Fig. 99) to represent a fixed bar, having a joint at B fitted with a lever B C, from the extremity of which a weight is suspended; and D E a cord fixed at D to the bar A B, and at E to the lever B C. By shortening the cord D E we cause the lever to turn about its fulcrum B, to some such position as that marked by the dotted lines E′ C′. So in the human arm (Fig. 100), the upper bone is the bar jointed at the elbow; the radius bone terminates in the hand, in which a weight may be placed; the cord is the biceps muscle, fixed at the upper end, and terminating at the lower end in a tendon, which is fixed to the radius. The longitudinal contraction of this muscle pulls the tendon, and thus causes the radius to turn upon the elbow-joint, and raise the weight at its extremity.

Fig. 99.



Besides the direct movement of the bones as levers, such as we have described, there are numerous modified motions, sideways or rotatory, which are all effected by the contraction of muscles specially arranged for their respective purposes. For instance, in order to turn the hand upside down, it is necessary to make the arm rotate or turn upon its axis. This is effected by muscles placed spirally round the bones of the arm. By diminishing the length of one of these, the bones are caused to twist round. And so for every movement of every part of the frame, a special muscle is provided to effect the required motion by simple contraction.

Fig. 100.



The force or contracting energy of some of these muscles is enormous, as may readily be believed, when it is remembered that they are attached to the short end of a losing lever, and yet are capable of sustaining great weights at the extreme end, where the weight acts with immense leverage.

Some of the muscles are not placed exclusively under the control of the will, but act regularly without any effort of volition. Such are the muscles which effect the action of the heart, and organs of respiration. Some muscles, again, seem to be put in action by an effort of will of which we are not conscious. Such are those of the eye to direct and focus it, and those of the tongue, mouth, and throat in speaking. Although we *will* to speak or articulate certain sounds, we never think of the particular muscles that we must put in action, in order to effect the articulation desired. So in walking and other actions which have become familiar by habit, no thought is given to the special muscular movements required. It seems to be enough to *will* to walk, and the muscles obey. It is only when fatigue and exhaustion render their exercise painful, that we have to employ special acts of volition in order to effect our purpose.

In making use of muscular power as a moving force, it is important to call into exercise those muscles which require the least effort of will for their movement, and to apply them in the way least calculated to fatigue. The animals chiefly employed—the horse, the ox, and the camel—can only be used in particular ways, as for bearing and dragging loads. The horse and the ox are best adapted for dragging, as neither of them is capable of sustaining great weights. The camel, on the other hand, moves with facility under a very considerable load placed upon its back. The elephant is employed in tropical countries both for carrying and dragging, and appears to have enormous strength for either purpose. When human power is employed, it may be exercised in various ways. The operation in which man seems capable of exerting the greatest power, for the longest period, is that of rowing. In moving the oar against the resistance of the water, almost every muscle of the body is called into operation. The spine, bent forwards in the back-stroke, is thrown back as the pull is taken; the shoulders and arms are also thrown back, the legs are stiffened against the foot-board, and thus immense power is applied to the oar, without excessively straining any one or two particular muscles. In excavating earth or clay, conveying loads up steep inclinations by a wheelbarrow, and generally in the operations for which *navigators* are employed, a large amount of power is developed. The muscular frames of these men, and their long practice in particular operations requiring great strength, enable them to continue for long periods at work without much fatigue; and to one watching minutely their mode of working, while there is little appearance of effort, yet there is manifest a regulated play of the muscles, and a sort of contrivance for doing the work with the least possible movement, which indicate that every one of these muscular movements is the result of habit, without the need for a special effort of will.

In pumping, as in rowing, numerous muscles are exercised, and accordingly this kind of labour can be continued for a long period. There is, however, a monotony about the operation, and a want of visible effect to satisfy the mind of the workman, which tend to make him weary of his work. In rowing a boat, excavating, lifting or moving a load, there is a visible progress made, and the workman has a satisfaction in observing the change effected by his exertion, and can reckon the advance he has made, and the amount still remaining to be done; but in the continuous discharge of a body of water from a pump, drawn probably from an unseen source, and flowing into an unseen reservoir, or into one so large that additions to its contents produce no visible effect, there is nothing to reckon by, no progress apparent; and the workman accordingly becomes fatigued, more from want of mental satisfaction, than from actual weariness of body. It is true that cases frequently occur where seamen and passengers on board a leaky vessel, work for many days continuously at the pumps. But in such a case, life is at stake; and the excitement of danger, fear of death, and hope of safety, are impulses to exertion capable of overcoming much bodily fatigue and mental lassitude. In all operations demanding manual labour, it is good economy to let the workman see the effect of his efforts: let his mind be satisfied, and his body will the longer withstand fatigue. Where labour is used as a punishment, it is certainly an aggravation of the penalty to make the labour of a kind that manifests no result. The perpetual walking up the rounds of a treadmill, or perpetual turning a winch to drive unseen machinery, is therefore a penal labour of a most severe character, although the actual muscular exertion which either demands is not great. Prisoners working at the treadmill always prefer grinding corn to "grinding air," as they express the act of simply turning the wheel.

As rotatory motion is generally that kind of movement best applicable to machinery, being most easily modified in direction and velocity, labour at the winch is the kind of manual exertion chiefly used. Before steam machinery became common, the number of operations effected by manual labour was very much greater than it is now.

At present, except for special purposes—such as driving a printing-machine, or a turning-lathe, where the quantity of work to be done would not warrant the application of costly motive power—manual labour at the winch is little used. Engineers of the last generation, with whom human and animal labour was an important consideration as a source of motive power, devoted considerable care to experiments as to the best modes of applying it, and the quantity of power developed. The main result of their deductions was, that in moving machinery, the power of a horse was on the average equivalent to a weight of 33,000 lbs., lifted 1 foot high in 1 minute; and this has accordingly been adopted by engineers as a standard by which all powers, whether of steam-engines, water or wind-mills, are measured.

The power of a man is about one-fifth of that of a horse; that is to say, on the average, a man can exert a power equivalent to the lifting of a weight 33,000 lbs. one foot high in 5 minutes, or 6,600 lbs. one foot high in one minute. These estimates are not applicable to a single effort for a short period, but to labour such as could be sustained for hours daily, and continued on successive days. When the power of a man is continuously applied to a winch, it should not be estimated at more than one-half of that given above; that is to say, 3,300 lbs. raised one foot high in one minute. It is found in practice, that a man working a winch can, for a considerable period, move his hand through 120 feet per minute, exerting an average pressure of 30 lbs. At some parts of the revolution of the winch he exerts more than double this pressure, at other parts less than half; but, on the whole, the mean pressure may be taken at 30 lbs. Now, 30 × 120, gives a power of 3,600 lbs. raised one foot per minute, which is rather above the estimate of 3,300, given above. If the radius of the winch be 1 foot, the diameter of the circle in which the hand revolves is 2 feet, and its circumference $6\frac{2}{7}$ feet; therefore he makes about 19 revolutions per minute, for $19 \times 6\frac{2}{7} = 120$ nearly. For a short period, he could turn the winch at the rate of 25 or 30 revolutions per minute, and exert an average pressure at the handle of 40 lbs. to 50 lbs. But this high estimate should only be used in calculating when a weight is to be lifted during some minutes, and not when the work is constant. For driving machinery, affording a constant resistance during several hours, the lower estimate of the man's power, viz., 3,300 lbs., raised one foot high in one minute, should be taken.

In carrying a load on his back, over level ground, a man can develop a power of about 8,000 lbs. moved over one foot in one minute.

In carrying a load up a staircase, his power is equivalent to 2,000 lbs. lifted one foot high in one minute.

In dragging a hand cart on level ground, his power is about 20,000 lbs. moved one foot in one minute.

In rowing a boat, the power developed is about 25,000 lbs. moved one foot in one minute.

For temporary efforts, the following estimates have been made:—

A man can bear, for a short time, standing still, about 300 lbs. weight.

He can lift vertically about 280 lbs.

He can grasp by his hand with a pressure of about 100 lbs.

The principal applications of manual labour are not those in which great force is required to be developed. Dexterity and skill of manipulation are the qualities chiefly desired in a workman. As more and more progress is made in mechanics, so does the necessity for employing the bodily forces of men diminish. Indeed, a large proportion of the skilled workmen now employed are engaged in merely watching the operation of self-acting machines. Machines are more rigorously true in the work they perform than the hand; but they are limited to the constant repetition of similar operations. They cannot set their work, adjust their own movements, or vary their efforts, as man can do; but in all these matters they may be controlled by man. It is not our province to inquire into the moral effect produced on workmen, by the extended use of self-acting machinery. It is true that much of their corporal labour is saved, and that a vast deal more work is done more economically; and necessaries and luxuries are thus brought within the reach of millions who would else be deprived of them. At the same time, it must not be forgotten, that the workman is, to a certain extent, degraded into a mere machine, only a little elevated above that, the operations of which he watches and controls. He has no longer to acquire skill and dexterity in his craft—machinery does the work better than he could ever hope to do; he has not to think out the easiest and most effective methods of performing it—for the machine does a certain kind of work; the material is placed on it, the power is applied, and he has only to look on. Farther, the kind of work about which he is employed almost exclusively, is of the same unvarying character; and he is thus subjected to a monotony of occupation, which leaves many intellectual faculties dormant. In former generations, the millwright was a man conversant with machinery in general, and with the various operations required in its manufacture and application. He could make patterns, mould, forge, turn and fashion timber and metal to his uses; and generally—we may say necessarily—was a man of intelligence and ingenuity. Now we have patternmakers, moulders, smiths, turners, fitters, and workmen for attending planing, screwing, slotting, punching, and other machines; all, in a manner, different trades, requiring no versatility of mechanical talent, and not even dexterity of hand.

No doubt the vastly increased quantity of work is now done in all the better style for this subdivision of labour; but we fear the moral and intellectual character of the workman is considerably lowered.

2. NATURAL MOVEMENTS OF AIR.—History affords us no information as to the period when, or the race by whom, the movements of the winds and tides were converted into useful mechanical forces. Many savage nations, who for ages could have had no intercourse with people more civilised than themselves, possess vessels that float on the surface of the waters, impelled by the wind or the tidal currents of the sea and rivers, as well as by oars; and it is probable that the idea of utilising the motion of the wind, or the current of the water, suggested itself to many separate individuals, without any communication among each other. The most simple mode of applying the force of wind is that which is of most general use, the propulsion of vessels on the water. The most casual observation of the natural effects of wind, shows its greater power on larger surfaces than on small ones; and a little reflection would offer a reason for this, and suggest the extension of surface to receive the pressure of aërial currents, when greater force is sought to be derived from them. A savage floating in his canoe, finds that, by holding up the blade of his oar to catch the favourable breeze, he makes progress without effort; by holding up two oars, the velocity of his progress is increased; and by stretching between the oars a mat or skin, so as to increase largely the surface on which the wind can press, the speed of his canoe is proportionally augmented. From the first rude notion of a sail, the steps of transition to the complex rigging and arrangements of canvas in a first-rate man-of-war are easy and obvious; indeed, in making use of wind-power for propelling vessels, there are only two points requiring consideration: those are, first, the quantity of the force developed or required; and, secondly, the direction in which it is to be made to act. The amount of wind-force depends upon the velocity of its movements, and the quantity of surface on which it acts. At first sight it might appear, that by doubling the velocity of the wind, we should double its pressure on a certain area: but this is by no means the case, for on doubling the velocity, the pressure is quadrupled; on tripling the velocity, the pressure is increased nine times; and so on, the pressure being always proportioned to the square of the velocity, or the velocity multiplied by itself. On a little consideration, this law becomes obvious, as we will endeavour to show. Let us suppose the air to consist of a number of particles or

molecules; even if it do not consist of actual solid particles, we may, at all events, suppose it to consist of a number of separate masses, as small and light as we please; and though rare and attenuated as compared with solid bodies, yet certainly as much as they, subject to the general laws which govern all matter. Now, if we double the speed with which any one of these masses moves, we double the force with which it strikes on any body placed in its way; if we triple its speed, we triple the force of its blow; and so on, the force being always exactly proportional to the velocity, when any one mass or particle is taken into account. But when we extend our conception to the motion of an unlimited number of such particles, which constitute a continuous fluid, we observe that, by doubling the speed of the fluid's motion, we double the number of masses striking any body opposed to it in a given time; by tripling the speed we triple the number striking; and so on, the number of particles striking, as well as the force of each, being proportional to the velocity of movement.

Upon the whole, then, the pressure on any surface, arising from a continuous series of blows from masses of air, must be as the force of each, multiplied by the number in a given time; and as, on doubling the velocity, the number is doubled, the force or pressure is 2 × 2, or 4 times, on tripling the velocity the pressure is 3 × 3, or 9 times, and so on, the pressures being always, as we have stated above, proportional to the velocities multiplied by themselves, or the squares of the velocities. It is convenient to estimate the pressures of wind currents on some unit of surface, such as one square foot, while the velocities are generally stated as being at a certain number of miles per hour. The following table gives the pressures per square foot of surface produced by winds of different degrees of strength, as distinguished by their respective names, with the corresponding velocities in miles per hour.

Table of the Velocities of Winds in miles per hour, and their pressure in lbs. on a surface of one square foot.

	Miles per hour.	Pressure. lbs.
Hardly perceptible	1	0·005
Gentle breeze	5	0·123
Brisk gale	10	0·492
Very brisk gale	20	1·968
High wind	30	4·429
Very high	40	7·873
Storm	50	12·300
Great storm	60	17·715
Hurricane	80	31·490

The following is a simple rule for determining very nearly the pressure per square foot, when the velocity in miles per hour is known:—Multiply the velocity by itself, halve the product, and point off two figures to the right.

Example 1.—Required the pressure of a wind blowing at 40 miles per hour. 40 × 40 = 1600; half is 800; pointing off 2 figures, we have 8 lbs., which nearly agrees with 7·873, the pressure in the table.

Example 2.—Required the pressure of a tempest at 70 miles per hour.

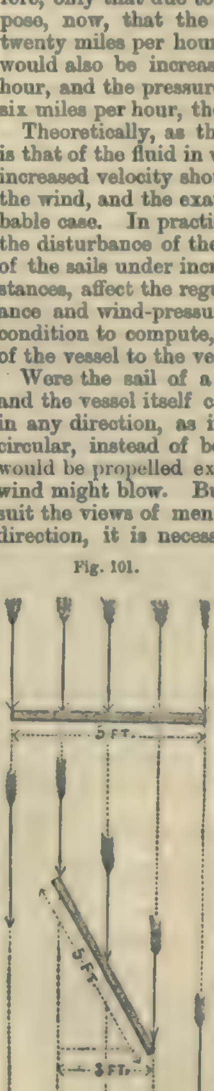
$$\begin{array}{r} 70 \\ 70 \\ \hline 2)4900 \\ \hline 24{\cdot}50 \text{ lbs.} \end{array}$$

The pressure of a wind on any surface, such as a square foot, being known, it is easy to estimate that on any other surface; for if, instead of 1 square foot, 2 square feet were opposed to the wind, we should find the pressure doubled in amount; on 3 square feet it would be tripled; and so on in regular proportion. Knowing, then, the velocity of the wind, we compute its pressure on any known surface by multiplying the pressure on 1 square foot by the surface in square feet. Thus, if we wished to ascertain the pressure of a gale at 20 miles per hour on a ship's sail 20 feet wide by 30 feet high, since 20 × 30 = 600 square feet of surface, and the pressure of the gale on 1 square foot being nearly 2 lbs., we have 600 sq. ft. × 2 lbs. = 1200 lbs., the total pressure on the sail.

When the wind is made use of as a motive force, the surface on which it blows must move with it, for if it simply rested opposed to the air, it would sustain pressure, but develop no motive force. The sail of a ship at anchor is certainly pressed on by the wind, and tends to force the vessel from its moorings; but until it does force it, no motive power is developed, for no motion is produced. But when a ship is in motion, the sail is, to a certain extent, going with the wind, and therefore receives a pressure due only to the excess of the velocity of the wind over that of the ship. Suppose the wind were blowing at the rate of ten miles per hour, and the ship sailing before it at the rate of seven miles per hour, the actual velocity with which the wind strikes the sail is only three miles per hour, the difference between its rate and that of the ship. The pressure on the sail is, therefore, only that due to three miles per hour. If we suppose, now, that the velocity of the wind increased to twenty miles per hour, the speed of the vessel propelled would also be increased probably to fourteen miles per hour, and the pressure on the sail would be that due to six miles per hour, the excess of twenty over fourteen.

Theoretically, as the resistance to the vessel's motion is that of the fluid in which it moves, the pressure due to increased velocity should follow the same law as that of the wind, and the example given above would be a probable case. In practice, however, the form of the vessel, the disturbance of the surface of the water, the bagging of the sails under increased pressure, and other circumstances, affect the regularity of the laws of water-resistance and wind-pressure so much, that we are not in a condition to compute, accurately, the ratio of the speed of the vessel to the velocity of the wind.

Fig. 101.



Were the sail of a vessel fixed in a middle position, and the vessel itself capable of moving with equal ease in any direction, as it would be if it were made quite circular, instead of being long and narrow, the vessel would be propelled exactly in the direction in which the wind might blow. But as this result would by no means suit the views of men desiring to sail in some particular direction, it is necessary to contrive the form of the vessel, and the position of the sails, so that the pressure of the wind in one direction may be converted into a pressure in another direction. The vessel is, therefore, made long and narrow, so that it may be subject to much less resistance from the water, when moving in the direction of its length, than if it were to move sideways; the sails are made capable of being turned about to different angles with the length of the vessel, so as to receive the wind obliquely; and, to direct the vessel and overcome any tendency of the wind to blow the front or back part of the vessel round out of its proper course, a rudder or helm is mounted at the stern, to balance, by its resistance in the water on one side or the other, the force tending to make the vessel deviate. When the wind strikes on a surface presented to it obliquely, its pressure is diminished. Suppose a certain surface five feet wide (Fig. 101) exposed directly to the wind, or at right angles to the direction of the wind, the pressure on it may be considered to be made up of five pressures each on one foot of the width. But if the same surface be turned obliquely to the wind, so that while the surface itself still remains five feet wide, the quantity of air intercepted is to be measured by three feet in width, the length of the line drawn at right angles to the direction of the wind intercepted between parallels to it from the extremities of the surface, then the pressure is only that on three feet of surface.

But besides the loss of surface from obliquity, there is also a loss in intensity of pressure. A column of air A D (Fig. 102) striking a surface exposed obliquely to it, would be reflected in D B, and press upon the surface in the line C D, which is perpendicular to the surface, and bisects the angle contained between A D, the line of impact, and D B, the line of reflection. The quantity of pressure compared with what it would be if the surface were not oblique, is found by taking A D any length, to represent the direct pressure, and drawing A C and D C respectively parallel and perpendicular to the oblique surface. Then, while A D measures the direct impulse, C D measures its effective impulse to move the surface in the direction D E, and A C measures the loss from obliquity, or the amount of force expended parallel to the oblique surface. and therefore not effective upon it.

Fig. 102.

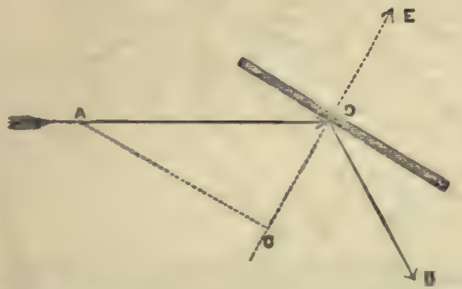


Fig. 103.

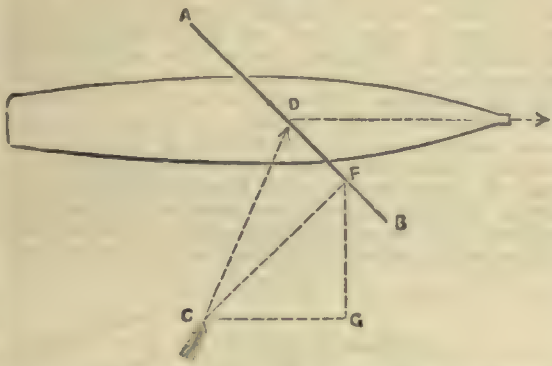
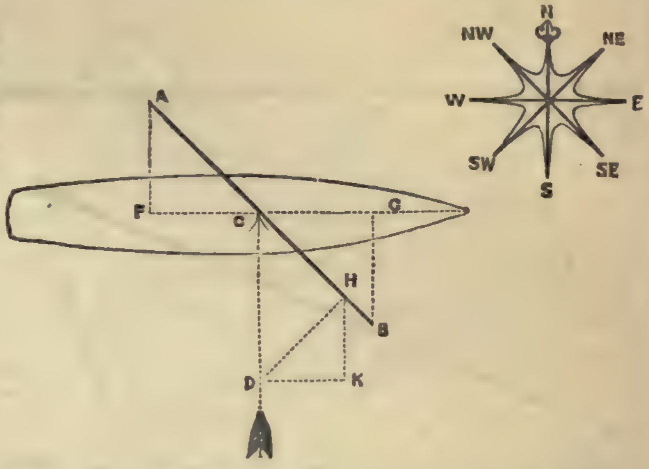


But farther, it is seldom the case that the effective pressure of the wind on the surface of a sail set obliquely to it, is employed directly. If A B (Fig. 103) represent the surface of the sail of a vessel, C D the direction of the wind, D E the direction of the vessel's course, we may take C D any length, representing the force of the wind; then C F, perpendicular to the sail, measures its effective force on the sail, and the length of C G, parallel to D E, and intercepted by F G, which is perpendicular to D E, measures the effective force in the direction of the ship's course. The line F G measures the effort of the wind to propel the vessel sideways, or to make what is technically called *leeway*.

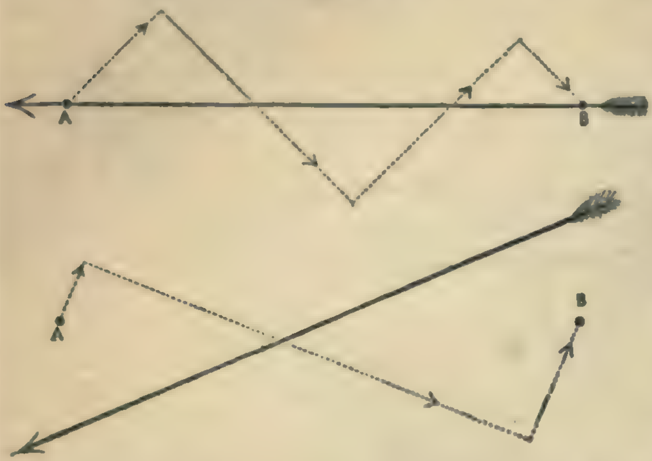
We may take a practical example as an illustration of how the effective impulse of the wind may be computed:—A sail 20 feet wide and 20 feet high is set with its edges directed to N.W. and S.E.; the wind blows at 30 miles an hour from the south, and the vessel sails due east with a speed of 10 miles per hour. Having drawn a plan of the vessel (Fig. 104), showing D C the direction of the wind, and A B that of the sail, in the first place from A and B we draw parallels to D C, cutting off F G, the effective width of sail to receive the wind. A B measures 20 feet, and F G would be found to measure about 14 feet; therefore the effective surface of the sail is 14 width × 20 height = 280 square feet. The velocity of the wind 30 miles per hour being represented by D C, its velocity, resolved perpendicularly to the sail, is measured by D H, about 21 miles per hour. This velocity, resolved into D K, in the direction of the vessel's course, becomes 15 miles per hour, which is to the actual speed of the vessel, 10 miles, as 3 to 2. The pressure on the surface of the sail is not that due to 21 miles per hour, the measurement of D H, because the vessel and sail are continually escaping from the wind; but to the excess of D H over the speed of escape, or the same part of 21 as 5 (the excess of the wind's velocity in D K over 10, the velocity of the vessel) is of 15, the wind's velocity in D K. As 5 is $\frac{1}{3}$rd of 15, and 7 is $\frac{1}{3}$rd of 21, the effective pressure on the sail is that due to 7 miles per hour—about 0·245 lbs. per square foot. This multiplied by 280 square feet, the effective surface of the sail, gives $68\frac{1}{2}$ lbs. for the pressure tending to blow off the sail from the mast while the vessel is moving at 10 miles per hour. Were the motion of the vessel entirely obstructed, the pressure on the sail would be that due to 21 miles per hour, about $2\frac{1}{4}$ lbs. per square foot, or $280 \times 2\frac{1}{4} =$ 630 lbs. The tendency of the wind to produce leeway, or to force the vessel sideways from its course, happens in this case to be the same as its direct force, for K H is equal to D K. If the vessel be six times as long as it is broad, the resistance to its movement sideways should be 6 times that to its direct movement, without taking into consideration the form of the part immersed. The shape, however, is made so as to offer as much resistance as possible sideways; so that, under equal impulses, the resistance to side-movement or leeway may probably be at least 10 times that to direct movement. It might be possible to compute the angle at which a sail should be set when the direction of the wind and the course of the vessel are given, so as to obtain the greatest possible effect. But as, in practice, the sails of a vessel are numerous and various in position and direction of action, it would be difficult to apply such a computation. A sailor, after a few trials of his vessel under sail, is able to estimate very correctly the angles of his sail and course with the direction of the wind, so as to get the best effect. If the wind blow almost directly against the ship, it is necessary to tack. If, for instance, in sailing from A to B (Fig. 105), the wind blew from B towards A, or nearly so, the vessel would be steered in various tacks or directions oblique to that of the wind, making progress on the whole. The choice of those tacks, so as to get over the given distance with as little deviation as possible, or, at all events, to do it with the least possible loss of time, is an important part of the sailor's art.

Fig. 104.



The force of wind has occasionally been applied to moving bodies on land, but not in a manner that can be generally used. Some of the Arctic voyagers having to travel long distances in sledges over ice, have taken advantage of a favourable wind to propel their vehicles by means of kites attached to them. Chariots have also been made with sails, so as to be propelled by wind along a road, as ships are propelled at sea. But the uncertainty and variations of the wind render such applications of its power matters of curious experiment rather than of practical utility.

Fig. 105.



Windmills.—For giving motion to machinery, windmills have been and still are very extensively used. Engineers of the last generation devoted great attention to the construction of windmills, and brought them to great perfection. The introduction of steam-power—a power economical, manageable, and always to be depended on—has, in a great measure, superseded that of wind as a mover of machinery. It is true that after the first cost of a windmill, the power is comparatively inexpensive; but it is so variable in intensity—sometimes, when it is not required, exerting great force, and sometimes, when it may be most wanted, totally ineffective—that it is generally preferable to apply a force, perhaps considerably more expensive in its production, but constant, steady, and completely under control.

Windmills are of two kinds, horizontal and vertical. The former have been very little used, for it is found in practice that they are by no means so effective as the latter. The mode of constructing a horizontal windmill is like that represented on the plan (Fig. 106), or some modification of the same principle of construction. A wheel, A, mounted on a vertical axis or shaft, and having flat vanes or boards fitted round its circumference, is inclosed in a circular casing, which is fitted with boards fixed obliquely, or in such lines as, if produced inwards, would touch the circumference of the wind-wheel. By this arrangement, the wind, from whatever point it may blow, causes the wheel to revolve in the same direction. Part of the breeze passes between the oblique boards of the casing, and acts on the blades of the wheel; while part is intercepted by the boards, and either reflected inwards so as to propel the blades in the same direction, or reflected outwards so as not to act upon them in the opposite direction. Sometimes horizontal windmills have been made with a casing partially surrounding the wind-wheel (Fig. 107), and capable of being turned round by means of a vane, so as to permit the wind only to act on one side of the wheel, while the other is completely sheltered.

Fig. 106.

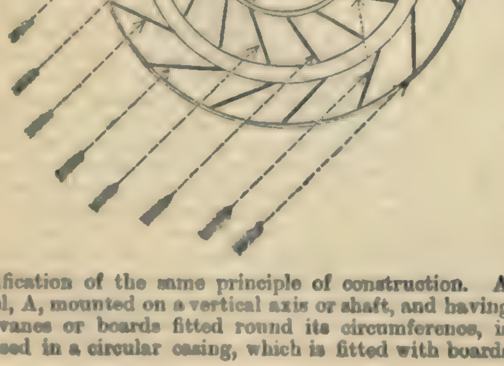


Fig. 107.

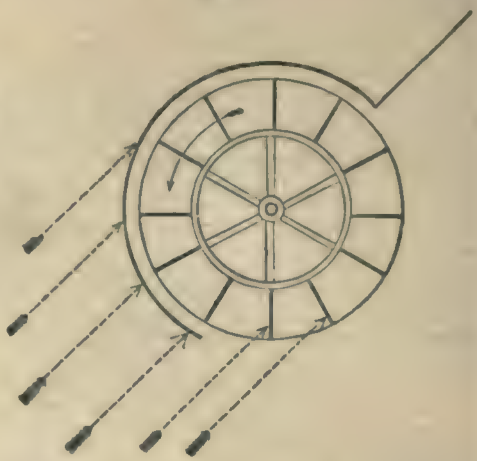
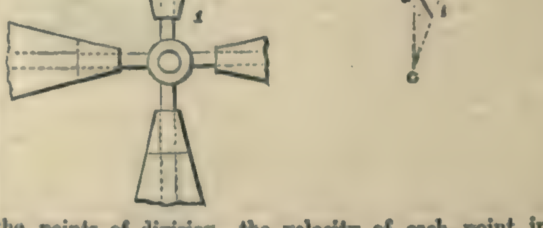


The vertical windmill, as is well known, consists of an axle or shaft, nearly horizontal, mounted in bearings at the summit of a tower, with four or more blades or sails attached to it. These sails are set at an angle with the axis, so that when the wind blows directly on the face of the mill, its oblique action on the sails is resolved into two forces—one in the direction of the axis, and the other perpendicular to it, the direction in which the sails revolve. Numerous experiments and computations were made to determine the most advantageous angles for setting the sails, and their most effective forms and proportions. If we suppose the radius of a sail divided into six equal parts (Fig. 108), and circles traced through the points of division, the velocity of each point in revolving, is proportional to the part of its circle intercepted between two radii, or proportional to its own radius. If, then, we make a series of plans of the sail at these different parts, we see that as we approach the centre we should increase the obliquity of the sail to its

Fig. 108.



plane of motion, so as to allow for its more slow escape sideways from the impulse of the wind. The sails accordingly are not made flat surfaces, inclined equally to the plane of their revolution, but surfaces of varying inclination, somewhat like portions of screw blades, twisting as it were from a certain obliquity at their extremes to a greater obliquity at the centre. The angles found most advantageous in practice are given by the celebrated engineer Smeaton as follow, as well as those used by some other engineers :—

Distance from centre	1	2	3	4	5	6
Inclination to plane of motion (Smeaton)	18°	19°	18°	16°	12½°	7°
Ditto (otherwise).........	24°	21°	18°	14°	9°	3°

In the angles given by Smeaton, an irregularity is observed in the first, which should, by theoretical reasoning, be greater than the second; whereas Smeaton makes it less. The following rule may be adopted as a very near approximation. To find the angle at which the sail should be inclined to the plane of revolution at any distance from the centre :—

Rule.—Multiply 18 twice by the distance from the centre; divide the product twice by the total radius, and subtract the quotient from 23; the remainder is the inclination in degrees.

Example.—In a windmill 60 feet in diameter, required the inclination of the sail 20 feet from the centre.

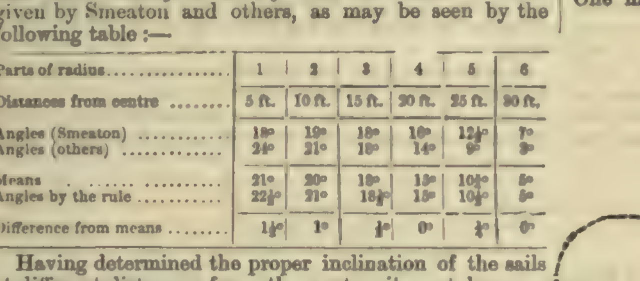
Here 30 feet is the total radius, and $\frac{18 \times 20 \times 20}{30 \times 30} = 8$, which, subtracted from 23, gives 15°, the angle of that point.

Were we to divide the radius 30 feet into 6 equal parts, and calculate the angles at each point, we should find them correspond nearly with the means of those given by Smeaton and others, as may be seen by the following table :—

Parts of radius................	1	2	3	4	5	6
Distances from centre	5 ft.	10 ft.	15 ft.	20 ft.	25 ft.	30 ft.
Angles (Smeaton)	18°	19°	18°	16°	12½°	7°
Angles (others)	24°	21°	18°	14°	9°	3°
Means	21°	20°	18°	15°	10¾°	5°
Angles by the rule	22½°	21°	18½°	15°	10½°	5°
Difference from means	1½°	1°	½°	0°	¼°	0°

Having determined the proper inclination of the sails at different distances from the centre, it next becomes important to inquire how much of the surface of the whole circle should be filled with sails. Mills are generally made with four strong wooden arms, or radii, fixed firmly in a central socket, and steadied and stiffened by tie-rods, connecting their extremities together, and with a projecting strut on the central boss. The width of each sail at the extreme, should be about half of the radius; so that in a mill 60 feet diameter, or 30 feet radius, each sail would be 15 feet wide at the extreme. The part of the arm next the centre, for about ⅙th of the radius, that is, 5 feet in the case supposed, is not fitted with sails, because the surface there is so little effective, as well from its short leverage as from its obstructing the wind reflected from the head of the turret behind it. The width at the inner end should be ⅓rd of the radius, or 10 feet. The surface of each sail is therefore 312½ square feet, and the total of the four is 312½ × 4 = 1,250 square feet.

Fig. 109.

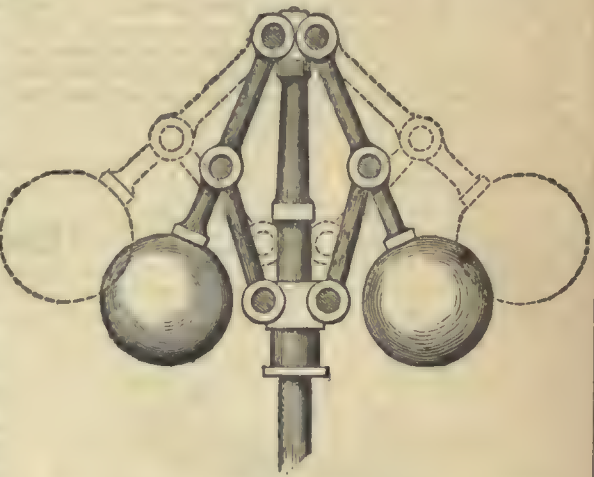


If A C be	. . .	30 feet.
Then A E	. . .	25 "
A D or E F	. .	10 "
A B	. . . .	5 "

The total area of a circle 60 feet in diameter is somewhat above 2,800 square feet, so that not half the surface of the circle is clothed with sails. There would be no disadvantage in extending the surface by making the sails broader, or more numerous, until it became ¾ths of the whole surface. Beyond this, additional sail-surface is disadvantageous, for it appears to obstruct the free passage of the currents reflected from the sails, and thus clogs their motions. It is found advantageous to arrange the surface of a sail somewhat in the proportions of the diagram (Fig. 109), which represents the front view of one sail.

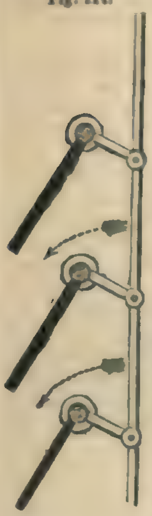
The covering of the surface, so as to catch the impulse of wind, formerly consisted of canvas fixed on a roller at one side of the arm, on which it could be rolled like a window-blind; or from which it could be unrolled so as to cover the whole sail, which was filled in with wooden framing to support the canvas pressed against it by the wind. Sometimes the canvas, instead of being in one sheet, was subdivided into numerous separate sheets mounted on rollers; and apparatus was provided so that the canvas might be wound on the rollers or unwound at pleasure, while the mill was in motion. As the wind is exceedingly variable, and as the quantity of work required of the mill also varies to a considerable extent, it was found necessary to provide some apparatus by which the mill might regulate itself, so that its velocity should not be excessive at one time and too small at another. One mode of effecting this object was to apply to the machinery of a mill a governor, like that of a steam-engine (which we shall have occasion to describe in detail hereafter). This governor consists of two heavy balls suspended from the summit of a vertical revolving spindle by jointed rods (Fig. 110). The spindle being at rest, the balls hang close to it on each side; but on the spindle being caused to revolve rapidly, the balls, impelled by centrifugal force, fly away from the central axis. as marked by the dotted lines. A system of levers and rods connected this apparatus with the sail-rollers, so that when the balls flew outwards, from increased velocity, the sails were furled; and when they fell inwards, from diminished speed of revolution, the sails were unfurled. The quantity of surface thus presented to the wind was adjusted to its force, and a tolerably equable velocity of the machinery was attained. In some more recent mills, an ingenious contrivance for regulating the surface of sail accord-

Fig. 110.



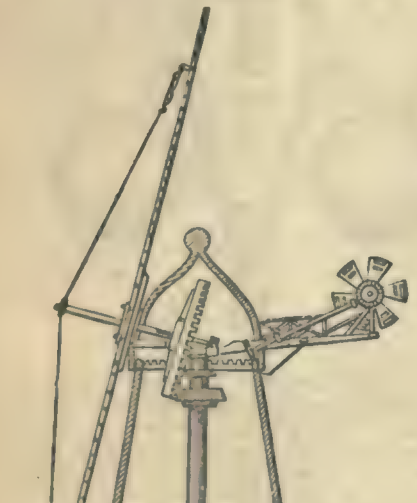
ing to the force of the wind, has been successfully adopted. The sails consist of a framework filled in with louvre-boards hinged on pivot-pins near one of their edges, and all connected by levers and rods, with a sliding-boss on the central axis of the windmill (Fig. 111). When the wind blows strongly against the louvre-boards, it forces them out of their vertical position, and passes freely through the openings between them. The surface of the sails is thus diminished by the pressure of the wind itself. To prevent its being too much diminished, the sliding-boss connected with the louvre-boards is pressed upon by a lever loaded by a certain weight sufficient to balance, as far as may be desirable, the pressure tending to force aside the louvres, and thus to keep them, to a certain extent, up to their work. When the load on the mill—that is to say, the quantity of work effected by it—is varied, the weight may be varied accordingly; and thus the effective amount of surface in the sails may be adjusted to the average force of the wind, and the work to be done by it. When the wind-force exceeds or falls short of its average, the greater or less inclination of the louvres very nearly compensates for the variation.

Fig. 111.



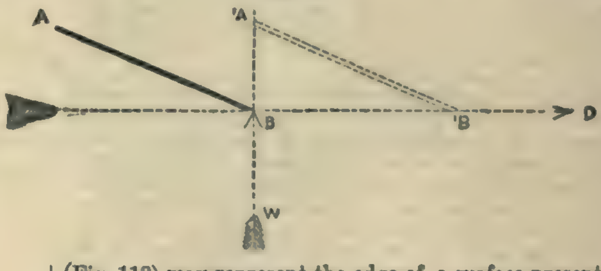
The sails of a windmill should directly face the wind in order to receive its most advantageous action; but, as the direction of the wind often changes, it is necessary to adopt some arrangement for varying that of the mill-shaft accordingly. The summit of the mill-tower, in which the mill-shaft is mounted, is therefore made to revolve, so that at any time the direction of the shaft may be varied, and the sails presented to the wind. In old mills, and indeed in many small mills still existing, this change of direction is effected by hand. A long lever is fixed to the movable cap or summit of the tower, and extends obliquely to the ground. The miller watches the direction of the wind, and by moving this lever, turns the cap round to its proper position. But in large mills this would require considerable power; and, moreover, constant attention would have to be paid to the changes of the wind. Were a single change neglected, the mill might be destroyed; for as the sails are made and strengthened by tie-rods to receive the wind's pressure on their face, a change of the wind to the opposite direction might throw a great strain on their back, for meeting which no provision is made. A simple mode of making the change of direction self-acting, is to fit the back of the cap with a large vane, which, like that of a weathercock, would cause the sails to be presented to the wind from whatever quarter it might blow. But when mills are of considerable size, the vane would require to be very large and cumbrous. The contrivance generally employed is neat and ingenious. Behind the cap (Fig. 112), on the side opposite that through which the wind-shaft passes, a framing is made to project outwards. On this framing there is mounted a small windmill, on an axis transverse to that of the main arms. The cap rests on rollers fitted in the circular top of the tower, so that it may move freely round; and a toothed circular rack is also fixed on the summit of the tower. A spindle, fitted with bevil-gearing so that it may be caused to revolve by the revolution of the small mill, conveys motion to a toothed pinion, which gears into the circular rack. When the main mill has its face presented to the wind, the small one stands edgeways to it, and therefore remains at rest; but as soon as the wind veers, it begins to act on one side or the other of the small mill, and thus causes it to revolve. The pinion is thus made to travel along the fixed rack, and turn the cap of the mill round, until the main mill is again brought to face the wind in its new direction. This arrangement is found to be very effective; and when it is properly applied, the mill requires no attention in respect of the direction of its sails to the wind.

Fig. 112.



In estimating the velocity with which the sails of a windmill revolve, we have to consider not only the force of the wind upon them, but also the resistance to their motion occasioned by the work done by the mill. A B (Fig. 113) may represent the edge of a surface presented obliquely to the wind, and capable of moving in the direction C D at right angles to that of the wind. If the surface be free and unresisted in its motion, and the wind be considered to produce its full effect upon it, the proportion of its velocity to that of the wind would be estimated by that of the line B B′ to the line B A′; for it is clear that while the wind travels over the distance B A′ the surface moves to the position dotted, that is, over B B′. But if the motion of the surface be resisted, its velocity in relation to that of the wind is diminished. In the case of windmill sails, we may suppose such a load of work on the mill that the velocity of the sails is not more than half what it would be were there no resistance. We may, therefore, assume that the velocity of the sail relatively to the wind would be expressed by the ratio of half the length of the line B B′ to the length of A B. Taking the wind as a gentle breeze, the velocity of which, in the table, is about 5 miles per hour, and the inclination of the sail or angle A′ B B′ half way from the centre 18°, we should find the half of B B′ to be about 1½ times A′ B, or the velocity of the sail 1½ × 5 = 7½ miles per hour—about 660 feet per minute. If the windmill be about 60 feet in diameter, the diameter of the middle point of the arm is 30 feet; the circumference of the

Fig. 113.



circle in which that point revolves is 94 feet, and the number of revolutions made per minute is therefore $\frac{660}{94}$ — about 7.

If, now, we calculate the speed of the extremities of the arms, we find that it is 1,320 feet per minute, or about 15 miles per hour; three times that of the wind, which we have assumed as 5 miles per hour. Did we assume a wind of greater velocity, we should have to take into account the self-regulating arrangement, which diminishes the amount of surface exposed, and therefore prevents the mill from attaining so much increase of speed as it would without regulation. Under ordinary circumstances, the speed of the outer extremities of the arms ranges from 20 to 30 miles per hour. We may assume 30 miles per hour when the wind blows at 10 miles, with a pressure of about ½ lb. on the square foot. The total surface of the sails unfurled, in a mill 60 feet diameter, is 1,250 square feet; we may suppose half lost by furling; leaving 625 effective. As the surface is set obliquely to the wind, the pressure in the direction of motion would be reduced from ½ lb. to about ⅐ lb., as a mean over the whole of the arms, giving a total pressure in the direction of motion of about 90 lbs. The mean velocity of the arms is half that of the extreme, 15 miles per hour, or 1,320 feet per minute. We have, therefore, 90 lbs. moving at 1,320 feet per minute, which is equivalent to a force of 90 × 1,320 = 118,800 lbs., moving at 1 foot per minute. A horse-power is reckoned as equivalent to 33,000 lbs., moved 1 foot per minute; therefore, the power of the mill we have reckoned is about 3½ horse-power.

When we double the diameter of a mill, we quadruple its power, for we quadruple its effective surface. The areas of circles are proportional to the squares of their diameters; and as the similar parts of the areas are occupied by sails, they are also as the squares of the diameters.

It is not at all an easy matter to estimate the powers of windmills. The proper guide as to power, velocity, and construction, is experience. Some of the works of Smeaton contain much valuable information respecting this branch of Practical Mechanics; and to these we must refer such of our readers as require a more full discussion of the subject than our limits permit us to offer.

As a force applied to the movement of machinery, wind has few advantages, except its little cost after the first outlay for a windmill has been made. It is chiefly available in flat countries, where there is no opportunity of obtaining the preferable power of water, and where there is little interruption to the aërial currents. In hilly countries windmills are often subject to derangement, from the excessive force of the gusts of wind that occur in such regions. In tropical countries, particularly islands and places near the sea-shore, the daily occurrence of the land and sea-breezes, occasioned by the action of the solar heat on the land, provides a certain amount of wind-power, which may be almost always depended on. But in these countries, on the other hand, there often occur tornadoes, or hurricanes of extreme violence, that sweep away almost everything that may oppose their progress; and thus frequently destroy windmills, and occasion renewed outlay in their re-construction. The principal use to which windmills are devoted in temperate climates, is for grinding corn; in tropical climates, such as the West Indian Islands, they are employed for driving sugar-cane mills. In fenny and marshy countries, such as Holland, or some of the eastern counties of England, they are used for drainage, either by working pumps or turning a wheel contrived for lifting the drainage water from the surface of the ground into canals at a higher level, by which it is carried off into the sea. In all situations, however, where the cost of fuel is not extravagantly great, steam-power is gradually superseding that of wind, because its certainty of action more than repays the cost of its production. Whole districts, the drainage of which is dependent on wind-power, may frequently remain many weeks under water from the prevalence of calm weather, and the agricultural operations of the season may be so seriously interfered with, that whole crops are lost, or become immensely deteriorated. In sugar-growing countries, again, the derangement of wind-machinery by a hurricane or tempest, may occur at the season when the sugar-canes have to be crushed; and the loss of a few days in crushing the canes, may seriously damage the sugar in respect of quantity as well as quality. Upon the whole, then, whenever the cost of fuel is not excessive, it is not advisable to incur the outlay of extensive works for securing wind-power. A very small steam-engine, kept constantly in operation, is far more effective than a windmill of much greater power, because the latter is so variable and uncertain in its action. The only operations suited to wind-power, are such as need not necessarily be completed at certain periods, but may be conducted occasionally as the wind may serve. Nor should the machinery driven by wind require very nice regularity in its action; for, notwithstanding all the ingenious arrangements for equalising the wind-force, it is still unsteady at the best.

Every part exposed to the wind should be greatly in excess of the strength required to resist the average strain to which it may be exposed. The tempest of an hour—nay, a momentary gust—may frequently destroy a windmill that has stood under ordinary winds for years. As a safeguard against too much strain, the windmill should always be left free to revolve, even if the machinery which it drives be thrown out of gear. The shaft or axis of the mill generally carries a large wheel, to which is fitted a strap of iron loaded so as to press on its circumference, and act as a friction-break either to hold the mill fast for purposes of repair during light winds, or to check its velocity when the winds are too strong for the work required.

WATER POWER.—The movements of water are much more serviceable for the purposes of power, and steady in their operation, than those of air. In level countries, where the streams are slow and languid in their flow, this power is not attainable; but in hilly countries, where the rivers and streams fall frequently from a high level to a lower, water-power is easily obtained, and is most advantageous as a steady, inexpensive prime mover. The most common way of employing water-power is to cause the current to act on the circumference of a large wheel, so as to give it a rotatory motion, which is communicated, by means of shafts and wheel-work, to the machinery required to be driven. Such water-mills are generally used for grinding or thrashing corn, crushing bones for manure, raising water to irrigate land; in mining districts, for crushing or otherwise operating on the ores; and in manufacturing districts, for working cotton, woollen, or flax machinery. Water-wheels are of three kinds, named according to the mode in which the water-current is made to act upon them:—

1. Undershot, when the wheel is fixed over a stream with inconsiderable fall, but considerable velocity.

2. Overshot, when the fall of the water is so great that the stream may be directed upon the upper part of the wheel.

3. Breast-wheels, when the stream can be directed on or near the middle or breast of the wheel.

1. *The Undershot-wheel* may be best understood by conceiving the action of the paddles of a steam-vessel reversed; that is to say, while in a steam-vessel the paddles are caused to revolve, and were the vessel fixed would produce a current in the water by their revolution, in the case of the undershot-wheel, the natural current of the water pressing on the floats immersed in it, causes the wheel to revolve. It is sufficiently clear that the power derived from this arrangement depends upon the intensity of the pressure which the water exerts on the floats, and the amount of surface pressed upon. If we suppose the wheel at rest, and its float standing vertically in the water, we may easily compute the pressure on every square foot of its surface by ascertaining the speed at which the water flows against it. This pressure, like that of the wind, is proportional to the square of the velocity of current; for by doubling the velocity, we

bring double the number of particles in contact with the float, and we also double the force of each particle in striking it; so that, upon the whole, we quadruple the pressure. So, also, by taking 3 times the velocity, we have 9 times the pressure; and, generally, if we know the pressure due to one velocity, such as 1 foot per second, we can compute that due to another velocity, such as 10 feet per second, by multiplying the velocity by itself, and taking the pressures in those proportions.

By an investigation of the mechanical laws which govern the motion of fluids, we ascertain that the velocity with which a fluid flows from an orifice in any vessel, is the same as that which a heavy body would acquire by falling through a height equal to that of the fluid column above the orifice.* This is found by the following rule:—Multiply the square root of the height (in feet) by 8; the product is the velocity (in feet per second). Thus, if a stone were dropped from a precipice 100 feet high (neglecting the resistance of the air to its fall), its velocity when it strikes the bottom would be about 80 feet per second; for 10 is the square root of 100, and 8 × 10 = 80 feet per second. If, on the other hand, we knew the velocity, we should be enabled to calculate the height of fall by reversing the rule; that is to say, divide the velocity (in feet per second) by 8, and square the result for the height (in feet). Thus, if we ascertained that a stone had in its fall acquired a velocity of 80 feet per second, we should reckon that it had fallen 100 feet, for $\frac{80}{8} = 10$, and 10 squared or $10 \times 10 = 100$.

These rules do not take into account the resistance offered by the air to the motion of the body falling through it. In falling through great heights, this resistance has very great effect on the velocity; but for small falls, it may be neglected without material error. If now, we apply these computations to the flow of currents of water, we can calculate the height due to a certain velocity of current; that is, the head of water whose pressure on its lower particles gives them the velocity in question. Thus, if on measuring the velocity of a stream at a rapid, we found it to be 16 feet per second, since $\frac{16}{8} = 2$, and $2 \times 2 = 4$, we should reckon that, in order to have this velocity, it must be pressed on by a column or head of water 4 feet high. It must, therefore, press upon any body immersed in it with the same force as it is itself subjected to; for it is the peculiar property of fluids to convey pressures equally in every direction through them.† It does not necessarily follow that, at the point where the velocity is measured, there is an actual fall of 4 feet: it is sufficient that the water has somewhere fallen enough to acquire the velocity measured, or that any forces whatever have combined to give it that velocity, or to reduce its velocity to that degree. The velocity is, in fact, the expression of the result of all the forces and resistances, that have acted on the water up to the point where it is measured. Having computed the head of water pressing, it is easy to compute the amount of pressure exerted on a square foot. A cubic foot of water weighs 62½ lbs.; therefore the bottom of a cubical box, measuring 1 foot every way, is pressed on by a force of 62½ lbs. when the box is filled with water; in other words, the pressure of a column of water 1 foot high, is 62½ lbs. on every square foot of bottom surface. Were the height of the column increased, the pressure would be increased in like proportion; every additional foot of height would throw an additional pressure of 62½ lbs. on every square foot. The intensity of pressure (in lbs. per square foot), then, is 62½ times the height in feet. Thus, the pressure due to a head of 4 feet, is 62½ × 4 = 250 lbs. per square foot. We may now combine the two computations—that for head due to given velocity, and that for pressure due to given head—into one rule, for determining the pressure per square foot due to a given velocity, as follows:—As the square of 8 is 64, which does not much differ from 62½, we may, without material inaccuracy, avoid dividing the velocity by 8 before squaring the quotient, and again multiplying by 62½, and thus have the very simple rule.

Square the velocity (in feet per second), and the result is nearly the pressure (in lbs. per square foot). Thus, when the stream is moving with a velocity of 16 feet per second, its pressure per square foot is 16 × 16 = 256 lbs. nearly. By the former computation, we found 250 lbs., less by 6; that is, less than $\frac{1}{41}$st part of the whole. So far we have found the means of computing the pressure on a float-board *at rest*, in a stream flowing with a given speed; but in the case of an undershot water-wheel, the float is in motion in the same direction with the current, and therefore the relative velocity of the latter, in acting upon it, is so much diminished. The relative velocities of the float and of the current may, of course, be varied by applying more or less resistance to the motion of the wheel. It is necessary to know the relation of the two velocities, so as to derive the best possible effect from the current. If we take a particular case, and try various relations, we may find the most advantageous—bearing in mind that the result to be obtained is the maximum of power or useful effect; that is to say, the pressure on any float multiplied by the velocity of its motion, which product gives the power of that float as a mover of machinery. If we take the velocity of a current as 6 feet per second, and form a table of velocities of float from 0 feet per second up to 6 feet per second, of pressures due to the excess of the stream's velocity over that of the float, and of the powers or products of those pressures multiplied by the corresponding velocities of float, we shall find the power greatest when the velocity of the float is exactly 2 feet per second, or ⅓rd of that of the stream. Thus—

Velocity of stream.		Velocity of float.		Excess of stream over float.		Pressure or excess squared.		Power or press. × veloc.
6	....	0	....	6	....	[illegible]	....	0
”	....	1	....	5	....	25	....	25
”	....	2	....	4	....	16	....	32
”	....	3	....	3	....	9	....	27
”	....	4	....	2	....	4	....	16
”	....	5	....	1	....	1	....	5
”	....	6	....	0	....	0	....	0

Were we to take any other velocity of stream we should find the same result, that the velocity of the float should be ⅓rd of that of the stream, in order to attain the maximum effect.‡ If this rule be adhered to, the excess of the stream's velocity over that of the float is ⅔rds of itself; and the pressure per square foot would be the square of ⅔rds of the stream's velocity, or $\frac{4}{9}$ths of the square of the velocity, since $\frac{2}{3} \times \frac{2}{3} = \frac{4}{9}$. The power would depend on the number of square feet pressed upon, and the velocity of the float, and would therefore be found by multiplying the surface of the float by $\frac{4}{9}$ths of the square of the stream's velocity, and the product by the float's velocity, or ⅓rd of the stream's velocity. As there are generally several floats immersed in the water, it may appear that the surface acted on is considerably larger than that of one float; but when it is remembered that the volume of water contained between any two of the floats, if it press the one forward by its direct action, must equally press the other backward by its reaction, we cannot safely estimate more than the surface of one float as really effective. The velocities of currents are generally reckoned in feet per second, while the velocities of moving parts of machinery, in estimating

---

* See *ante*, *Hydrodynamics*, p. 761.

† See *ante*, p. 751.

‡ If $V =$ velocity of stream, $v =$ velocity of float, $p =$ pressure per square foot $= (V - v)^2$ and $P =$ power $= pv = \overline{V - v}|^2 v$, to find v, so that P may be a maximum.

$$P = \overline{V - v}|^2 v = V^2 v - 2Vv^2 + v^3.$$

$$\frac{dP}{dv} = V^2 - 4Vv + 3v^2 = 0.$$

$$\therefore v^2 - \frac{4}{3}Vv = -\frac{V^2}{3} \text{ and } v^2 - \frac{4}{3}Vv + \frac{4}{9}V^2 = \frac{1}{9}V^2.$$

$$\text{Hence } v - \tfrac{2}{3}V = \pm \tfrac{1}{3}V, \text{ or } v = V, \text{ or } \tfrac{1}{3}V.$$

$\frac{d^2P}{dv^2} = -4V + 6v$, and substituting for v each of its values.

$-4V + 6V = 2V$ positive, gives P a minimum when $v = V$.

$-4V + 2V = -2V$ negative, gives P a maximum when $v = \frac{1}{3}V$.

power, are reckoned in feet per minute. Taking a horse-power as 33,000 lbs. lifted one foot high in one minute, and assuming the circumferential speed of an undershot-wheel as one-third of that of the current, we may estimate its power as a mover of machinery by the following rule :—

Multiply the surface of the float (in square feet) three times by the velocity of the stream (in feet per second), and divide the product by 3,800 ; the quotient expresses the horse-power.

Example.—An undershot-wheel, having floats 2 feet deep and 10 feet wide, is moved by a stream running at $7\frac{1}{2}$ miles per hour : required its power.

Here the surface of a float is $10 \times 2 = 20$ square feet.

The velocity is $7\frac{1}{2}$ miles per hour : or (as a mile is 5,280 feet, and an hour 3,600 seconds) the velocity is $\frac{5280 \times 7\frac{1}{2}}{3600} = 11$ feet per second.

The power therefore is $\frac{20 \times 11 \times 11 \times 11}{3800} = 7$ horse-power.

The speed of the floats being $\frac{1}{3}$rd of that of the current, is $\frac{11}{3}$ feet per second, or $\frac{11 \times 60}{3} = 220$ feet per minute. We may take this as the speed of the middle part of the float ; and if the wheel be 23 feet in extreme diameter, its diameter at the middle of the floats would be 21 feet, and circumference there 66 feet ; if this move at the rate of 220 feet per minute, the wheel must make $\frac{220}{66} = 3\frac{1}{3}$ revolutions per minute.

The speed of a stream may be generally estimated by throwing on it a body that floats, but is immersed some depth—as a bar of wood loaded at one end to float vertically—and watching the time occupied by its passage over a certain known distance. Care should be taken that the body fairly attain the speed of the current before its motion is reckoned in the time.

It is advantageous to make the inner edges of the floats to stand somewhat above the general level of the water, which becomes heaped up behind them, and would otherwise pour over the edges (Fig. 114). Indeed, the difference of level caused by this heaping up of the water behind, and its hollowing in front of a float, almost measures the head of water pressing on it. When practicable, the stream should be narrowed to the width of the wheel (Fig. 115), as by this means not only is its velocity augmented by the necessity of a certain body of water passing more quickly through a diminished channel ; but also the water, acting on the floats, is prevented from escaping sideways without giving its full effect.

Fig. 114.

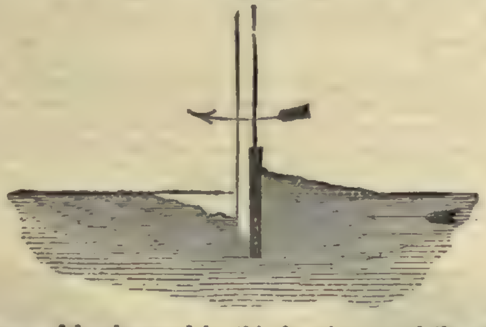


Fig. 115.

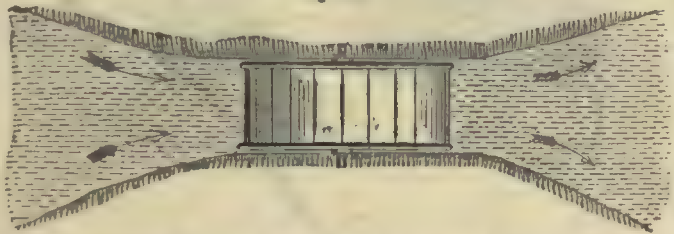
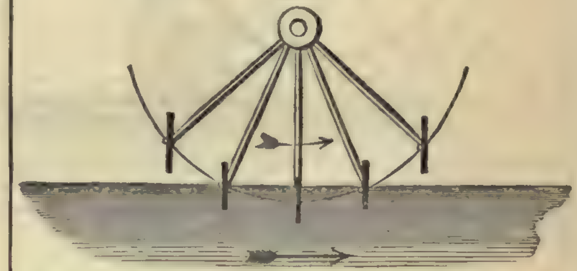


As the velocity of streams to which undershot-wheels are applicable is never very great, and as the velocity of the floats should not much exceed one-third of that of the stream, such wheels are necessarily slow in their revolution, and can therefore be applied with most advantage, in driving machinery where quick speeds are not required. When it is necessary to convert the slow revolution of the wheel to rapid motions in the machinery, there are considerable losses from the friction of the gearing. For such purposes as that of working pumps or fulling-mills, and generally for slow, heavy work, these wheels are very serviceable. The principal objection to their use arises from the circumstance, that with a stream of average rapidity, very little power is obtained without a very large and cumbrous wheel, involving considerable outlay, and extending over a great breadth of the stream. By making the diameter of the wheel large, no greater power is obtained, except what may be attributable to the more direct action of the water on the floats, which enter and leave the water more vertically when the wheel is large. The circumference of a large wheel should move with the same speed as that of a small one ; and, therefore, the greater the wheel, the smaller number of revolutions does it make in a given time. The only way of increasing the power is to extend the surface of the floats. This may be done by making them deeper or wider. Additional depth of the float, even where the depth of the stream permits it, is by no means so effective as additional width ; for a wide shallow float enters and leaves the water with ease, while a deeper one presses the surface of the water down in entering, and lifts it up in leaving, and thereby encounters considerable resistance to its motion.

Occasionally undershot-wheels have been made like the feathering paddles of steam-vessels, where the floats are capable of being turned on pivots (Fig. 116) so as to maintain a vertical position while immersed in the water, and thus receive its most direct impulse, while they enter and leave it with the least possible resistance.

Fig. 116.



When it is considered that twice in every day a great tidal stream flows and ebbs along our coast and in our estuaries, it is surprising that advantage has not more frequently been taken of this enormous power by the erection of undershot-wheels along the course of the tidal currents. In this country tide-mills are rare ; and neither their number nor magnitude render them important as sources of power. Occasionally, however, they have been employed with advantage. Where there is a great tidal stream, and consequently a considerable difference between the levels of high and low-water, fixed wheels would be almost useless ; for at high-water they would be too much immersed, and at low-water too little. It is in such cases necessary to mount them on a floating stage or barge, so that the whole mill may rise and fall with the tide, the amount of immersion remaining constant. Again, as the tide flows alternately in opposite directions, when it is required that the machinery move only in one direction, it is necessary that tide-mills, in such cases, should be fitted with apparatus by means of which the direction of movement may be reversed; or, where the mill is floated on a barge, the swinging of the barge by the tide effects the required change of position to suit the change in direction of the current.

If it were practicable to make use of the tidal stream in such a river as the Thames, without interfering with its navigation, the power derived from it would be enormous. If we suppose the breadth, 1,200 feet, occupied by tidal mills side by side, with floats immersed 3 feet deep, the total float-surface would be 3,600 square feet in one section of the river. The velocity of current we may take, on the average, as 3 miles per hour, nearly $4\frac{1}{2}$ feet per second; and the power, according to our rule, would be

$$\frac{3600 \times 4\frac{1}{2} \times 4\frac{1}{2} \times 4\frac{1}{2}}{3800} = 86 \text{ horse-power.}$$

Were such mills repeated at intervals of 220 feet along a mile of the river, there would be 24 of them, and the total power would be 86 × 24 = 2064 horse-power in a mile of the river's length. It is not, of course, presumed that such an arrangement is feasible: it is only offered as an illustration of the great mechanical power that might be derived from the natural movements of the water in tidal estuaries. In some rivers, such as the Rhine and the Seine, barges are moored carrying tidal mills of this kind. In such streams the level does not greatly vary, and the current sets continuously in one direction, so that the power is applied with constancy and facility.

Fig. 117.

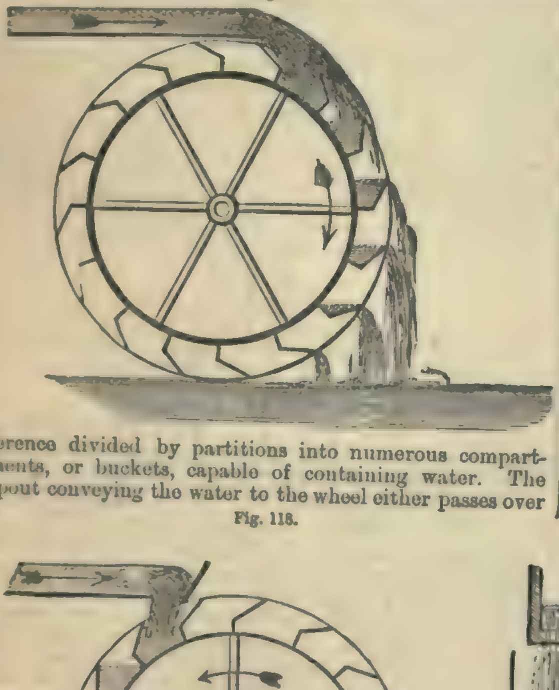


Fig. 118.

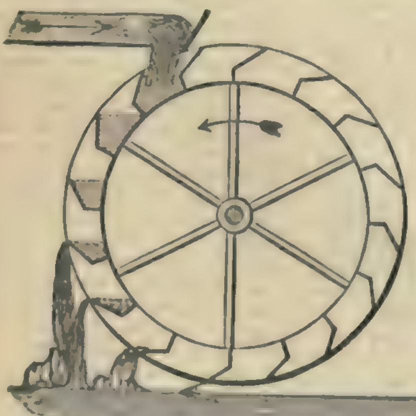


2. *The Overshot Water-wheel* (Fig. 117) has its circumference divided by partitions into numerous compartments, or buckets, capable of containing water. The spout conveying the water to the wheel either passes over its summit, or has a check at its end (Fig. 118), so as to discharge the water into the buckets a little beyond the summit of the wheel. As the wheel revolves, each successive bucket is brought under the spout and becomes filled with water, the weight of which, acting on one side of the wheel, is the moving force. The buckets, as they descend, become gradually emptied, and return up the unloaded side of the wheel, to be again filled, and descend.

Such wheels are only applicable where there is a considerable fall of water; for the height of the head, above the stream as it flows away from the wheel, technically called the *tail-water*, must be equal to the diameter of the wheel, or nearly so. In overshot-wheels the velocity of the water is no element of power, except in so far as the quantity conveyed by the spout to the wheel depends upon the velocity with which it flows. If the velocity of discharge be considerable, a positive disadvantage results from the too rapid dash of water into the buckets, causing it to overflow, while the bucket remains only partially filled. It is easy to see that the quantity of water issuing from the spout during the time which a bucket occupies in passing under it, should barely exceed that which the bucket will hold; if it fall short of that quantity, the bucket is only partially filled in its passage; and if it much exceed that quantity, the force of its flow causes it to dash over and become wasted without effectually filling the bucket. The diameter of the wheel being limited by the height of the fall, when it is desirable to take advantage of a large quantity of water discharged from the spout, the breadth of the wheel must be increased, and the water in the spout caused to spread itself out to a wide sheet, so as nearly to cover the whole breadth of the wheel. The sheet of water should always be a few inches narrower than the face of the wheel, to save the water from dashing ineffectively over the edges (Fig. 119). Another point of great importance in the construction of the buckets, is to leave a passage for air at the inner upper angle of each bucket, *a*, *a*, *a* (Fig. 119), otherwise the bucket can become only partially filled, in consequence of the elasticity of the air confined in it compelling the supply-water to dash over the edges instead of filling the bucket.

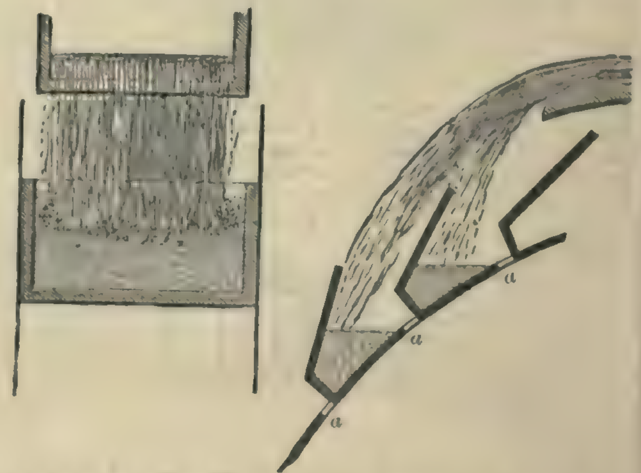
In constructing an overshot-wheel it is necessary to give consideration to the following points:—

1. The point of the circumference at which the spout should discharge so as best to fill the buckets.

2. The best form of bucket for receiving the water, and for retaining it, through a considerable part of its descent.

3. The best speed at which the circumference of the wheel should travel so as to obtain the greatest effect from the moving load of water which its buckets contain.

Fig. 119.



If we suppose that a fall of water about twenty-two feet in height is to act upon an overshot-wheel (Fig. 120), we may make the wheel about twenty-four feet in diameter, and the depth of the buckets, measured towards the centre, two feet. Dividing this depth into two equal parts, each one foot, marked by the dotted circle (Fig. 121), dividing the circumference of this circle into a convenient number of equal parts B B equal to the numder of buckets (40 in the diagram), and drawing lines C B A towards the centre of the wheel through the points of division, we are enabled to determine the form of the buckets. The casing extending between A A is called the sole of a bucket, and is left with a narrow slit open at A for the escape of air from the bucket when the water pours into it. The board A B is called the start, and the inclined part B C the arm of the bucket. Sometimes this inclined part is made in two parts at different degrees of obliquity, like the lines B D, D E; of which B D would be called the arm, and D E the wrist, the start A B being called the shoulder. These names are doubtless given from the resemblance of the section to the form of a bent arm. The whole circumference of buckets and soles is called the shrouding.

Fig. 120.

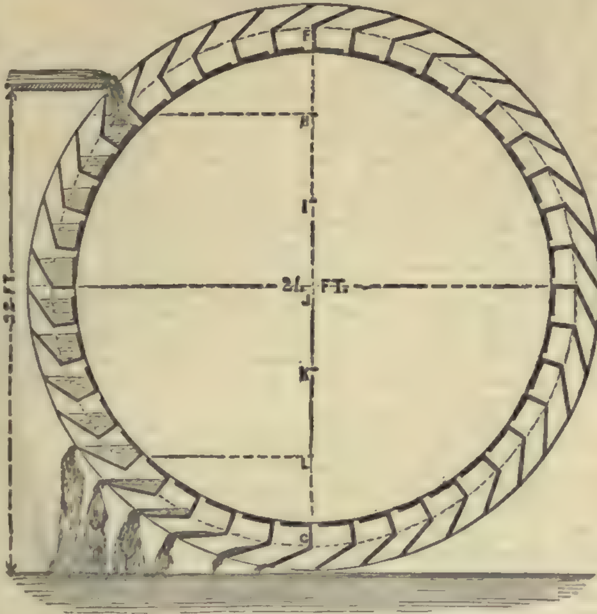


Fig. 121.

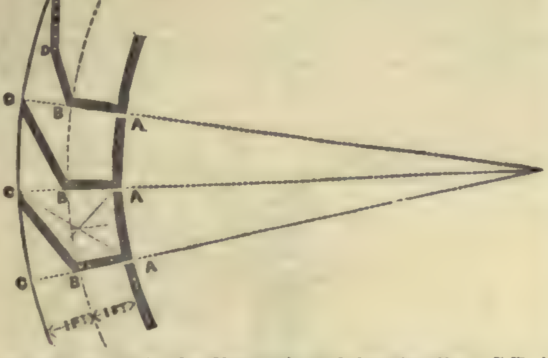


On dividing the vertical diameter F G of the mean circle of the shrouding into six equal parts at the points H, I, J, K, L (Fig. 120), and drawing horizontal lines through H and L to meet the circumference, we observe that at the upper line the bucket is filled, and therefore, the weight of its contents begins to act in causing the wheel to revolve, while at the lower line it begins to empty itself, and its action may there be considered to cease; or whatever effect the water may have beyond this point is so small that it may be neglected as an element of power. The total effect of the water, then, in causing the wheel to revolve, may be reckoned to be that of the weight of water contained in ten buckets descending through a height equal to two-thirds of the diameter of the mean circle, viz., $22 \times \frac{2}{3} = 15$ feet nearly. The diameter of the mean circle is equal to the height of fall; and we may, therefore, by taking a wheel of just proportions, generally obtain a descending weight acting through a vertical height two-thirds of the height of fall; and the weight itself, consisting of the contents of one-fourth of the total number of buckets. The capacity of those buckets for containing water depends manifestly on the breadth of the wheel or the length of the buckets, as well as their sectional area. The area of those in the diagram, reckoning up to the level line bounded by the air-slit at their filling-point, and by the lip of the bucket where the discharge begins, may be taken at little above $1\frac{1}{8}$ square foot; and we may suppose, for facility of calculation, that their length or the breadth of the wheel is 1 foot, giving each bucket a capacity for containing $1\frac{1}{8}$ cubic foot of water, weighing about 70 lbs. The contents of the 10 buckets, therefore, weigh 700 lbs.; and this weight is constantly moving with the velocity of the wheel.

In determining the absolute power to drive machinery, we must ascertain the velocity in relation to that with which the water flows from the spout. The circumference of the wheel must move at such a rate that no bucket shall pass the spout without being filled from it. The total circumference of the wheel being $75\frac{1}{2}$ feet, divided into 40 equal parts, we have, for the distance from lip to lip of each bucket, $\frac{75\frac{1}{2}}{40} = 1{\cdot}888$ nearly, or about $1\frac{7}{8}$ foot. If the wheel make one revolution per minute, each bucket passes any fixed point in $\frac{1}{40}$th of a minute, or $1\frac{1}{2}$ second; and the velocity of any point in the circumference is $\frac{75\frac{1}{2}}{60}$, about $1\frac{1}{4}$ foot per second. It has been stated, that the most advantageous circumferential velocity of an overshot-wheel is at the rate of 2 to 3 feet per second. Taking $2\frac{1}{2}$ feet per second for the case we are discussing, the wheel would make 2 revolutions per minute, and each bucket would pass a fixed point in $\frac{3}{4}$ths of a second. As the water issuing from the spout has a certain depth or thickness, some time of the bucket's passage must be deducted in order to ascertain the time allowed for influx of the water. Deducting $\frac{1}{3}$rd of the time, that is, $\frac{1}{4}''$ from $\frac{3}{4}''$, we have $\frac{1}{2}''$ as the time during which the bucket remains under the spout to be filled; and in this time $1\frac{1}{8}$ cubic foot, the contents of the bucket, must flow from the spout—that is, $2 \times 1\frac{1}{8} = 2\frac{1}{4}$ cubic feet in 1 second. As the spout is 1 foot broad, and we must not reckon the depth of water in it above 6 inches or $\frac{1}{2}$ a foot, the sectional area of the water-channel is $\frac{1}{2}$ a square foot, through which $2\frac{1}{4}$ cubic feet must flow per second. The velocity of the water must therefore be $2 \times 2\frac{1}{4} = 4\frac{1}{2}$ feet per second. Should the velocity of the stream be less than this, either the wheel must move more slowly or the spout must be inclined to meet it at a lower level, so that the water may attain greater velocity from additional fall. Should the velocity of the stream exceed this, either the wheel must be permitted to move more quickly, or it and the spout must be widened, so as to present greater capacity of bucket and diminish the speed of influx.

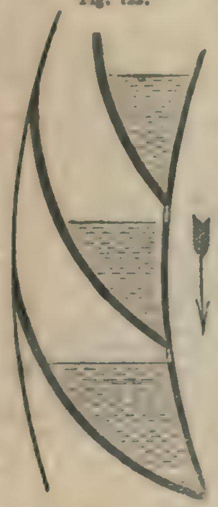
Recurring to the power of the wheel, which we suppose to revolve at the speed of $2\frac{1}{2}$ feet per second, or 150 feet per minute, with a force of 700 lbs. at its circumference, we find the effect to be equivalent to $700 \times 150 = 105000$ lbs. moved 1 foot per minute, $\frac{105000}{33000} =$ about $3\frac{1}{8}$ horse-power.

Had we estimated it in another way by taking the quantity of water issuing from the spout, viz., $2\frac{1}{4}$ cubic feet per second, or 135 cubic feet per minute, weighing about 8,440 lbs., and reckoning its fall or effective movement 15 feet, the distance descended while it remains in the buckets, we should have found the power to be $\frac{8440 \times 15}{33000}$ = about 3⅚ horse-power. But it must be remembered that all the buckets do not act with their full leverage to turn the wheel in descending through 15 feet, being nearer the centre of the wheel above and below the middle level than when they pass that point. The former estimate, therefore, of 3¼ horse-power, is to be taken as the more correct one.

In order to ascertain what fraction it is of the power actually developed by the descent of the water—that is, of the force necessary to raise the water up again to the level whence it flowed—we have to consider that 2¼ cubic feet of water issue from the spout every second, and descend 22 feet, or that a weight of 2¼ × 62½ = to about 140 lbs., moves 22 feet per second, or 22 × 60 = 1320 feet per minute; or that 140 × 1320 = 184,800 lbs. moved through 1 foot per minute. This is equivalent to $\frac{184800}{33000}$ = rather more than 5½ horse-power. Of this the mill has been found to render 3¼ horse-power, or about 57 per cent. available for driving machinery.

It has been stated by some engineers, that as much as 70 to 80 per cent. of the power expended by the fall of water has been made available by means of overshot-wheels; but we are inclined to think that, with the best known construction and proportions, the useful effect does not certainly exceed 70 per cent. of the water-power.

Fig. 122.



Of late years, many of these wheels have been made of iron: the partitions of the buckets are constructed of iron plates, bent to a curved form, and the obliquity is made considerably more than in the wooden shrouding of former times (Fig. 122). The diameter of such wheels is made somewhat greater than the height of fall, so that the water enters the buckets some distance below the summit, where the inclination of the bucket is suited for the reception of the stream. Even if the buckets were filled at the summit of a wheel, and did not empty themselves till they reached the lowest point, the additional effect of their contents would be of little advantage, as it would act more to press the wheel down on its bearings than to turn it round. It will be found advantageous in practice to reckon the diameter of the wheel as ⅛th more than the fall. Thus, for a fall of 24 feet, we should make the wheel 24 and ⅛th of 24, 3; altogether 27 feet in diameter.

It has been recommended that the velocity of the wheel should be made dependent on the height of the fall; that is to say, that it should be ¼th of the velocity which the water would acquire in reaching the bottom by free descent. We can see no reason why such a rule should be observed; for, as we have formerly stated, the velocity of the circumference should be so proportioned to that of the water flowing from the spout, that the buckets may be properly filled during their passage. It is true that, by inclining the spout, we may increase the speed of the stream flowing from it, and thus render a greater velocity of wheel practicable; but, being limited to a certain fall, whatever inclination we give to the spout, we take so much from the height after the water is delivered on the wheel, and consequently reduce the moving weight on the descending side of the wheel. We are, therefore, inclined to adhere to the maxim formerly received among millwrights, that the velocity of the wheel's circumference should not exceed 3 or 4 feet per second, and that, perhaps, it would most advantageously be fixed at 2 to 3 feet per second.

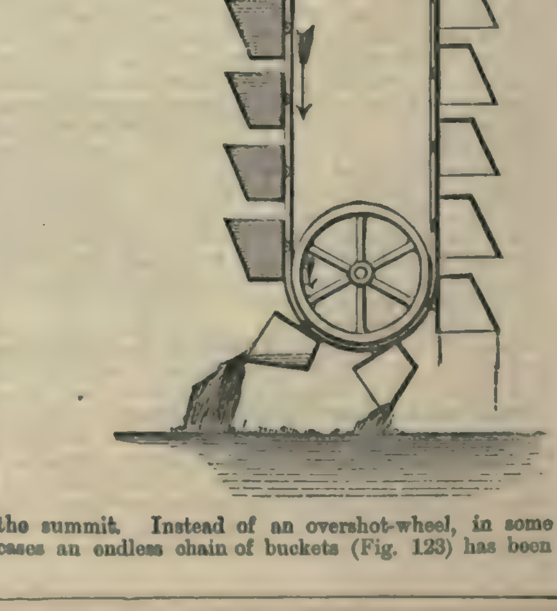
The number of buckets may be determined by making it double the number of feet in the wheel's diameter: thus, in a wheel 24 feet in diameter, the number of buckets would be 48. According to this rule, the space from lip to lip of buckets would always be about 1½ feet. Where the stream in the spout is wide and shallow, it may be made less; and where the stream is deep, it should be greater. But, practically, its size within a few inches is of no great importance; and we should recommend that a division of the circumference by 6, 8, 4, or such numbers and their multiples, should be made, so as to bring each division nearly to 18 inches.

In order to provide for the escape of air from the buckets, it is better to make their width exceed, by several inches at each side, that of the stream, than to provide air-slits in the sole; for, by this arrangement, each of the buckets may be made to hold a considerably greater quantity of water than when the air-slits limit its depth.

Every precaution should be taken to secure a free flow for the tail-water, as the resistance arising from the immersion of the lower part of the wheel in a languid stream, takes considerably from its effective force. It is better to sacrifice a few inches of head by inclining the tail-course, so as to give the water some velocity (at least that of the wheel) in its escape, than to let it act as a drag on the wheel, by making the tail-course too nearly level.

All descriptions of wheels where the water is received on their circumferences, fall under the denomination of overshot-wheels, even if the water be not shot over their summits; indeed, according to the systems now pursued in rendering water-power available, there is no case where a really *overshot*-wheel should be adopted. Instead of making the diameter of the wheel less than the height of fall, so that the spout could be carried over it, the diameter should always be greater, as we have described, so that the water may be delivered at some point below the summit. Instead of an overshot-wheel, in some cases an endless chain of buckets (Fig. 123) has been

Fig. 123.



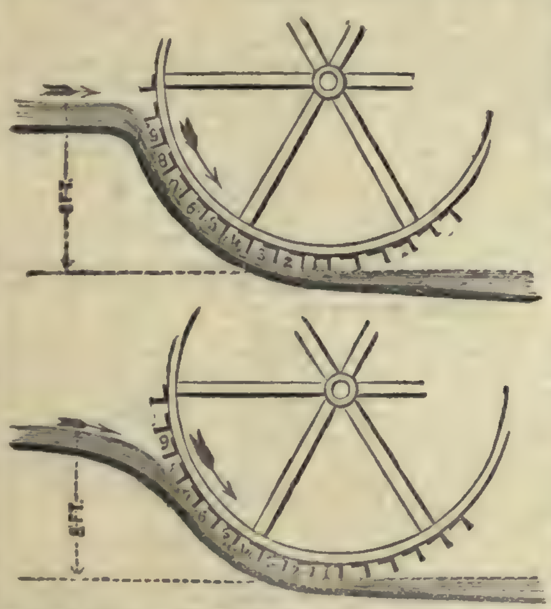
employed for obtaining power from a fall of water. In theory, this arrangement appears one likely to prove more effective than that of the wheel, for the weight of water is retained in the buckets, and acts with constant force throughout the whole descent. Practically, however, the apparatus is not of so substantial and permanent a character as the wheel; the chain has numerous joints, all subject to wear and decay from rust; and when they become deranged, the increased friction and inequality of action considerably diminish the efficiency of the apparatus.

3. *The breast-wheel* is an arrangement intermediate between the undershot and overshot-wheels. It consists of a wheel fitted with floats or paddle-boards round its circumference, revolving with its lower part in a channel which nearly fits it. Each float has a back-plate or sole, so that the wheel is somewhat like an overshot-wheel, with buckets open on their outer sides. When a considerable stream of water falls over a height not sufficient to render an overshot-wheel applicable, and yet greater than would be required for an undershot-wheel, the breast-wheel is applied with great advantage. The floats fit as nearly as possible, without rubbing-friction, to the bottom and sides of the channel, or sweep, in which they revolve; and thus, after passing the point where the water is delivered upon them, they act almost as close buckets, containing a load of water which urges them onwards.

At the point where the floats receive the water, some force arises from the impulse or velocity with which the water strikes them, as well as from the mere weight of their contents. Some millwrights have thought this impulse a most essential element of power, and have therefore contrived the spout so as to throw the water on the floats with great velocity. Others, and among them Smeaton, whose opinions on such matters are always to be received with respect, have arranged the spouts so as to deliver the water on the wheel at as high a level as possible. By this arrangement the impulse from velocity is lessened, but the height through which the water afterwards acts by weight is increased.

If we suppose that a certain stream, flowing with a velocity of 8 feet per second, and having a fall of 8 feet, is applied to driving a breast-wheel 20 feet in diameter, having 40 floats (Fig. 124), we may inquire whether it be more advantageous to deliver the stream at once on the wheel, or to slope its course downwards 3 feet before it meets the floats. In the one case we have the impulse due to a speed of 8 feet per second on one float marked 9, and the weight of the water contained in eight others, marked 1 to 8 inclusive. In the other case we have the impulse due to the increased velocity of stream upon one float marked 7, and the weight of water acting on six others marked 1 to 6 inclusive. Farther, as in the second case the velocity of the delivered water is greater, its stream must be shallower, and therefore it must strike on a less area of float; and if the wheels move at rates respectively proportional to those of their streams, the same quantity of water being supposed to be delivered in each case, each of the buckets in the second wheel must contain less water than each of those in the first. Let us assume that in each case the wheel revolves at a rate which makes its circumference travel at one-third of the velocity of the stream, which we found to be the most advantageous speed for receiving impulse in the case of undershot-wheels. In the first case the velocity would be $\frac{8}{3}=2\frac{2}{3}$ feet per second. In the second case we must calculate the velocity of stream due to increased fall. The fall to produce 8 feet per second is 1 foot; and adding to this the 3 feet of additional fall, we have a fall of 4 feet; the velocity due to which is 8 times its square root, or 16 feet per second. The circumference of the second wheel, then, travels at the rate of $\frac{16}{3}=5\frac{1}{3}$ feet per second, twice the velocity of the first; and if in the first the buckets be exactly filled, in the second they can only be half filled, or need have only half the capacity. If we take the area of float in the first case to be 1 square foot, and in the second ½ square foot, the float marked 9 in the first sustains a pressure due to 8 feet per second, the velocity of the water, less by 2⅔ feet per second its own velocity; that is, to 5⅓ feet per second, equivalent to a column ⁴⁄₉ths of a foot high on 1 square foot of area, about ⁴⁄₉ths × 62½ = 28 lbs. moving at the rate of 2⅔ feet per second, or 2⅔ × 60 = 160 feet per minute, which gives a power of 28 × 160 = 4,480 lbs. moving at 1 foot per minute. In the second case the float 7 is pressed on by a column sufficient to give 16 less by 5⅓, that is, 10⅔ feet per second, which implies a height of 1⁷⁄₉ foot; and this pressing on ½ square foot gives 56 lbs. moving at 5⅓ feet per second, equivalent to 17,920 lbs. moving at 1 foot per minute, 4 times the effect of float 9 in the first case, as might have been surmised, because the velocity is doubled.

Fig. 124.

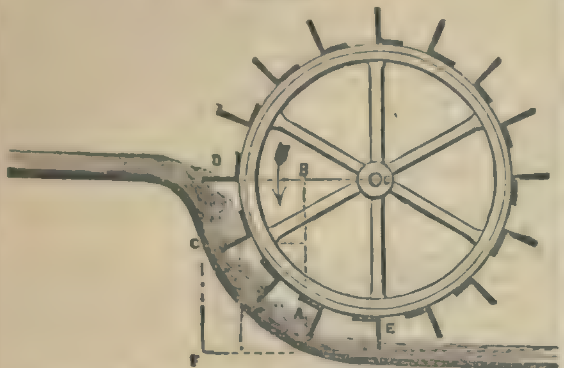


It remains now to compute the effect of the remaining floats in producing power. The total quantity of water issuing is 8 cubic feet per second, or 8 × 62½ × 60 = 30,000 lbs. per minute. In the first case this keeps 8 buckets continually full, and moves them at 2⅔ feet per second, or 160 feet per minute; in the second case it keeps 6 buckets half filled, or 3 buckets quite full, and moves them at 5⅓ feet per second, or 320 feet per minute. As each bucket holds 1 cubic foot, or 62½ lbs., the power of those in the first case is 8 × 160 × 62½ = 80,000 lbs. moving 1 foot per minute; and of those in the second, 3 × 320 × 62½ = 60,000 lbs. Adding to each of these results the power derived from the impulse of the water, we have in the first case 84,480 lbs. moved through 1 foot per minute = 2·54 horse-power; in the second case 77,920 lbs., equivalent to 2·36 horse-power. The result is, therefore, in favour of the first case; and thus Smeaton's view of the circumstances is borne out.

If the floats be tolerably well fitted to the sweep, so that there is little loss of water by escape past their edges, the circumferential speed of the wheel should be considerably more than one-third of that of the stream. A rate as high as two-thirds or three-fourths is practically attained with advantage. When this is the case, the impulse from excess of the stream's velocity over that of the float is much diminished, and the principal element of power is the load of the water contained in the buckets. If, then, the fall of the spout be made just sufficient to deliver the water supplied by the stream or reservoir, all the rest of the fall is most advantageously applied in the sweep, care being taken that sufficient fall is left to carry off the tail-water with full velocity, so that it do not become heaped up, and retard the ascending floats.

In estimating the power of a breast-wheel, we may suppose, for the sake of simplicity, that the water is delivered on the horizontal line of the centre, and keeps all the buckets, from that line to the bottom, full (Fig. 125). Now the effect of the weight of any bucket, such as A, to turn the wheel, depends upon the leverage with which it acts, which would be measured by the length C B of the horizontal line intercepted between the centre of the wheel and the middle of that bucket. Were we to divide the circumference from D to E into a great number of equal parts, and calculate their combined effect as dependent on the leverage with which they respectively act, we should find it to be the same as if one weight—bearing the same proportion to the total weight in the circumference D E as the length of C D, the radius, bears to the portion of the circumference D E—acted on at D. In other words, the effect of all the weight of water in D E to turn the wheel, is the same as that of a column D F of the same width and thickness hanging at D. The same principle is true if the water do not deliver at the level of the centre of the wheel; for if it be delivered at G, the effect of the weight of water between G E would be the same as that of a column of equal area and of the height G F acting at D.

Fig. 125.



If, now, we take the particular case of a wheel 25 feet in diameter, with buckets 1 foot broad and 1 foot deep, receiving the water at the level of the centre, and making 3 revolutions per minute, we may compute its power, and the proportion which its useful effect bears to the expended power of the water. The buckets being 1 foot deep, the circle passing through their middle points would have a diameter of 24 feet, and therefore a radius of 12 feet and a circumference of 75½ feet, making 3 revolutions per minute. The water in the buckets, therefore, moves at the rate of $75\frac{1}{2} \times 3 = 226\frac{1}{2}$ feet per minute; and the weight of the column, having an area of 1 square foot, and being 12 feet high, is $12 \times 62\frac{1}{2} = 750$ lbs. The power then is $\frac{750 \times 226\frac{1}{2}}{33000} =$ about $5\frac{1}{6}$ horse-power.

The quantity of water required to fill the buckets is 226½ cubic feet per minute, for it must three times fill the whole circumference every minute; and as there must be considerable waste from the inaccuracy with which the floats fit the bottom and sides of the sweep in which they revolve, we may reckon 20 per cent. more, or altogether 270 cubic feet per minute, to cover this waste; that is, 4½ cubic feet per second. If we take the stream at the spout 1 foot wide, and 9 inches or ¾ths of a foot deep, its area must be ¾ths of a square foot, through which 4½ cubic feet have to flow per second. The velocity of the water must, therefore, be 6 feet per second, or that due to a fall of nearly 7 inches. The water in working the wheel has to descend 12 feet, and we must allow at least 5 inches more of depth at the bottom of the wheel to clear the floats of back-water, and the total descent is therefore 13 feet: in other words, in order to raise the water up to the proper level to work the wheel, we should have to lift 270 cubic feet 13 feet high every minute. The power required for this would be $\frac{270 \times 62\frac{1}{2} \times 13}{33000}$ = about $6\frac{5}{8}$ horse-power. We found the effective power of the wheel about $5\frac{1}{6}$ horse-power; that is, 77 per cent. of the power expended. We believe that, practically, this estimate would be found too high, and that we could not depend on obtaining, in useful effect, more than 60 to 70 per cent. of the water-power expended.

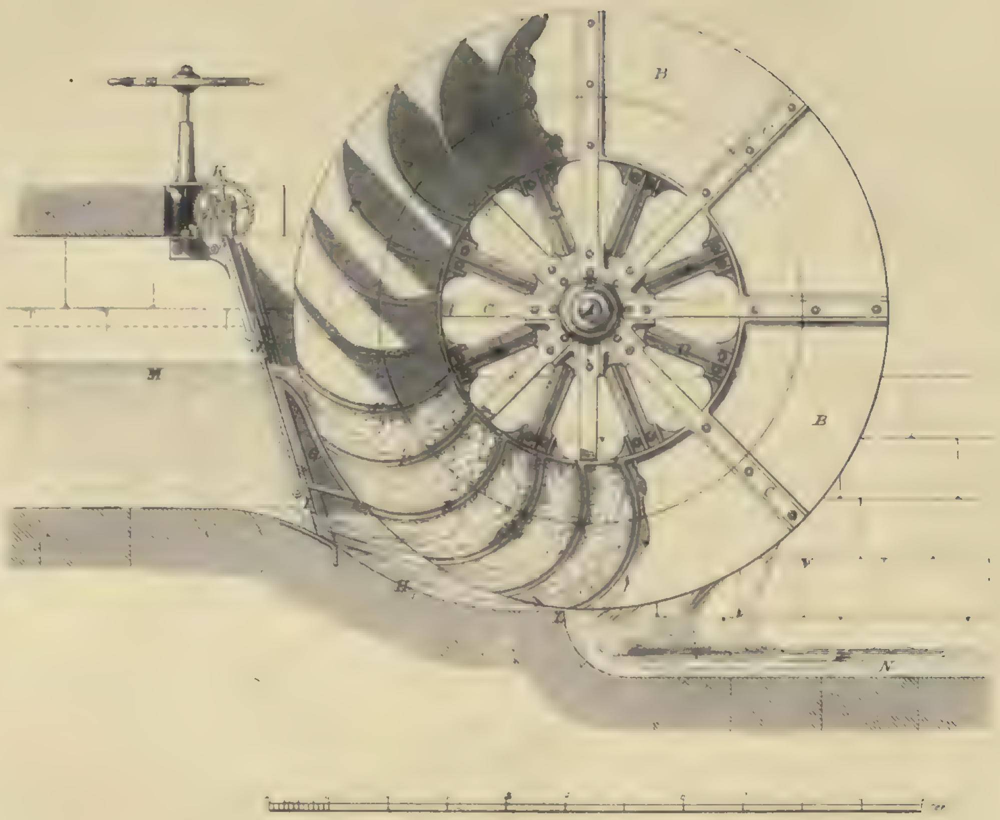
The annexed plate represents an ingenious and, we believe, a very effective construction of water-wheel, combining in one the principles of a breast and undershot-wheel. A strong boss, E, is fitted on to the main shaft or axle, A, on which the wheel turns. Two sets of arms, C C and D D, extend as radii from this boss, some of them, C, C, supporting the sides, B, of the buckets, and the others, D, D, supporting their bottoms or soles. The buckets or floats, F, F, are bent plates extending across the outer part of the wheel, and terminated at both ends by the casing, B, part of which is supposed to be removed in order to show the form of the buckets and the action of the water on them. The head of water, M, is fronted by a double sluice presenting two openings, I and J, at the lower and upper levels respectively, these openings being separated by a casting, G, formed in front to suit the sweep of the wheel. A hand-wheel and suitable gearing, K, are arranged above the sluice for causing it to slide up or down, and thereby regulating the amount of opening at I and J. Under the wheel the masonry, H, is formed in a curve suited to the motion of the water from the lower opening I, and is made to approach close to the edge of the wheel at L, so that no water may pass without acting on the floats. N is the tail-water, which is kept quite under the level of the wheel, so as to give no resistance to its rotation. By this construction, the water which issues from the higher opening, J, fills the buckets, and acts by weight to cause them to descend; while the water which issues from the lower opening I, with the increased velocity due to the head of water in M pressing upon it, rushes into the buckets, and presses the floats onwards, as in an undershot-wheel.

The terms *undershot*, *overshot*, and *breast-wheels*, have been applied in a somewhat different way from that in which we have used them. The term *undershot* has been used when the water is delivered on the wheel anywhere below the level of its centre, and thus the wheels which we have called *breast*-wheels would be among the *undershot;* the term *overshot* has been used in those cases only where the spout is actually carried over the summit of the wheel; and the term *breast* has been applied to wheels where the water is delivered somewhere above the central level. We think, however, that the classification we have adopted here is more distinct, as it refers not only to the different points where the water is delivered, but also to differences in the construction of the wheels. Thus, the *undershot*-wheel is that which receives the water-pressure on simple paddles or floats immersed in the current, and is acted on by its force only; the *overshot*-wheel receives the water at a high level in buckets formed in its circumference, and is moved simply by the weight of water contained in them; the *breast*-wheel receives the water on paddles or floats nearly fitting a sweep in which they revolve, and is thus put in motion partly by the weight of water lodged on and between the floats, and partly by the pressure on the floats arising from the velocity of the current. The peculiar construction of each kind of wheel is adapted to different conditions of the fall of water.

The undershot-wheel is to be used when there is a volume of water moving with considerable velocity, but with very little local fall, as in the case of river streams and tidal currents. The velocity of the current of a river arises from numerous little falls, or from a continuous inclination, without any considerable difference of level within a limited space. The velocity of a tidal current, again, arises from the pressure of the tidal wave, or body of ocean water, elevated above its average level

See page 832

COMPOUND BREAST & UNDERSHOT
WATER-WHEEL.



by the gravitating influence of the moon; but this wave appears only as a gentle and almost imperceptible inclination of the water surface, except in some estuaries, such as the Solway Frith, where it presents itself as an elevated body of water rushing with considerable velocity towards the land.

The overshot-wheel is applicable when the water has a considerable local fall, nearly equal to the diameter of the wheel; and the breast-wheel when the local fall is not great—less, for instance, than half the diameter of the wheel—but when it is of considerable volume, and moves with considerable velocity. In order to apply either an overshot or a breast-wheel, it is generally necessary to make extensive arrangements for conducting the water from an elevated level to the wheel, instead of permitting it to follow its natural channel. When a stream has a considerable fall—such as 40 or 50 feet in each mile of its length—a dam or weir is built across it at some convenient position, so as to check its progress there, and a new channel is formed for conveying its waters to the mill, and thence back to the bed of the stream at some point below the dam. As the artificial channel is made with only sufficient declivity to secure the flow of the water in such quantities as may be required, it is thus possible to obtain at the wheel, nearly the total fall which the channel of stream has, estimated from the point where the dam is built, to that where the tail-water of the mill re-enters. If, for instance, the stream in its natural channel is found to have a fall of 60 feet in a mile—this difference of level being made up either of numerous small local falls or of a continuous declivity, or both—an artificial channel is formed by its side, or as near it as the levels of the ground permit, having a constant declivity for half a mile, amounting to 5 feet of difference of level; the water acts on a wheel with a fall of 20 feet, and a declivity of 5 feet is allowed in the length of the tail-course. The difference of level in the channel for half a mile—that is to say, 30 feet—is thus made up, and the power due to $\frac{2}{3}$rds of that fall is thus secured for driving machinery. The current of the stream itself would probably not have so great a velocity at any place as to make it practically available for an undershot-wheel, on account of the irregularities of its channel, and the numerous resistances opposed to its progress.

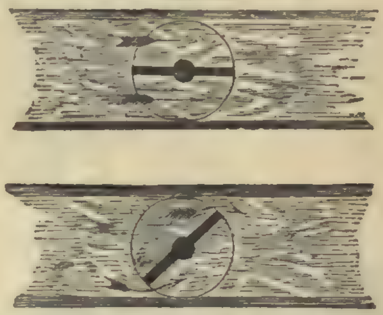
DAMS, OR RESERVOIRS.—Where there is no stream of sufficient magnitude to give the necessary power, and the power is not required to be constantly in operation, it is usual to form a large dam or reservoir for collecting the constant small tribute of the stream, so that the volume of water thus accumulated may be employed to drive the mill as occasion requires. For moving agricultural machinery, such as thrashing-machines, this plan is very commonly resorted to. The corn of a farm is generally thrashed in the winter season, when there is the best supply of water in the streams, and from the drainage of the soil. A small mill-dam or reservoir collects, during the night, sufficient water to drive the mill through the following day. And it is thus possible, even in localities where apparently no water-power can be obtained, to secure enough for the work to be done, by executing a properly contrived dam, and turning into it the drainage of the surrounding fields.

When water is applied to manufacturing purposes, requiring the constant supply of large volumes of water, reservoirs or dams are sometimes executed on a gigantic scale, in order to store up the superfluous supply of rainy weather against a season of drought. In some of the hilly districts of England and Scotland, these works are of a most important character, and the interests of large local populations are dependent on their efficiency and permanence. When the differences of level in the district are considerable, numerous mills are worked successively by the same water, that which has driven the higher, flowing along an artificial channel till it arrives at the next lower; and so on, in constant succession for great distances. In such cases, the mill-owners frequently combine to execute works for the benefit of all, and of much greater magnitude than a single capitalist could undertake. By such arrangements, they are enabled to throw an immense dam or retaining-wall across some valley, and thus collect in a vast reservoir the drainage of an extensive range of hills, which would otherwise flow along its natural course to the sea without being turned to useful account as a mover of machinery. While the rains or melting of the snows contribute much more water than is required, the reservoir is filled; and when the water in it attains the highest level required, it is permitted to overflow into its natural channel. When the season of drought arrives, the mills, that would otherwise be at a stand-still, derive an ample supply from the reservoir, extending, in some cases, over many square miles of valley. When the depth of this reservoir is considerable, great strength is required in the dam; and, notwithstanding the ingenuity and labour expended on some of these structures, they sometimes give way; and the enormous volume of water thus suddenly set free rushes impetuously onward to the sea, devastating whole districts in its course, destroying crops and buildings, and too frequently causing a great sacrifice of life.

The sluices or valves for opening and closing the water-channel of a mill are generally of very simple construction; they consist of a plate of wood or metal, made to fit against a framework fixed in the channel, and pressed against it by the water. This plate is made to slide upwards in grooves fitting it at each side; and when it is of large dimensions, it is raised or depressed by racks and pinions, or screws fitted with appropriate gearing, as represented at K, I, and J in the engraving of the compound wheel. By opening or shutting the sluice, the wheel is put in motion or stopped at pleasure. A channel is always provided to carry off the surplus water to the tail-course of the wheel, when it rises in the spout or lead, above the sill of the waste channel.

REGULATORS.—Various contrivances have been applied to regulate the speed of water-wheels. The most effectual is the steam-engine governor, or conical pendulum. A throttle-valve, or plate, moving on an axis or pivots at its middle, is fitted into the lead (Fig. 126). When it presents its edge to the current, it offers very little obstacle to its course; but when it is turned into an oblique position across the current, it arrests all the water except what can pass through the openings left between its edges and the sides of the lead. As it is poised on pivots in its middle, the pressure of water on each limb is the same; and the only force required to move it in either direction is that required for overcoming the friction of its pivots, and the resistance of the water to its movement through it, a force very inconsiderable. The governor is connected, by rods and levers, to a valve of this description in such a manner, that when, from too great velocity of the water-wheel, the governor-balls fly out from their axis, the valve is closed, or partly so, and the supply of water to the wheel diminished. When the wheel moves too slowly, the balls fall down to the axis, and cause the valve to open for the passage of a greater volume of water to the wheel. By this arrangement, the movement of the wheel is regulated with great nicety, and the quantity of water supplied to the wheel is suited exactly to the work which it has to do. The consequence is, a great saving of tear and wear to the

Fig. 126.



machinery, and a regularity of movement better suited to all those mechanical operations to which motive power is applied.

POWER OF STREAMS.—The power which can be derived from a given stream of water may be computed with tolerable accuracy. When, by levelling the ground, it is ascertained how much fall may be secured, making ample allowance for the declivity of channel to and from the intended wheel, the volume of water delivered in a certain time is to be computed by measuring the area of the existing channel, and the velocity with which the water flows through it. The area of the channel may be found by dropping a plumb-line, at numerous equal-measured intervals, across some part of the current where the water moves with tolerably equable velocity, and tracing out the section according to the measurements so taken. The area can then be calculated by the ordinary rule for mensuration of superficies: for example, if the total width of the surface of the stream be 9 feet, and the soundings taken at every foot be those marked in Fig. 127 (in feet and fractions of a foot), the area is the sum of all those depths, viz., 8 square feet. The velocity of the current may then be ascertained by throwing into it a floating body at some distance above a marked length of channel, so that before it floats within the range of the marked distance, it may have attained the speed of the current. The time of its passage over the marked distance may be then observed by a stop-watch. We may assume, for instance, that the marked distance is 20 feet, and that the floating body occupies 5 seconds in passing this; we conclude that its velocity is $\frac{20}{5} = 4$ feet per second. We must not, however, assume this to be the velocity of the whole stream, for at the bottom, and particularly at the shallow sides of the channel, the friction of the water on the rough surface considerably retards it. The effect of this retardation may be often observed upon a streak of foam spreading across the channel, the middle part advancing rapidly and breaking away from the side portions, which sometimes are even caused to move backwards by the eddying currents. In a shallow stream, like that in the case we have supposed, we should not, perhaps, be safe in assuming more than half the middle surface speed as the average of the whole stream, say 2 feet per second. Multiplying this by the area, we find that $8 \times 2 = 16$ cubic feet of water per second is delivered by the stream.

Fig. 127.

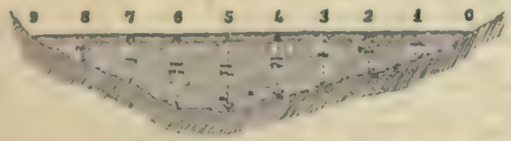


Fig. 128.

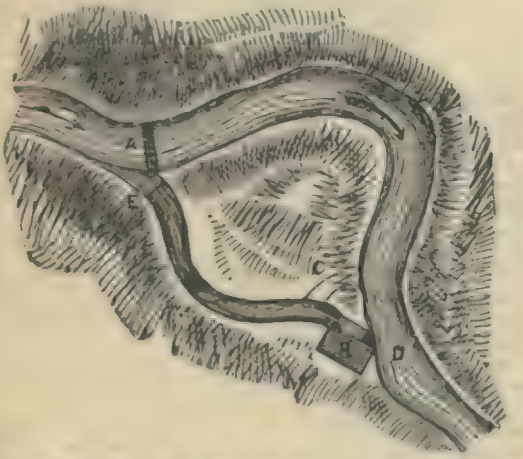
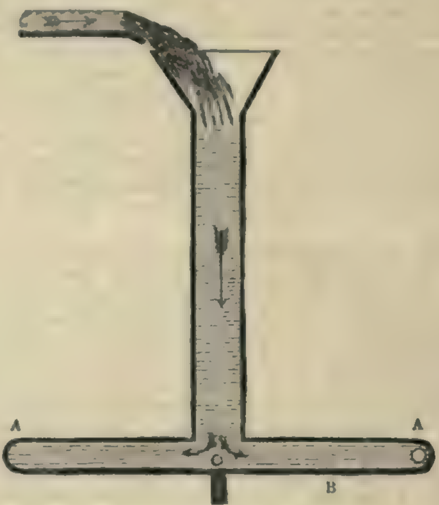


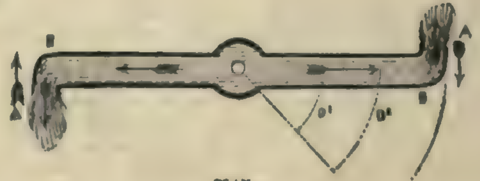
Having levelled the ground in the neighbourhood of the stream, we find that by building a dam 4 feet high at A (Fig. 128), and excavating a channel with a gentle declivity to B, a convenient site for a mill, and thence into the bed of the stream, we can get a fall of 15 feet at the mill-wheel, allowing for declivity of channel from A to B, and a proper fall for the tail-water from B to the stream at D. We should, therefore, have 16 cubic feet of water per second falling down 15 feet of vertical height as our moving power. To lift this quantity up the height of its fall, we should require $\frac{16 \times 60 \times 62\frac{1}{2} \times 15}{33000} = 27$ horse-power. By a proper arrangement of wheel, we may expect to secure about $\frac{2}{3}$rds of this for effective working power, which we should therefore estimate at $27 \times \frac{2}{3} = 18$ horse-power. A sluice would be fitted across the lead at E, so that the water might be excluded from it for purposes of cleaning or repairing the channel; and the proper sluice and regulating valve would be fitted at the mill with a sluice and waste water-course C for emptying the lead when the entering sluice at E is closed.

TURBINES.—When the volume of water is small, but the fall considerable, an apparatus called a turbine is frequently applied with great advantage. The principle of its action is similar to that of the well-known firework called the Catherine-wheel, or of the revolving jet sometimes applied to fountains. For a considerable period it has been known as a philosophical toy, called Barker's mill. This consists of a vertical tube, with two horizontal branches closed at the end, mounted on a vertical axis on which it can freely revolve (Fig. 129). Near the extremity of the horizontal arms, holes A A are made on opposite sides; and when water is poured into the upper part of the tube, it flows through these holes, and makes the arms revolve in the opposite direction. The cause of their motion may be very simply explained. If we suppose the apparatus at rest, and the holes closed, when the tube and arms are filled with water, every square inch of the inner surface of those arms is equally pressed on by the column of water in the vertical tube;

Fig. 129.



SECTION.

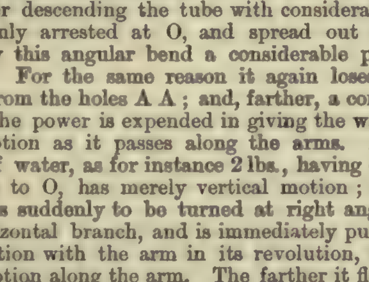


PLAN.

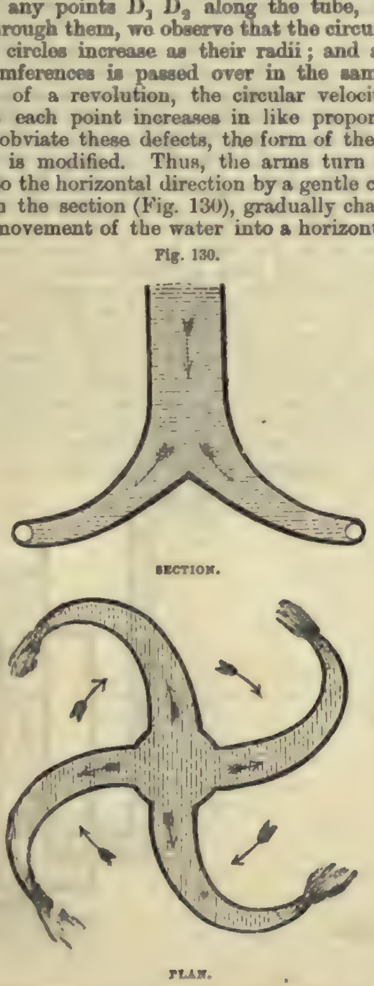
for it is the property of fluids to communicate pressure equally in all directions.* Under these circumstances, there is no tendency to produce motion in any direction; but if the holes A A be opened, then, while the pressure on one side of the tube B remains the same as before, that on the other is lessened by as much as its surface is diminished. If we suppose each hole to have an area of one square inch, then each side of the tube B sustains a pressure on one square inch more than the other side; in other words, there is a pressure on B exceeding that on A by that due to the area of the hole in A. This excess of pressure causes motion in the direction in which it acts—that is, opposite to the flow of the water issuing from the holes; and the force of the movement depends upon the amount of unbalanced area in each arm, and the intensity of pressure upon it.

In the simple Barker's mill there is considerable loss of power from impediments to the flow of the water. The water descending the tube with considerable speed, is suddenly arrested at O, and spread out laterally; losing by this angular bend a considerable part of its velocity. For the same reason it again loses speed in issuing from the holes A A; and, farther, a considerable part of the power is expended in giving the water a circular motion as it passes along the arms. A certain weight of water, as for instance 2 lbs., having descended the tube to O, has merely vertical motion; half of it (1 lb.) has suddenly to be turned at right angles along each horizontal branch, and is immediately put into circular motion with the arm in its revolution, as well as direct motion along the arm. The farther it flows along the tube, the more rapid is its circular motion; for if we take any points D_1 D_2 along the tube, and trace circles through them, we observe that the circumferences of these circles increase as their radii; and as each of the circumferences is passed over in the same period, the time of a revolution, the circular velocity of the water at each point increases in like proportion. In order to obviate these defects, the form of the tube and its arms is modified. Thus, the arms turn from the vertical to the horizontal direction by a gentle curvature, as seen in the section (Fig. 130), gradually changing the vertical movement of the water into a horizontal movement with little loss of force. And again, the arms, of which there may be any convenient number, bend also horizontally, as seen on the plan; so that while they revolve, the water contained in them is really moving almost in a straight line, instead of being swept round in a circle.

Fig. 130.



SECTION.



PLAN.

As the mouths of the arms must be made of such an area as to permit the issue of the water at the proper velocity due to its fall, if they are made too small, less water passes them than can be supplied, and the machine is not so powerful as it might be with the given supply of water. If, on the other hand, the mouths are made too large, the velocity of the issuing water is diminished; and the pressure on the opposite sides of the arms tending to drive them round, is diminished with it. The area of the mouths being decided according to the quantity of water, and its velocity from vertical fall, the arms are made to taper gradually to that area, so that the velocity of the water may gradually increase to suit the gradually diminished area of its channel, as it would naturally do during its vertical descent. Due consideration having been given to these points, as well as to the best mechanical arrangements for strength, durability, and economy of execution, the machine becomes a turbine, practically applicable in many cases with great advantage. M. Fourneyron in France, and Messrs. Whitelaw and Stirrat in Scotland, have executed many of these machines, and made interesting experiments on their power and the best modes of constructing them. Their simplicity and efficiency, and the small space they occupy, give them an advantage over water-wheels; and it is said that they are capable of deriving from a fall of water, quite as much effective power as wheels of the best construction, even if the volume of water be large. Experiments conducted by Morin in France, lead to the conclusion that turbines are actually more effective than wheels under similar circumstances, the useful effect averaging from 70 to 78 per cent. of the power of the water. It has been found that even the immersion of the arms to a depth of several feet in water does not materially affect their action; so that even greater height than that of the fall, measured to the level of the tail-water, can be taken advantage of.

In estimating the power that may be derived from a given fall by means of a turbine, $\frac{3}{4}$ths of the power required to raise the water up again, may be reckoned as the usual effect. Thus if the volume of water be 16 cubic feet per second, and the fall 15 feet, the power required to raise it would be $\frac{16 \times 60 \times 62\frac{1}{2} \times 15}{33000} = 27$ horse-power; and the power of the turbine to drive machinery may be taken at $\frac{3}{4}$ths of 27, about 20 horse-power.

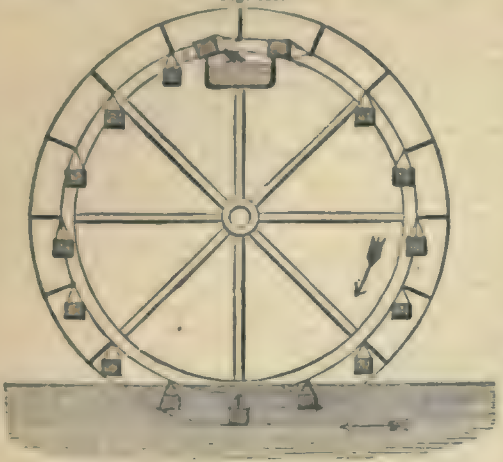
It is probable that turbines will in many cases take the place of water-wheels. They are as yet comparatively novel, and not widely known, or looked on with prejudice; but as improvements are gradually made in their construction and adaptation, and as they become more common in their application, these prejudices will doubtless give way, and no longer interfere with the extended use of a simple and elegant apparatus, instead of the large and cumbrous wheels now generally used. For regulating the motion of turbines, arrangements may be made similar to those used for governing water-wheels; the quantity of water supplied to the turbine being regulated according to the speed required, and the work to which it is applied. The power of the turbine is found to be very nearly proportional to the quantity of water passing through it; so that having found its maximum power, or the greatest quantity of water that it will use, we can employ $\frac{1}{2}$ or $\frac{3}{4}$ths of that power by reducing the supply of water to $\frac{1}{2}$ or $\frac{3}{4}$ths of the maximum.

CONTRIVANCES FOR RAISING WATER.—Before quitting the subject of water-power, we may notice some contrivances by which a volume of water is made to raise a smaller volume to a greater height for purposes of irrigation or the like. The simplest of these is the Persian wheel. A breast or undershot-wheel of the ordinary kind, has a number of buckets hung on pivots to its circumference (Fig. 131). These buckets dip into

---

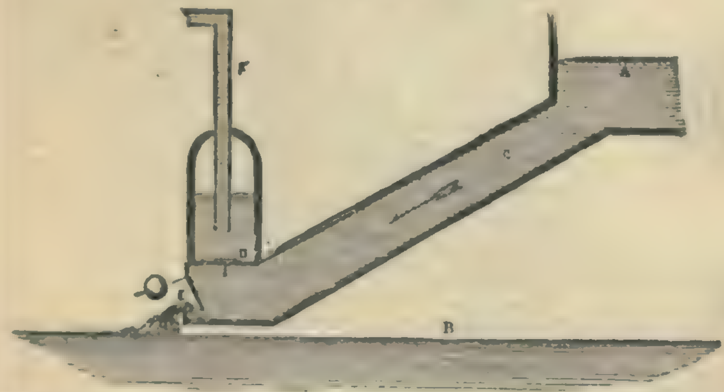
* See *ante*, *Hydrostatics*, p. 751.

Fig. 131.



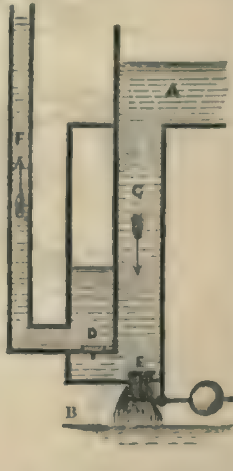
the water at their lowest level, and being filled, are carried up one side till they come in contact with the side of a spout fitted near the summit of the wheel. They are canted over by this spout, and discharge their contents into it, to be conveyed away for their required purposes. The empty buckets descend on the other side, to be again filled and lifted as before. Thus the force of a stream having inconsiderable fall is made to lift a certain quantity of water nearly the whole height of the wheel. The power of the wheel is expended on lifting a continuous weight of filled buckets up one side; and the quantity of water contained in them, as well as the height to which it is lifted, depends upon the size of the floats of the wheel and the pressure of the stream upon them. We may suppose a wheel 20 feet in diameter, with floats 8 feet broad and 1 ft. 6 ins. deep, worked at the circumferential velocity of 4 feet per second by a stream flowing at the rate of 12 feet per second. Subtracting 4 from 12, we get 8 feet per second as the excess of velocity of the stream over that of the float of the wheel; and the pressure due to that excess is ($\frac{8^2}{64}$ or 1 square) that of a column of water 1 foot high. The area of the float is $8 \times 1\frac{1}{2} = 12$ square feet; therefore the total pressure on the float is equivalent to 12 cubic feet of water, and it moves at the velocity of 4 feet per second, or 240 feet per minute, giving the same force as $240 \times 12 = 2880$ cubic feet of water moved 1 foot per minute. We may deduct $\frac{1}{3}$rd of this to allow for various losses, thus leaving an effective power equivalent to 1920 cubic feet of water lifted 1 foot high per minute, or $\frac{1920}{20} = 96$ cubic feet lifted 20 feet (the height of the wheel) per minute. As the wheel's circumference may be taken at 60 feet moving at the rate of 120 feet per minute, the wheel makes 2 revolutions per minute, and therefore twice in every minute lifts the contents of all its buckets, amounting to 96 cubic feet as we found above. The buckets may therefore altogether contain 48 cubic feet; and if their number be 24, each may have a capacity of 2 cubic feet. If we estimate the quantity of water acting on the wheel as the area of the float multiplied by the velocity of the stream, it appears that 8 ft. $\times 1\frac{1}{2}$ ft. $\times 12$ ft. $= 144$ cubic feet passes per second, or $144 \times 60 = 8640$ cubic feet per minute, of which 96 or $\frac{1}{90}$th part is lifted 20 feet high by the wheel which it moves.

Fig. 132.



The hydraulic ram is an ingenious contrivance, by which a small fall of a considerable body of water is made to raise a much smaller volume of water to a considerable height. From a reservoir A (Fig. 132), at the height of a few feet above the lower level of the stream at B, a large pipe conducts the water; this pipe has an aperture D, on its upper side near to its lower end, and the aperture is closed by a valve opening upwards, into an air-vessel, from which a small pipe F leads to a cistern at a level considerably above that of A. At the lower end of the inclined pipe there is a hinged valve E, opening inwards, and kept open by a weight fixed on a lever projecting from the valve. This weight is adjusted nicely, so as to counterbalance the pressure of the water on the surface of the valve E, but not greatly to exceed it. When the weight opens the valve, the whole of the water in the inclined pipe C begins to flow downwards, and issue at the opening made by the valve at E. Having acquired a certain velocity, it presses with greater force on the valve, and closes it in opposition to the weight, thereby completely arresting its own flow; but the momentum of the large body of water flowing along the pipe C cannot be suddenly destroyed, but must expend itself somewhere. It therefore lifts the small valve D with considerable force, and part of it flows into the air-vessel and up the pipe F. The momentum being thus absorbed, and the water in the pipe C having become still, the valve E again is opened by the weight, and the operation is repeated. Thus, by the alternate opening and closing of the valve E, under the quiescent and moving pressures of the water, a certain portion of the water is forced up the pipe F, and is prevented from returning by the closing of the valve D. The object of the air-vessel is to provide an elastic spring for the water propelled upwards: every time that the water is injected into it, the air in its upper part is compressed into a smaller space; and being perfectly elastic, tends to resume its former volume. It therefore exerts a pressure on the water, and continues its flow along the pipe F during the intervals that elapse between the successive discharges through the valve D. In estimating the power of this apparatus to raise water, we may suppose it arranged with the flow-pipe vertical instead of inclined, as it is usually made for convenience, the principle not being altered, but the details of calculation simplified by the vertical arrangement (Fig. 133). We may suppose that the height from the valve to the surface of the water in A is 4 feet, and that the area of the valve E is 1 square

Fig. 133.



foot. The pressure on the valve is, therefore, the weight of 4 cubic feet of water; namely, 4 × 62½ = 250 lbs. The effect of the weight to lift the valve by means of its lever must be somewhat greater than this. If the valve could be suddenly lifted so as to leave an opening to the full extent of its area, 1 square foot, the water would descend in C at the rate of 16 feet per second, the velocity due to 4 feet head; but as the valve opens gradually, and is only open for a short time, and that not to its full extent, we may take the velocity of the descending column at not more than ¼th of this rate; that is to say, at 4 feet per second. When this movement ensues, the valve is pressed on not only by the weight of the column above it, as before, but also by the weight of such a column as is due to a velocity of 4 feet per second, which will be found by calculation to be ¼th of a foot high, adding 62½ × ¼, about 15½ lbs. to the load on the valve. This additional load overcomes the leverage of the weight, and closes the valve; but the column of water, 1 foot in area and 4 feet high, contained in C, amounting to 4 cubic feet, is thus arrested whilst moving at the rate of 4 feet per second; and its momentum, which is equivalent to that of 4 × 4 = 16 cubic feet, moving at 1 foot per second, or 1 cubic foot at 16 feet per second, must be given out as a force propelling the water along the small pipe at the side. If we suppose that this pipe communicates with a cistern 36 feet high, the velocity due to that height is 48 feet per second; and the momentum of 1 cubic foot, moving at 16 feet per second, being equivalent to ⅓rd of a cubic foot moving at 48 feet per second, we should expect that this quantity—⅓rd of a cubic foot—would be propelled upwards to the high cistern at each closing of the valve. We must, however, recollect, that the momentum of the larger volume has not only to balance that of the smaller—it must considerably exceed it, because it has to lift the valve, to give the motion upwards to the column, to overcome friction in the pipes and other impediments, and, upon the whole, may be reckoned effective to the extent of not more than ¼th of its estimated force. We may estimate, then, that $\frac{1}{12}$th of a cubic foot is propelled up to the high cistern by the descent of 4 cubic feet through 4 feet from the lower cistern. Should the action not last so long as a second, a smaller volume will descend, and a proportionally smaller quantity will be sent upwards, and conversely; but the number of times the descent and ascent take place in a given period will be greater or less accordingly.

We have presented this calculation only as a rough approximation to the practical results. We are not aware that any carefully-conducted experiments with hydraulic rams have been given to the world, and we therefore do not venture to offer any estimate as a guide for practice; but have merely discussed a case with the view of opening the questions that have to be considered in dealing with such apparatus. In many situations where it may be desirable to raise water for the purpose of ornamental fountains, or of domestic supply, the hydraulic ram is applicable with great advantage. A neighbouring stream may be dammed so as to provide a fall of a few feet, if it have not sufficient local fall naturally; and the apparatus once fixed and properly adjusted, will continue effective for a long period. It is exceedingly simple, entirely self-acting, and seldom liable to derangement, if care be taken to fix gratings on the pipe, so that dirt or extraneous matter of any kind may be prevented from interfering with the action of the valves.

3. WEIGHT AND ELASTICITY OF BODIES.—The gravitating attraction which the earth exerts on bodies near its surface, and the force with which elastic bodies tend to resume the condition from which they have been withdrawn, are frequently employed for giving motion to machinery, chiefly when the power required is small, but exerted for considerable periods. Weight and elasticity are not really sources of power; they rather afford the means of storing up efforts of short duration for subsequent use during longer periods. Before a body can act by its weight, it must be lifted to the height whence it has to descend; and, in the same way, before a body can act by its elasticity, its condition must be changed to the extent through which it has afterwards to return. Thus, in winding up a clock or watch, as much power is exerted as is afterwards given out by the weight or spring in moving the machinery with which either is connected. The weight of the clock, and the spring of the watch, are merely instruments for absorbing, at the moment, a certain amount of power, and giving it out by degrees afterwards. The simplest, and, it may be said, the only general mode of employing the weight of a solid body to give impulse to machinery, is to attach it by a chain or string to a cylindrical barrel mounted on bearings at some height from the ground, and connected by gearing with the machinery which it is intended to move. The barrel being caused to revolve by hand, or any other convenient power applied to it, the string is wound round it, and the weight raised from the ground. When left to itself, the weight, attracted again towards the earth, descends, unwinding the string from the barrel, causing it to revolve, and thus giving the necessary impulse to the machinery. Did the machinery offer no resistance, the weight would always descend with a speed accelerated at every moment of its descent by the continued action of gravity, which exerts as much influence on a body in motion as on one at rest. In dropping a stone from a considerable height, whatever be its weight, we find that, during the first second of its descent, it acquires a velocity of 32 feet per second. Its velocity at the commencement was nothing, for it began to move from a state of rest; at every one of the instants into which we may conceive a second of time divided, it acquired more and more velocity, until it attained the final velocity of 32 feet per second. All these acquisitions in speed are equal in equal times, because the force of gravity is constant, and therefore exerts equal influences in equal times. Had the body descended during the whole second at the final velocity of 32 feet per second, it would of course have passed through 32 feet of space; had its velocity remained the initial velocity, which was nothing, it would have descended through 0 feet; but as the velocity began with 0 and ended with 32, its average throughout the second was 16 feet per second; and therefore the body descends in the first second through 16 feet. During the next second, the body, starting with a velocity of 32, acquires an additional velocity of 32, and therefore ends with a velocity of 64 feet per second; the average being 48 feet per second, and therefore the descent being 48 feet of height. Adding this to the space descended during the first second, 16 feet, we find that in the first 2 seconds the total descent is 64. Were we to pursue the investigation farther, we should find the velocity at the end of the third second 96 feet per second, and the total descent 144 feet, and so on according to the following law:—The velocity (in feet per second) acquired by a falling body is 32 times the time (in seconds).

The space (in feet) passed through by a falling body is 16 times the square of the time, or the square of 4 times the time. Hence it follows that the time (in seconds) occupied by the descent of a falling body through a given height (in feet), is ⅛th of the square root of the height; that the velocity (in feet per second) is 8 times the square root of the height; and that the height is the square of ⅛th of the velocity.

Example 1.—Required the velocity acquired by a falling body in 5 seconds.

32 × 5 = 160 feet per second.

Example 2.—Required the height fallen by a body in 5 seconds.

16 × 5 × 5 = 400 feet, or (4 × 5 =) 20 × 20 = 400.

Example 3.—Required the time occupied by a body falling through 400 feet.

Sq. root of 400 is 20, and ⅛th of 20 is 5 seconds.

Example 4.—Required the velocity acquired in falling 400 feet.

Sq. root of 400 is 20, and 8 times 20 is 160 feet per second.

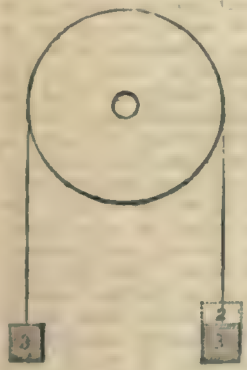
Example 5.—Required the distance fallen by a body when it has acquired a velocity of 160 feet per second.

$$\frac{100}{8}=20, \text{ and } 20 \times 20=400 \text{ feet.}$$

These rules only apply correctly when a body falls in vacuo, for the resistance of the air materially retards the velocities, especially when they become considerable, and when the body has considerable bulk in relation to its weight. Were it not for this resistance, every raindrop, descending as it does from a height of many hundred feet, would strike with a force as fatal as that of a rifle-bullet.

When part of the weight of a falling body is balanced by the ascent of some weight connected with it, its velocity is materially diminished. When two equal weights, each 3 lbs., are hung by a string over a pulley (Fig. 134), they exactly balance each other—that is to say, the gravitating attraction exerted on one is equal to that exerted on the other; and as the one cannot descend, in accordance with this force, without causing the other to ascend in opposition to it, no motion takes place; but if we add to the one 2 lbs., we apply to that side the gravitating force of 2 lbs., and the motion takes place in obedience to it. The force of 2 lbs. has, however, not only to put in motion its own mass, but also that of the two weights, in all 8 lbs., or 4 times its own weight; and therefore the velocity which they all acquire in 1 second can only be the ¼th of that which the 2 lbs. alone would acquire—that is to say, 8 feet per second instead of 32. The distance passed over must therefore be only ¼th of what it would be were the moving weight left to itself without having to put the others in motion. In all such cases, then, of weights partly balanced, if we know the total of the weights put in motion, and the excess of the one over the other, we find the velocity or the space in a given time by the following rule:—

Fig. 134.



Find the space or velocity as before, multiply by the excess of one weight, and divide by the sum of all.

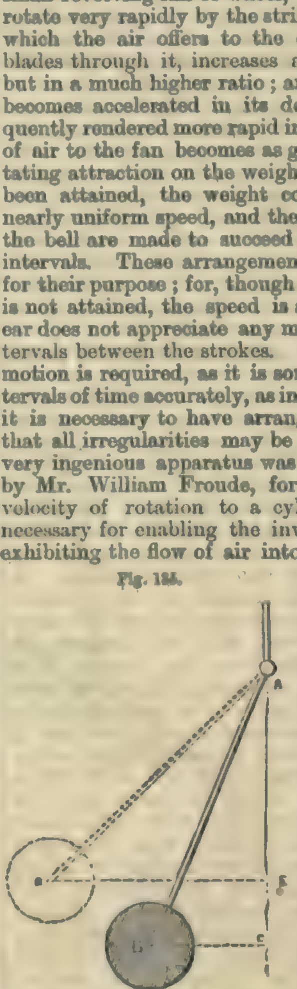
Example 6.—Required the space passed through in 4 seconds by a weight of 19 lbs. connected by a string over a pulley with one of 13 lbs.

The excess of the one is 6 lbs.; the sum of both is 32 lbs. The space would be for a single weight, $16 \times 4 \times 4 = 256$ feet, and

$\frac{256 \times 6}{32} = 48$ feet is the space descended in 4 seconds under the circumstances given.

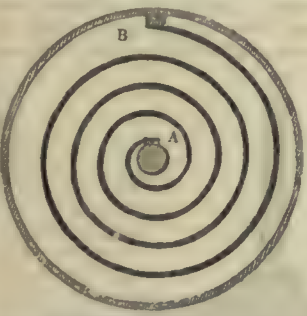
It does not often happen that, in practice, two different weights are hung over a pulley as we have just described. The effect, however, is just the same if there be one weight acting on a barrel, and if the movement of the barrel be resisted by some known force. If, for instance, we had a weight of 19 lbs. attached to a barrel connected by machinery with some other load, and we found that 13 lbs. hung to the barrel, instead of 19 lbs., would exactly balance the load upon the machinery, so that no movement of the barrel took place, we should estimate, as we have done above, that 19 lbs. had to set in motion itself and 13 lbs., the drag of the machinery, and that the space passed through in four seconds would be 48 feet, as we have computed. All such estimates, however, are made without regard to the resistance caused by friction. The rubbing surfaces of machinery are so irregular, and subject to such changes of condition by wear, temperature, deficiency of lubrication, and other causes, that friction cannot be estimated as a regular resistance. No machinery moved by a weight, without some special regulating apparatus, can be expected to move with uniform velocity, or with velocity varying according to any uniform law on account of these irregularities of resistance. The law of motion which a falling body obeys is, therefore, scarcely ever practically applicable. In all machinery moved by weights, some contrivances are introduced for providing a resistance so much greater than that of the mere friction, that the weights upon the whole may be made to descend uniformly, and not with the accelerated velocity due to gravitating force alone. Thus, in the time-keeping part of a clock, the weight which puts the whole in motion, is arrested at every moment of its descent by the pendulum and escapement. The motion of the weight downwards becomes in this case a series of extremely short descents, recurring at equal intervals, whenever the pallets of the escapement permit the train of wheels to move. The weight employed is so much in excess of the resistance from friction, that the irregularity in the time of each of its partial descents is exceedingly small. The regularity of the clock's motion, therefore, depends upon the uniformity of the times which the pendulum occupies in each of its beats, the interval during which the weight descends and the train moves, being too small for any irregularity to manifest itself. In the striking part of a clock, there is no necessity for extreme regularity. The whole striking train is kept at rest until the time-keeping part comes to such a point, that it removes the obstacle to the motion of the striking-weight. This, being relieved, begins to descend, and would go on descending with accelerated velocity, moving its train of wheels, and causing the hammer to strike the bell faster and faster, were not a resistance provided, sufficient to prevent the acceleration from becoming too great. The apparatus generally used for giving this resistance, consists of a small revolving fan or wheel, with flat blades, caused to rotate very rapidly by the striking train. The resistance which the air offers to the quick passage of the fan-blades through it, increases as their velocity increases, but in a much higher ratio; and gradually, as the weight becomes accelerated in its descent, and the fan consequently rendered more rapid in its rotation, the resistance of air to the fan becomes as great as the effort of gravitating attraction on the weight. When this velocity has been attained, the weight continues to descend with nearly uniform speed, and the strokes of the hammer on the bell are made to succeed each other at nearly equal intervals. These arrangements are sufficiently complete for their purpose; for, though a perfectly uniform motion is not attained, the speed is so nearly regular that the ear does not appreciate any marked difference in the intervals between the strokes. When a perfectly uniform motion is required, as it is sometimes for measuring intervals of time accurately, as in astronomical observations, it is necessary to have arrangements more delicate, so that all irregularities may be properly compensated. A very ingenious apparatus was contrived some years ago by Mr. William Froude, for giving perfectly uniform velocity of rotation to a cylinder. This motion was necessary for enabling the inventor to obtain diagrams exhibiting the flow of air into a vacuum, the propelling power of a screw on a boat fitted with it, and other interesting mechanical phenomena. In one of his apparatus he employed a flat disc B (Fig. 135) at the end of an arm suspended by a joint from a vertical axis A, caused to rotate by a train of wheels connected with a weight and with the cylinder, which was required to be uniformly moved. The disc revolving through the air offered a certain resistance, depending on its velocity; and if at any instant the velocity increased, the disc immediately moved outwards from the vertical line, owing to

Fig. 135.



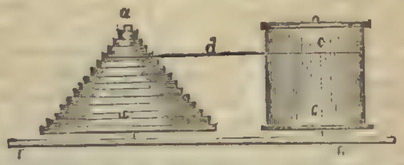
its increased centrifugal force, to some such position as that indicated by the dotted lines. When at this distance, the radius of its orbit D E was greater than the former radius B C; and therefore the speed with which the disc was driven through the air was proportionately greater, and the resistance of the air to its motion increased accordingly. The momentary increase of velocity, therefore, produced a considerable increase of resistance, and thus reduced itself to its average rate; and, conversely, a decrease of velocity diminished the resistance, and thus restored itself. By a proper adjustment of the disc as to area, the length of the arm by which it swung, and a weight on that arm, the apparatus served to move the cylinder for many minutes with a velocity in which there was not the slightest appreciable irregularity. A piece of paper was fixed on the cylinder, and a pencil, connected with a spring-balance acted on by the pressure to be measured, traced on the paper as it revolved a diagram, indicating the intensity of the pressure at every instant of the motion.

Fig. 136.



When the elasticity of a solid body is employed as a force for moving machinery, the body is called a spring, and generally consists of a strip of steel wound into a spiral form round an axis A, as shown in Fig. 136; one end of the strip being fixed to the axis, and the other at B to the side of the cylindrical box in which the spring is contained. When the box is fixed, as in a Geneva watch, the axis is turned round by a key, and the spring is thus drawn into closer convolutions. A wheel is fixed on the axis, and is connected by gearing with the escapement, and hands of the watch. The effort of the spring to unwind itself causes the axis to revolve in the direction opposite to that in which it was wound, and thus puts the train of wheels in motion. It is the property of all elastic bodies to exert a force which is nearly proportional to the amount of strain to which the body has been subjected. As we wind up the spiral spring of a watch, we apply greater and greater strain the farther we wind; and so when the spring unwinds itself it exerts the greatest force at first, and gradually decreases in power, the farther it is unwound. This decrease of force is an irregularity which no modification of the form of spring can obviate, but which may be considerably diminished by making the spring with a great number of convolutions. Thus, we may suppose that a spring of 20 convolutions, or turns, is wound up from its neutral condition to the full power required, by 10 revolutions of the axis. In unwinding itself it would lose by the first revolution $\frac{1}{10}$th of its force, by the second revolution another $\frac{1}{10}$th, and so on, until by five revolutions backwards it would lose $\frac{5}{10}$ths or $\frac{1}{2}$ of its full force. But if we suppose the spring had forty convolutions, and that we wound it up by 20 revolutions on the axis to the same force as the former spring, in unwinding itself it would lose by the first revolution $\frac{1}{20}$th, by the second another $\frac{1}{20}$th, and so on till by the fifth it would lose $\frac{5}{20}$ths or $\frac{1}{4}$th of its full force. The decrease of power in the second instance is only half that in the first, the axis performing in each case an equal number of revolutions. It is, therefore, important to give all springs which are required to exert a tolerably equal force throughout their recoil as great a number of convolutions as possible, and to employ as few revolutions of the axis as possible for moving the machinery. In other watches, where smallness of bulk is not so much studied, and in clocks moved by springs, the axis of the spring is fixed, and the box *c* (Fig. 137) containing it is caused to revolve by the recoil of the spring, and to wind upon its outer surface a small chain *d* attached to a fusee *a*. This fusee is a conical barrel, with a screw-groove cut in its surface to receive the coils of the chain. When the spring is beginning to recoil, and therefore acting with its greatest force, the chain pulls the fusee round at its upper part where the diameter is smallest, and therefore acts with least leverage on the train. As the spring loses force, the chain is pulled from a larger diameter of the fusee, and acts with more and more leverage on the train as its tension becomes less. By properly proportioning the increase in the diameter of the fusee to the diminution in the force of the spring, the power applied to the train can thus be made perfectly regular throughout the whole range of the spring's recoil. The fusee is not a regular cone, the outline of its section being part of a hyperbolic curve, that being the form which furnishes the proper proportion of increase of diameter to diminution of spring force.

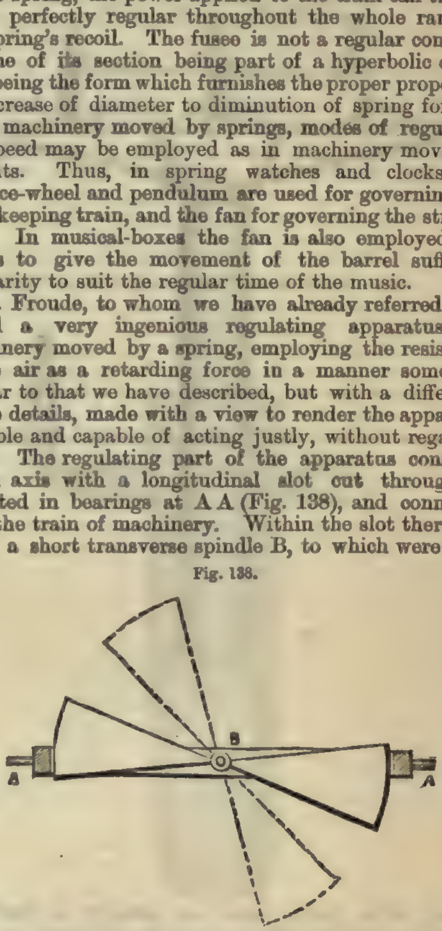
Fig. 137.



In machinery moved by springs, modes of regulating the speed may be employed as in machinery moved by weights. Thus, in spring watches and clocks, the balance-wheel and pendulum are used for governing the time-keeping train, and the fan for governing the striking part. In musical-boxes the fan is also employed, and serves to give the movement of the barrel sufficient regularity to suit the regular time of the music.

Mr. Froude, to whom we have already referred, contrived a very ingenious regulating apparatus for machinery moved by a spring, employing the resistance of the air as a retarding force in a manner somewhat similar to that we have described, but with a difference in the details, made with a view to render the apparatus portable and capable of acting justly, without regard to level. The regulating part of the apparatus consisted of an axis with a longitudinal slot cut through it, mounted in bearings at A A (Fig. 138), and connected with the train of machinery. Within the slot there was fitted a short transverse spindle B, to which were fixed two thin blades, kept in the position indicated in the figure by means of a small spring made to act on their spindle. When this apparatus was made to rotate with considerable velocity in the bearings A A, the blades tended, by their centrifugal force, to fly outwards to some such position as that marked by the dotted lines, and thus encountered more resistance from the air. By the proper adjustment of the area and weight of these blades and of the spring which acted on their spindle in opposition to their centrifugal force, extreme regularity in the motion of the train was maintained.

Fig. 138.

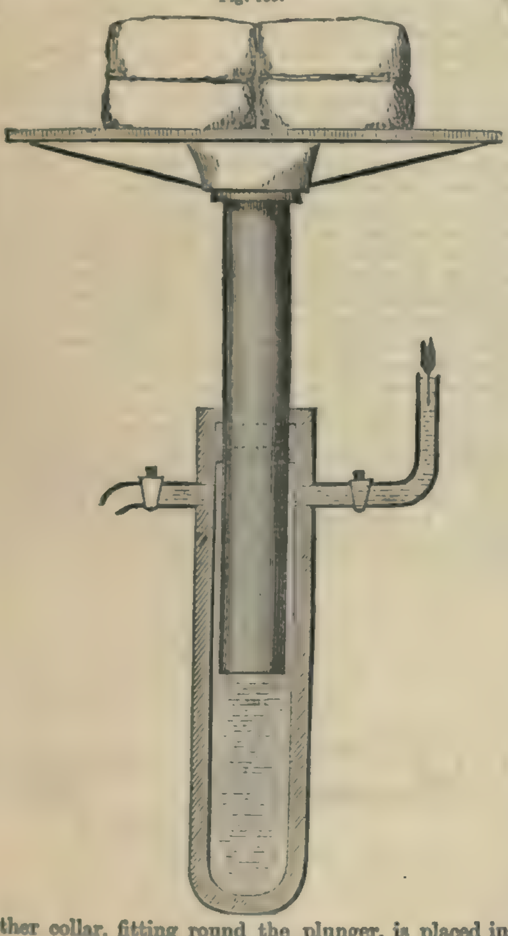


In general, for moving machinery with regular speed, weights are preferable to springs, because the force of a weight is constant, while that of a spring varies according to its tension. But weights act only vertically, while springs act in any direction. For all portable apparatus which cannot be maintained in a constant level so as to make the direction in which the weight acts constant, with relation to that on which it acts, springs must be employed. And so for the regulation of portable apparatus, escapements in which the elasticity of a spring is used for recoil, instead of the weight of a pendulum, must be likewise employed. The details of all such apparatus, and the many ingenious contrivances applied to them, form the subject of a distinct art, that of Horology.

PRESSURE AND ELASTICITY.—Besides contrivances for employing the weight and elasticity of solid bodies in giving motion to machinery, there are others by which the weight or pressure of liquids and the elasticity of gases are also applied for such purposes.

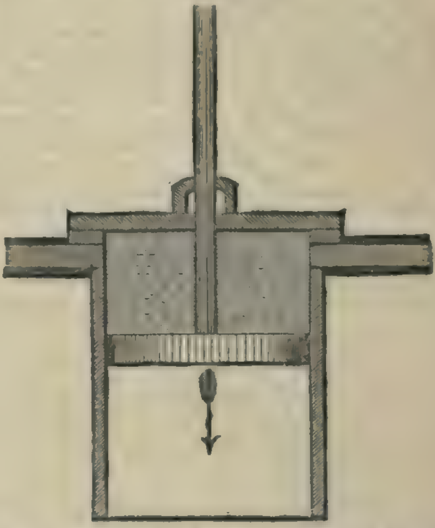
Among these the hydraulic lift and the hydraulic crane may be particularly noticed. The hydraulic lift, in its most simple form, consists of a cylinder closed at bottom, and fitted with a plunger or ram, which passes through the top and supports a stage (Fig. 139). A leather collar, fitting round the plunger, is placed in a recess provided in the neck of the cylinder, so as to prevent the escape of water around the plunger. A pipe from a high cistern conducts water into the cylinder, and another pipe permits the water to issue from it. Each of these pipes is provided with a stop-cock, so that the water may be admitted to the cylinder, or allowed to flow from it at pleasure. Since liquids communicate pressure equally in all directions, every part of the cylinder and the plunger is pressed upon, by a force proportioned to the height of the cistern which supplies the apparatus. Every 27 inches of height produces a pressure of 1 lb. on every square inch of surface exposed to it; and by making the area of the bottom of the plunger sufficiently large, a considerable weight can be raised on the stage which it carries. Thus if the cistern at the top of a house be 54 feet above the ground-floor, the pressure on the internal surface of any vessel on the ground-floor connected with it by a pipe, is 24 lbs. per square inch. If this vessel be a cylinder, such as we have described, fitted with a plunger 10 inches diameter, having therefore a sectional area of 78½ square inches, the pressure forcing this plunger upwards amounts to 78½, × 24 = 1884 lbs., and if from this we deduct 764 lbs. as a weight including that of the plunger and platform, there remains a pressure of 1120 lbs. forcing the plunger upwards. A load then of this amount, half a ton, may be placed on the platform when it is in its lowest position, and the cock being opened to the cistern, the whole will be raised to a height equal to that of the plunger, which may be made sufficient for lifting goods from one floor to another. By closing the cistern-cock and opening the other, the water is permitted to leave the cylinder; and the plunger, no longer subjected to upward pressure, descends to its former position.

Fig. 139.



The water-pressure may be made to act in a way somewhat different in detail, but similar in principle, by fitting the cylinder with a piston, connected by a rod passing tightly through the cylinder cover with a rope or chain, which may be led by pulleys in any convenient direction for lifting weights attached to it. The water-pressure acting on the piston, forces it down the cylinder, and thus pulls the chain and lifts the weight. Such an arrangement constitutes the hydraulic crane. The advantage of employing water for lifting weights in this manner consists in the circumstance that a small steam-engine, or other power, can be constantly employed in raising the water to a high cistern, and that great lifting power can be obtained for a short time by the expenditure of a portion of the water thus raised. The water lifted to a height, becomes, in fact, a reservoir of power, ready to be used when required, and accumulates the efforts of a small power acting through a considerable period, ready to be expended as a great power acting through a short time. Farther, this power is completely under control; for by the mere turning of a stop-cock, or the opening or closing of a valve, it can be put in action or arrested at pleasure; and the speed with which a weight is moved, and the height to which it is raised, can be regulated with the greatest nicety.

Fig. 140.



Apparatus has sometimes been applied in which water flowing from a high level, or compressed air, may be made to act as steam in a steam-engine, for giving motion to machinery. The construction of such apparatus is very similar to that of the steam-engine, and may be easily understood by one who has studied the arrangement of the latter.

The pressure of the atmosphere has also been employed as a moving force in the case of the atmospheric railway.

4. HEAT AND ELECTRICITY.—In treating of heat, electricity, magnetism, and chemical action, as sources of power, we embrace a very wide range of

matter, which may with advantage be sub-divided. We may here merely notice the branches which this division of the subject embraces.

Both heat and electricity appear to be universally the result of chemical action. They are not *new* forces created by the combination or separation of materials, but are merely the manifestations of force already stored up in bodies, and elicited by changes in their constitution. Practically speaking, however, heat may be said to be the force produced by the chemical action of combustion, or the union of oxygen with inflammable matter—a force which universally manifests itself as a repulsion, acting upon the particles of matter exposed to it. A pound of coal or carbon, or any other combustible, uniting with its proper equivalent of oxygen, produces a certain amount of heat, which is capable of expanding the bulk of any solid, liquid, or gaseous body exposed to it; of changing a solid into a liquid, or a liquid into a vapour, apparently by forcing the particles to a greater distance from each other. Combustible bodies are universally found throughout the earth; oxygen abounds in the atmosphere; and man has only to bring these two kinds of matter together, under proper conditions, in order to obtain the force developed by their union, which he can apply in many different ways as a motive power.

The various modes of thus applying heat may be distinguished under three heads.

1. The combustion of explosive substances, or substances like gunpowder, which very rapidly change from a condition in which they occupy small space, to one in which they occupy a very large space. The chief uses made of such forces are for blasting, and for giving motion to projectiles. The enormous force applied to these purposes may be best understood by observing, that any particular quantity of gunpowder, when ignited, expands to about 2,000 times its volume, in an interval of time so inappreciably small, that its expansion may almost be said to be instantaneous. Let us suppose, for instance, that a cannon of six inches bore is charged with a quantity of powder occupying about six inches of its length, and, on the powder, an iron ball is placed, weighing 32 lbs. Before the ignition of the powder, the surface of the ball is pressed on equally in all directions by the pressure of the atmosphere, about 15 lbs. on every square inch, or, its sectional area being 28 square inches, the total atmospheric pressure tending to push it in any direction is 28 × 15 = 420 lbs.; and as this pressure is exerted equally in every direction, no motion ensues. On the ignition of the powder, the pressure on one side is suddenly increased from that of one atmosphere, 420 lbs., to that of 2,000 atmospheres, or 840,000 lbs.; and thus a force is applied, at one side of the ball, exceeding 26,000 times its weight. Were this force continued for 1″ of time, the ball would acquire, in that time, a velocity 26,000 times that which gravity would give it, because the force is 26,000 times the weight or force of gravity; and as gravity gives in 1″ a velocity of 32 feet per second, the force of the gunpowder would in the same time give it a velocity of 26,000 × 32 = 832,000 feet per second, or nearly 570,000 miles per hour.

But, as the gun is comparatively short, seldom exceeding 9 or 10 feet in length, the pressure acts only during the short time which the ball occupies in traversing that distance. Also the elastic gases generated from the explosion of the gunpowder, instead of maintaining their enormous initial pressure during even this short period, lose more and more of it as they are permitted to expand by the forward motion of the ball; so that by the time it reaches the muzzle of the gun, their pressure would probably be reduced to less than 100 atmospheres. Moreover, as the ball does not precisely fit the gun, a considerable leakage is permitted round it, so that the pressure is still farther reduced, and even a certain back-pressure is caused by the gas which thus gets in front of the ball. From all these causes there results a diminished velocity of the ball, which seldom exceeds 2,000 feet per second, or about 1,360 miles per hour.

The whole subject of projectiles, and of the apparatus used for applying the combustion of explosive substances to give them motion, may be said to be in a transition state; and although of late years very great ingenuity has been displayed in contriving implements for this purpose, it would scarcely suit the limits of a work like the present to enter upon their discussion.

2. The combustion of fuel, without explosive violence, has been applied to cause the expansion of air for the purpose of producing motive power. The principle of this action is of a very simple character. Any volume of any gas, such as a cubic foot of air at a temperature of 32° (Fahr.), on receiving accessions of heat, increases in temperature and expands in bulk, and the amount of expansion depends on the increase of temperature, according to the following law:—For every added degree (Fahr.) of temperature, the volume expands $\frac{1}{480}$th part of itself. Thus, if the cubic foot were heated from 32° up to 72°, the increase of temperature being 40° (the difference between 32° and 72°), the increase of volume would be $\frac{40}{480}$ths, or $\frac{4}{48}$ths, or $\frac{1}{12}$th of a cubic foot; that is to say, 144 cubic inches. Or the volume at 72° would be 1 and $\frac{40}{480}$ths, or $\frac{520}{480}$ths of a cubic foot. If, now, this volume were heated up to 73°, or 1° more, its expansion would be $\frac{1}{480}$th, and its total volume would be $\frac{520}{480}$ths and $\frac{1}{480}$th; in all, $\frac{521}{480}$ths. Or its volume at 72° would be increased by $\frac{1}{520}$th of itself, on the accession of another degree of temperature. Now, if we observe that 480, the divisor which gives the expansion per degree of a volume at 32°, is 448 added to 32, and that 520, the corresponding divisor for 72°, is 448 added to 72, we readily see that the expansion per degree of any volume at any temperature is found by adding the constant number 448 to the temperature, and using the same as a divisor.* This leads to a rule by which, knowing the volume at any temperature, we can readily find the volume at any other temperature: thus—

Rule.—Add the constant number 448 to each of the temperatures, and state the proportion: as 448 + the temperature of the given volume is to 448 + the temperature of the required volume, so is the given volume to the required volume.

Example.—Required the expansion of 10 cubic feet, when heated from 60° to 212°.

			Given volume.		Required volume.
60°		212°			
448		448			
508	:	660 : :	10 cubic feet	:	13 cubic feet nearly.
		10			
		508)6600			
		13 nearly.			

Hence the expansion is nearly 3 cubic feet.

It may now be understood that, having the means of largely expanding any volume of air by adding heat, and of again contracting it by taking heat away, we have a force within our reach, capable of being applied as a motive power. Several contrivances for utilising this force have been made from time to time, but they all present so strong a similarity to the steam-engine, and they have, as yet, met with so little success in their

---

* Let V be the volume at 32°
v_1 ,, ,, at t_1 of temperature
v_2 ,, ,, at t_2 of temperature

$$\text{Then since } v_1 = \text{V} + \text{V}\,\frac{t_1 - 32}{480} = \text{V}\left(1 + \frac{t_1 - 32}{480}\right) = \text{V}\,\frac{448 + t_1}{480}$$
$$\text{and since } v_2 = \text{V} + \text{V}\,\frac{t_1 - 32}{480} = \text{V}\left(1 + \frac{t_1 - 32}{480}\right) = \text{V}\,\frac{448 + t_1}{480}$$
$$\text{eliminating V, we have } \frac{480\,v_1}{448 + t_1} = \frac{480\,v_2}{448 + t_2},\ \text{or } v_2 = v_1\,\frac{448 + t_2}{448 + t_1}$$

practical application, that we do not think it necessary to occupy space by separately discussing them.

3. By far the most important application of heat to produce motive power, is that which is made in the steam-engine. Of all apparatus by which man has succeeded in rendering natural forces serviceable to himself, this is, perhaps, the most ingenious, as it is the most widely employed. It therefore forms a branch of Applied Mechanics, so important, and at the same time so extensive, that we propose to devote considerable space in what follows to its discussion.

Electricity and magnetism are the forces which have been applied so successfully in the electric telegraph—an apparatus which has now attained so great importance, and embraces so many ingenious contrivances, that it has been thought advisable to give it special consideration in another section. (SECTION IV.)

The efforts which have, from time to time, been made to render these forces available as prime movers of machinery, have not yet been crowned with success. We may, therefore, in a practical work like the present, dismiss the contrivances for this purpose with a few brief remarks as to their general character, referring the reader to those parts of this work which treat more especially of electro-magnetism, and of the machinery in which it has been applied.

One of the effects of electrical action being to decompose bodies subjected to its influence in one way, and to reproduce them from their elements in another way, an engine was contrived to act by the alternate decomposition of water into its elements—the elastic gases, oxygen and hydrogen—and its recomposition by their combustion. The one operation, decomposition, changing the small bulk of water into a large volume of the mixed gases, afforded a pressure; while the converse operation of recomposition removed the pressure by re-condensing the large volume of the gases to the small bulk of water.

The application of electro-magnetism as a prime mover has been attempted in various ways, all of which depend more or less on two special properties, by which electricity and magnetism appear to be connected. One of these is, that a current of electricity moving at right angles to a bar of iron renders it magnetic, each end of the bar becoming a pole. When the current is reversed in direction, the poles are immediately reversed, that which was South becoming North, and conversely; and when the current ceases, the magnetism disappears. By coiling the electric-wire many times round the bar, the power of the magnet is rendered very great; and as by reversing or arresting the current each end may be made to attract, repel, or to become entirely neutral, it might be expected that the force so developed should be readily applicable to the production of motive power. It has been found, however, that the attractive and repulsive influences act with extremely little force at any distance from the poles of the magnet, and the consequent limitation of range has rendered their application to machinery very difficult.

The other property by which electricity and magnetism are connected is, that a conducting wire wound round a permanent magnet, has a current of electricity induced in it, and the cells of an electrical battery surrounding a magnet are put in rotation round it as an axis. The motion produced by the mutual action of these forces has not, so far as we know, been as yet applied to any useful purpose; and, although many neat contrivances of the kind have been exhibited on the lecture-table, we fear that in practice the cost of producing power in this manner, is such as to prevent it from coming into competition with the simple combustion of fuel.

CHAPTER V.

THE STEAM-ENGINE.

Contents.—EXPANSIVE POWER OF HEAT—ELASTICITY OF GASES—TEMPERATURE AND PRESSURE—VOLUME OF STEAM—CONDENSATION—EXPANSION—THE BOILER—CORNISH BOILER—MARINE AND LOCOMOTIVE BOILERS—CONSTRUCTION OF BOILERS—INCRUSTATION—BOILER FITTINGS—FEED—SAFETY VALVE—PRESSURE GAUGE—CYLINDER—VALVES—SLIDE—CYLINDER AND PISTON—SHUT-OFF AND THROTTLE VALVES—FEED-PUMP—CRANK AND CONNECTING ROD—ECCENTRIC CAMS—GOVERNOR—DIRECT-ACTING ENGINES—VERTICAL, HORIZONTAL, LOCOMOTIVE, AND OSCILLATING ENGINES—ESTIMATION OF POWER—INDICATOR—CALCULATION OF POWER.

IT is usual for writers on the steam-engine to give an outline of its history, tracing up from the earliest times, successive contrivances and suggestions for rendering the elasticity of vapours applicable as a motive power. This mode of introducing the student to the consideration of the mechanical arrangements, which now constitute a complete steam-engine, is not without its advantages. It is calculated to open his mind to the defects of successive inventions, and to the modes in which they have been gradually removed, until what was at one time looked on as an ingenious and interesting philosophical toy, has become at last an apparatus that has changed the whole face of civilised society, and almost brought the elements within the control of man. By watching the steps of inventors in this progress, the student becomes well prepared to comprehend the details of the perfected apparatus, and the reasons why certain modifications have been introduced as improvements, while others have been rejected as practically inapplicable. But it happens with the steam-engine as with almost all other mechanical contrivances, that its earliest forms are by no means the most simple; and that improvements have often consisted more in discarding useless complications than in adding new parts. We think, upon the whole, therefore, that the steam-engine may be best studied in its most simple forms, regardless of their historical sequence, especially when a practical knowledge of its construction and applications is desired, rather than a merely theoretical acquaintance with its principles. We propose, therefore, to discuss, in the first place, the general properties of steam, and the modes adopted for generating it in a manner suitable for rendering it available as a prime mover. And we will, secondly, consider the special forms of apparatus, or engines, through which the steam is made to act for producing the movement of machinery. By this course we shall hope to give the reader a clear view of the whole subject; and we shall take such opportunities as offer themselves, of referring to the various inventions that have, from time to time, been brought into use.

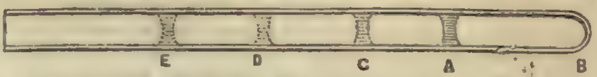
To the advantages arising from the use of steam as a motive power, to the changes that have been effected by its introduction, and the still greater changes that may be confidently expected from its more extended application, we need scarcely refer. These are patent to all; for in the present condition of society, few operations either of transit or manufacture are conducted, in which the steam-engine does not play the most prominent part.

EXPANSIVE POWER OF HEAT.—When a liquid is exposed to heat, it expands in bulk; and when the heat is carried to a certain point, part of the liquid rises from the rest in the form of vapour, occupying a much greater volume than it did in its liquid condition. It is probable that all substances, solid as well as liquid, are capable of being thus changed into the vaporous form. Some bodies, such as ether and alcohol among liquids, and iodine among solids, rise in vapour at comparatively low temperatures. Others, again, such as many of the metals, even after they have become liquid under the influence of heat, require very considerable accessions of temperature before they pass into vapour. Water, one of the substances most widely diffused in nature, and therefore most cheaply obtained, holds a middle course in this respect between these extremes, and attains, by no great accessions of temperature, properties which render it especially serviceable for human use. It is, indeed, among the most obvious of the beneficent arrangements of Providence, that this fluid—almost everywhere accessible, possessed of no corroding power like acids or alkalies, of no intoxicating qualities like spirits, not of inconvenient gravity like metals—should be at the same time capable of absorbing vast quantities of heat, and of giving it out in the shape of active motive power. It has been proposed to employ the vapours of ether, alcohol, sulphide of carbon, and mercury, for moving engines; but no advantages from their use in this way have presented themselves, such as could bring them into competition with water. We will, therefore, confine ourselves to it, as the only substance turned practically to account.

The atmosphere which envelops the earth, though invisible, is nevertheless possessed of weight, and presses on the surface of all bodies in it exactly as the water contained in a cistern presses on bodies immersed in it. The pressure of the atmosphere at the surface of the earth is about 15 lbs. on every square inch. This pressure varies with changes in the density of the atmosphere, but not to a great extent. The average is generally stated at somewhat less than 15 lbs. per square inch; but, for all practical calculations, 15 lbs. may be assumed without involving material error. Water contained in any vessel exposed to the air is thus pressed upon, and retains its liquid form at ordinary temperatures. But if the temperature of the water be raised to 212°, as measured by Fahrenheit's thermometer, its vapour at that temperature has an elastic force which exactly balances the atmospheric pressure, and part of the water consequently rises in the form of vapour, and mingles with the air, displacing as much of the latter as is equivalent to its own bulk. Were the pressure of the air removed, vapour would rise from the water at much lower temperatures than 212°, and occupy the vacant space in the vessel containing it. Thus, when a saucer containing water is placed under the receiver of an air-pump, as the air is extracted from the receiver, vapour rises from the water; and however low may be the temperature of the water, vapour continues to rise from it as the pressure of air on its surface is diminished. Even under the full atmospheric pressure, water is constantly evaporating at ordinary temperatures, for the air seems to have a power of dissolving water or taking it up in a vaporous form, just as water dissolves salt and retains it diffused through it in a liquid form.

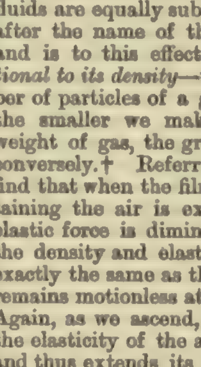
ELASTICITY OF FLUIDS.—At every different temperature at which vapour may exist, its elastic force is different, being greater the greater the temperature, but not proportionally so. When we inquire what is meant by the elastic force of a vapour, we can only say that it is a property common to all aëriform bodies, by which they react on any surface compressing them, or tend to expand into a larger volume than that in which they are confined. There seems, indeed, to exist, a repulsive force among the particles which constitute a gaseous body, pushing them asunder with equal power in every direction, and requiring some contrary compressing force to retain them in their places. We have no example of a gaseous body existing without being contained in an envelope of some kind, or being pressed upon by some surrounding medium. The air at the surface of the earth is pressed upon by the weight of air above it, and exerts an elastic force exactly balancing the pressure of the superincumbent fluid.* If its elastic force were greater than the force compressing it, it would expand and lift the air above it; or if less, it would collapse under a pressure greater than it could resist. As we ascend higher, the weight pressing on the air is diminished, because there being a certain amount of the atmosphere left below, there remains a less amount above. We find accordingly, that at any height above the earth's surface, the elastic force of the air is diminished in proportion as the pressure upon it is lessened. At the top of a high mountain, like Mont Blanc, the elastic force of the air is not more than half that of the air at the surface. If we were to introduce a drop of oil into a small glass tube closed at one end (Fig. 141), so that the oil should form a film, or diaphragm, across the tube at some point A, we should enclose between A and B a portion of air in the same condition as that surrounding us. If, now, we ascended a mountain, we should find the air-film at points C, D, E, successively, as we attained greater height. Before our ascent commenced, the elastic force of the air in A B pressed the oil-film outwards with exactly the same force as that of the weight of superincumbent air pressing it inwards, and accordingly the film remained at rest. As we ascended, we subjected the film to less external pressure, because we had less weight of air above us; and accordingly the elasticity of the air in A B overbalanced the pressure, and pushed the film to some such point as E; not by fits and starts, but gradually as we ascended.

Fig. 141.



We have now to inquire why there should be any point such as C, where the film could rest; in other words, why the elastic force of air in the tube, having once overbalanced the pressure of the external air, should again become equal to it, and no longer force the film outwards. The reply to this question involves the consideration of a most important law to which all elastic fluids are equally subjected. It is called Marriotte's law, after the name of the person who gave it to the world, and is to this effect:—*The elasticity of a gas is proportional to its density*—that is to say, the greater the number of particles of a gas we force into a certain space, or the smaller we make the space containing a certain weight of gas, the greater we make its elastic force, and conversely.† Referring now to the air in the tube, we find that when the film has arrived at C, the space containing the air is extended from A B to C B, and the elastic force is diminished in like proportion. In fact, the density and elasticity of the air within the film is exactly the same as that of the air without, and the film remains motionless at C as long as this equality subsists. Again, as we ascend, the external pressure diminishes; the elasticity of the air within pushes the film outwards, and thus extends its space until its elasticity is reduced to an equality with the pressure of the external air; and so on without limit. In descending, we should find the film moving inwards, according as it became subjected to a greater external pressure, to positions, such that the air confined within it became of a density sufficient to balance the pressure. Notwithstanding the extreme simplicity of Marriotte's law, it is one of the greatest importance, and should be thoroughly understood by any one desirous of an acquaintance with the steam-engine, for it applies to steam as closely as to any gas. From this law, it follows, that if we forced air or steam occupying a volume of 2 cubic feet into a vessel of the capacity of 1 cubic foot, we should find the elasticity doubled, because the density would be doubled, or the volume reduced to half. Conversely, if we permitted 1 cubic foot of air or steam to occupy a volume of 2 cubic feet, we should reduce its elastic force to half of what it was before expansion, because we should have doubled its volume, or reduced its density to half of what it was. In order to illustrate these facts, let us suppose that a cylindrical vessel is fitted with a piston that can

Fig. 142.



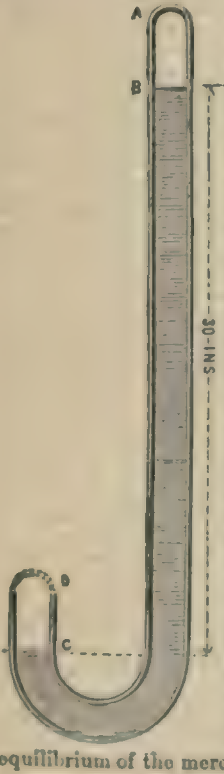
---

* See *ante*, p. 770, *Pneumatics*.

† See *ante*, p. 770, *Pneumatics*.

slide in it (Fig. 142), having an area of 1 square inch, and that a load of 20 lbs. placed on the piston forced it down to a position C D, an inch from A B, compressing below it the air or steam occupying the part A B D C of the cylinder. We should then say that the elasticity or pressure of the air or steam is 20 lbs. per square inch, because it balances or supports a load of 20 lbs. placed on a piston having an area of a square inch, exposed to its elastic force. If we suppose another inch added to the length of the cylinder, the added space A E F B being totally empty, and the former bottom A B suddenly withdrawn, so that the air or steam had its space or volume doubled, we should find 20 lbs. on the piston twice as much as it should be to retain the piston in its place, and we should have to replace it by a load of 10 lbs., because the elasticity of the air, or steam, would have become half of what it was before the doubling of its volume. We have already stated that the pressure or elasticity of the air, near the surface of the earth, is about 15 lbs. on every square inch. If then a cylinder like that which we have just described were filled with air under the piston, and placed in a vacuum, there would be required on the piston a load of 15 lbs. to retain it in its place. Were the load less than 15 lbs., the air under the piston would expand in volume and raise it; or were the load greater, the piston would be pressed downwards, increasing the density of the air below it, and proportionally its elasticity, until the load became exactly balanced. But a cylinder of the kind described, filled with air, and not placed in a vacuum, requires no actual weight on the piston, because the surrounding atmosphere affords a load exactly equivalent to the weight that would be required in a vacuum. If the cylinder were filled with steam instead of air, and with no load on the piston, the steam would be said to be at atmospheric pressure, because its elasticity tending to force the piston upwards, is exactly balanced by the pressure of the atmosphere tending to force it downwards. If the piston required a load of 15 lbs. upon it, the steam would be said to exert a pressure of two atmospheres, or of 15 lbs. above atmospheric pressure. So, if the steam sustained loads of 30 lbs., 45 lbs., 60 lbs., &c., placed on the piston, its pressure would be called that of 3, 4, 5, &c., atmospheres; or of 30 lbs., 45 lbs., 60 lbs., &c., above atmospheric pressure.

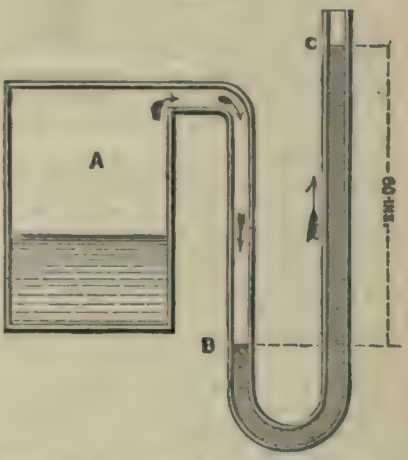
Fig. 143.



The pressure or elasticity of fluids, such as air or steam, is often expressed in terms of inches of mercury, or of the height of column of mercury which they can sustain. It happens that 2 cubic inches of mercury weigh very nearly 1 lb., and that 30 cubic inches weigh, consequently, about 15 lbs. Now, if we suppose a tube, having 1 square inch of sectional area, bent as in Fig. 143, and closed at both ends A and D, were filled with mercury to a height of 30 inches in one limb above the level in the other, the part A B being a perfect vacuum, and the part D C filled with air, since the weight of the column 30 inches high is 15 lbs., this pessure of 15 lbs. is communicated through the mercury in the bend to the air in C D, which consequently reacts with an elastic force equivalent to 15 lbs. on the surface of the mercury exposed to it. That is to say, the elasticity or pressure of the air in C D is 15 lbs., or 1 atmosphere; and the tube might be opened at D to the ordinary pressure of the atmosphere without effecting any change in the equilibrium of the mercurial column. The instrument in this form would become the ordinary barometer, which measures the pressure or density of the atmosphere by the height of a mercurial column sustained in a tube, every 2 inches of height of mercury corresponding to 1 lb. of pressure per square inch.

If a bent tube (Fig. 144) were connected with a vessel A containing water, on heat being applied to the water, steam would be generated in A, and press, by its elastic force, the mercury downwards in one limb of the tube and upwards in the other, until it attained such a position that the excess of weight of mercury in the one limb, and the pressure of the atmosphere on its upper surface C, should exactly balance the elastic force of the steam in A. If the height of C above B were 60 inches, the steam would be said to exert a pressure of 60 inches of mercury, or 30 lbs. per square inch above atmospheric pressure, or to have a total elasticity of 3 atmospheres.

Fig. 144.



TEMPERATURE AND PRESSURE.—We have already said that the elasticity of steam is greater the greater its temperature. There is no simple rule for calculating the pressure due to any given temperature, as the law which governs its variations is of rather an abstruse character. The following table of the pressures and corresponding temperatures of steam, or the vapour of water, is compiled from the results of numerous experiments made with a view to establish some law on the subject.

In a treatise like this we must abstain from the discussion of this law, on account of the advanced analysis required for its investigation. Nor need we offer a formula for calculating the pressure corresponding to a given temperature, as the table contains results sufficiently accurate for all practical purposes. The table only applies to the case of steam in a boiler, or vessel, in contact with the water from which it is generated. Were we to remove any portion of steam into another vessel, and then subject it to heat without water being in contact with it, we should simply expand its volume, as we should air or any other gas, by an increase of temperature; or confining its volume, elevate its pressure according to a totally different law, already discussed in reference to the heated air engine. (See p. 841). Or, were we to remove the steam to a separate vessel, and there cool it, a portion would be condensed, and the remainder would expand to fill the void, at a pressure reduced according to Marriotte's law.

In the first column of the table, the temperatures are marked in degrees of Fahrenheit's thermometer.

The second contains the pressures in atmospheres corresponding to the temperatures.

The third gives the pressure in inches of mercury, or the heights in inches of mercurial columns capable of balancing the elasticities.

The fourth column gives the pressures in pounds per square inch above that of the atmosphere; or the loads in pounds required, in addition to that of the atmosphere, to keep down a piston having an area of 1 square inch pressed upwards by the steam.

TABLE I.

Temperature, Fahrenheit.	Pressure in Atmospheres.	Pressure in inches of mercury.	Pressure in lbs. above atmospheric.
60°	0·017	0·5	14¾ below.
120°	0·120	3·6	13¼ "
180°	0·500	15	7½ "
212°	1·000	30	0 above.
250°	2·000	60	15 "
275°	3·000	90	30 "
290°	4·000	120	45 "
305°	5·000	150	60 "
320°	6·000	180	75 "
344°	8·000	240	105 "
372°	12·000	360	165 "
432°	20·000	600	285 "

We would remark, that for temperatures below 180° and above 344° the results are somewhat uncertain. It is within these limits, however, that any practical application of the table can be required, for we seldom have to do with steam pressing with elastic force of less than half an atmosphere on the one hand, or with pressures above eight atmospheres on the other.

VOLUME OF STEAM.—The great secret of the power derivable from steam, lies in the fact that a small volume of water is expanded by heat into a large volume of elastic vapour, tending to occupy a greatly increased space, and forcing any obstacle presented to its expansion, with the pressure due to its elasticity. The volume of steam produced from a given quantity of water has been variously stated; but we believe it may be very correctly estimated at 1600 times that of the water when the pressure is equivalent to 1 atmosphere. That is to say, a cubic inch of water contained in a vessel open to the air, when boiled off into steam, occupies 1600 cubic inches of bulk, and forces the air contained in the vessel away to the extent of that expanded volume; or expands with a force of 15 lbs. on every square inch, which is the measure of the atmospheric pressure, and therefore of the force resisting the expansion of the steam. But had the vessel containing the steam a volume of only 800 cubic inches, or half that to which the steam would expand at atmospheric pressure, then the density of the steam being doubled—or, in other words, the number of particles crowded into the space being doubled—the pressure on every part of the vessel would be doubled also. If the cover of the vessel were a movable piston having one square inch area, it would in this case require a load of 15 lbs., in addition to the atmospheric pressure upon it, to keep down the elastic steam within.

Looking at the question generally, we see that the volume occupied by steam from a certain quantity of water is inversely as the pressure, because the pressure is as the density, and the density is inversely as the volume. The following is the rule for calculating the volume of steam at any pressure, produced from a given volume of water.

Rule.—Multiply the volume of the water by 1600, and divide by the pressure in atmospheres.

Example 1.—Required the volume of steam at 4 atmospheres (or having a pressure of 45 lbs. per square inch above atmospheric pressure) generated from 3 cubic feet of water.

$$\frac{3\times1600}{4} = 1200 \text{ cubic feet of steam.}$$

Conversely, to find the quantity of water necessary to generate a given volume of steam at a given pressure.

Rule.—Multiply the volume of steam by the pressure in atmospheres, and divide by 1600.

Example 2.—Required the water necessary to generate 1200 cubic feet of steam at 4 atmospheres.

$$\frac{1200\times4}{1600} = 3 \text{ cubic feet of water.}$$

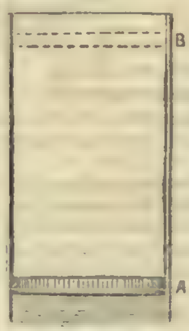
Example 3.—A cylinder 12 inches diameter and 20 inches long is filled 120 times per minute with steam, having a pressure of 30 lbs. above that of the atmosphere; required the quantity of water necessary to generate the steam.

The area of a circle 12 inches diameter is 113 square inches, and the capacity of the cylinder is 113 × 20 = 2260 cubic inches. This capacity filled 120 times gives a volume of steam = 2260 × 120 = 271,200 cubic inches. As the steam presses with 30 lbs. above that of the atmosphere, or altogether with 45 lbs., that is with 3 atmospheres, the volume of water is $\frac{271200\times3}{1600} = 508\frac{1}{2}$ cubic inches.

From these examples it is evident that a great force can be obtained by subjecting water to the action of heat. Just as a few grains of gunpowder on being ignited become suddenly transformed into a large volume of elastic gases, which by their expansive force propel a ball with great velocity, or burst asunder the solid rock; so a small quantity of water heated above 212° is changed into a perfectly elastic vapour, pressing upon the envelope containing it, and forcing any body, opposing its expansion, through a space sufficiently great to permit its enormous increase of bulk.

CONDENSATION.—But not only to the expansion of its volume does vaporised water owe its excellence as a moving force, for its increased volume can be suddenly reduced to a small bulk by the application of cold, or the removal of the heat which is necessary to its vaporous condition; and whatever force the steam exerted in expansion, is returned again by its condensation.

Fig. 145.



Thus if a vessel containing 1 cubic inch of water, and 799 cubic inches of air, were heated so as to turn the water into steam at twice the atmospheric pressure, the steam would force out the air and occupy its place; acting as it expanded with a pressure of 15 lbs. on every square inch above that of the atmosphere. Were the vessel now cooled so as to reduce the 800 cubic inches of steam to 1 cubic inch of water, the vacuum left by the condensed steam would be immediately filled by air pressed into it by the surrounding atmosphere with a force of 15 lbs. on every square inch. Were the vessel fitted with a piston or partition capable of sliding upwards or downwards in it, without permitting the passage of fluid round its edges, the effect would be the same; for if the piston at A (Fig. 145) were in contact with the water before boiling, and raised to B by its expansion into steam on heat being applied, it must, in rising, have been subjected to a pressure of 30 lbs. on every square inch of its under surface, so as to overbalance the atmospheric pressure on its upper surface by 15 lbs. On cold being applied so as to reduce the steam to its original volume of water, the pressure on the under surface of the piston being removed, that of the air on its upper surface again forces it downwards from B to A, its original position. Thus, both in the ascent and in the descent there is developed a force, applicable to the movement of machinery properly connected with the moving piston. In order that we may attain some notion of the amount of this force, let us suppose that the piston has an area of 1 square foot, and can rise and fall 2 feet, and that we have the means of generating and condensing the steam in the vessel 50 times in every minute.

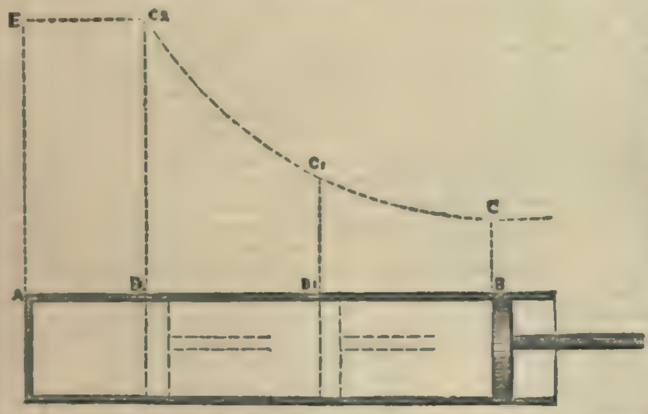
Since 1 square foot = ... 144 sq. in.,
And on every square inch the pressure is . 15 lbs.

The total pressure on the piston is . . . 2160 lbs.

This force is moved 2 feet up and 2 feet down 50 times per minute, or through a space of 200 feet per minute, and is therefore equivalent to 2160 × 200 = 432,000 lbs. moved through 1 foot per minute. A horse-power being reckoned at 33,000 lbs. moved 1 foot per minute, the force of the piston, as we have estimated it, is equivalent to $\frac{432000}{33000} = 13$ horse-power. From this example it will appear that by increasing the size of the piston, the distance through which it is moved, the rapidity of its alternations, and consequently the means of generating and condensing the steam, almost unlimited power can be attained.

In many steam-engines advantage is not taken of the power derivable from the condensation of the steam—its mere expansive power is employed; and, after having done its work, the expanded steam is allowed to escape into the atmosphere. This system is adopted for the sake of economy, lightness, and simplicity in the construction of the engine; and such engines are called *high-pressure* or *non-condensing*: *high-pressure*, because the steam must exert a pressure considerably higher than that of the atmosphere against which it has to act; or *non-condensing*, because the steam is not condensed after having done its work. In other steam-engines, called *low-pressure* or *condensing* engines, although greater power is derived from the steam, yet the machinery is rather more complex and heavy, and more liable to derangement; also a large supply of cold water is necessary to effect the condensation of the steam. Of late years many engines have been advantageously employed, in which the steam is first caused to act as it does in a non-condensing engine; but instead of being blown off into the air, it is afterwards made to do duty as in a condensing engine. Such are called *combined* engines, because the principles of expansion and condensation are combined in their action to a greater extent than in most others.

Fig. 146.



EXPANSION.—Before entering upon questions connected with the practical construction of the steam-engine, it will be advisable, in the first place, to discuss theoretically some of the principal facts connected with the expansion and pressure of steam, or generally of elastic fluids.

If we suppose a cylindrical vessel fitted with an air-tight piston, and containing within it a certain volume of air, steam, or any gaseous fluid perfectly elastic, we may represent the amount of pressure which the fluid exerts on the piston at B (Fig. 146) by the length of a vertical line B C. For example, if the area of the piston be 1 square inch, and the pressure on it at B be 15 lbs., we may draw a line or ordinate B C 15 inches long, taking 1 inch for each pound, or we might make it 15 half inches, or 15 tenths of an inch, using a half or a tenth of an inch to represent 1 lb. of pressure, or any other proportion that we may find convenient. If now we apply a force to the piston so as to push it along the cylinder to some place B_1, and there draw an ordinate B_1 C_1 having a length bearing to the pressure on the piston at B_1, the same proportion as the length of B C bears to the pressure at B; and if, farther, we drew an ordinate at B_2, and others at any number of intermediate points, we might, by tracing a curve C_2 C_1 C through all the points so determined, exhibit graphically the rate of variation of pressure according to that of volume or density. The law, to which we have already alluded, called Marriotte's law, is very simple, viz., that the volume multiplied by the pressure is always constant—that is to say, the length of A B (which represents the volume of gas when the piston is at B), multiplied by the height of B C (which represents the pressure at B), gives the same product as that of the length of A B_1 multiplied by B_1 C_1, or of A B_2 multiplied by B_2 C_2, the temperature remaining the same.[*]

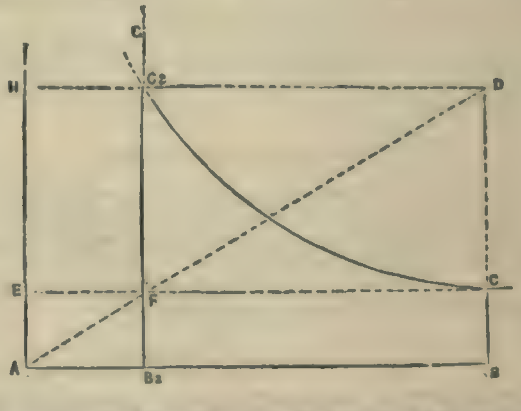
If, instead of filling the length A B of the cylinder with fluid, and then forcing in the piston so as to compress it, increasing the pressure in proportion to the increase of density, we supposed the piston to be at B_2, and the part A B_2 of the cylinder filled with elastic fluid, it would force the piston towards B with pressure gradually diminishing with the density according to the same law, and the curve C_2 C_1 C would terminate the ordinates representing pressures along the stroke or distance passed over by the piston. This is precisely the condition under which the piston of a steam-engine is ordinarily worked; and by taking a practical example we may ascertain what power is developed by the expansion of the steam. We shall suppose that in a steam cylinder of 1 square inch area the piston is close to the end A; and that by an opening there, steam, having a pressure of 4 atmospheres, 60 lbs. per square inch, is admitted so as to force the piston away from A to the position B_2, 1 inch from A. The steam-opening then being closed, the cylinder contains 1 cubic inch of steam 4 times the density of steam at atmospheric pressure, and pressing on the piston with a force of 60 lbs. When the piston has reached B_1, 2 inches from A, the steam has expanded to 2 cubic inches, and is therefore half its former density, or twice that of steam at atmospheric pressure, acting, therefore, on the piston with the force of 30 lbs. At B, 4 inches from A, the density is one-fourth of that at B_2, and the pressure on the piston is 15 lbs. By reckoning the pressures at a number of intermediate points, we might ascertain an average pressure of nearly 35 lbs. throughout the stroke, and thence calculate the power developed by the movement of the piston to be 35 lbs. moved through 4 inches, or 140 lbs. moved through 1 inch by the action of 1 cubic inch of steam at a pressure of 4 atmospheres—a quantity that would be generated from $\frac{1}{400}$th cubic inch of water.

Now, if we take another case, using the same quantity or weight of steam, but at a different pressure, we shall find a marked difference in the power developed. Let us suppose that steam at a pres-

---

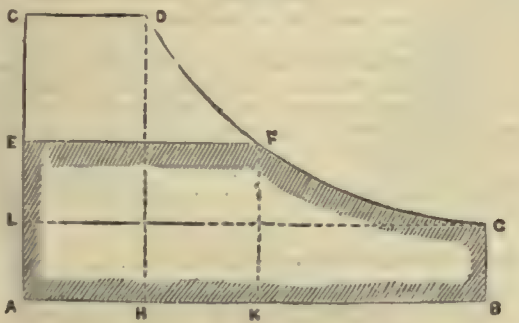
[*] The curve C_2 C_1 C (Fig. 146) is called the *hyperbola*, and it can readily be traced geometrically thus: If A B (Fig. 147) be the given volume or length of the cylinder when the pressure is B C, take any other point B_2 and draw an ordinate B_2 G cutting in F a line C E parallel to A B; join A F, and prolong it to meet B C in D, and through D draw D C_2 parallel to A B, cutting B_2 G in C_2; then C_2 is the point of the curve corresponding to B_2, for A B_2 × B_2 C_2, or the area of the rectangle A B_2 C_2 H, is equal to A B × B C, or the area of A B C E, as might readily be proved. Any number of points, such as C_2, being found, the curve can be traced through them. (See *ante*, p. 611, *Conic Sections*.)

Fig. 147.



sure of 2 atmospheres, or 30 lbs. per square inch, is admitted so as to force the piston through 2 inches of its stroke; we have 2 cubic inches of steam at 2 atmospheres, which are equivalent to 1 cubic inch at 4 atmospheres, and would be generated from the same quantity of water, $\frac{1}{400}$th cubic inch, at nearly the same expenditure of heating power. We should in this case find the average pressure on the piston, throughout the stroke of 4 inches, to be about 24 lbs., or equivalent to a weight of 96 lbs. moved through 1 inch. At first sight it appears startling, that by an expenditure of no more heating power in the first case, we should have obtained 45 per cent. more power than in the second; but such is the fact, nevertheless: and that it is so may be clearly seen by the diagram (Fig. 148). Let A B represent the stroke 4 inches long, A C the pressure, 4 atmospheres (represented by 4 inches in height), continued through 1 inch of the stroke, as shown by the line C D; then from D let the pressure-curve be drawn till it terminates at G, B G being 1 inch high, representing the terminal pressure 1 atmosphere. Then the area of the whole compound figure A C D F G B represents the total power developed in the first case by the expenditure of a quantity of steam represented by the area of A H D C. Again, let the pressure in the second case of 2 atmospheres, represented by A E, 2 inches high, be continued through 2 inches of the stroke to F; a portion of the same pressure-curve F G will enclose the pressures during the rest of the stroke. In this case the power is represented by the area of the shaded figure A B G F E, the quantity of steam expended being as the area of A K F E. Now the area of A K F E, or $2 \times 2 = 4$, is precisely the same as that of A H D C, or $1 \times 4 = 4$; while the area of A B G D C exceeds that of the shaded figure by the portion E F D C—so much clear gain of power by the higher initial pressure, and greater range of subsequent expansion. We have here supposed that no resistance is offered to the movement of the piston. If it be conceived to move in opposition to the pressure of the atmosphere, the gain by expansion of the steam is even more marked. A line G L represents the constant atmospheric resistance, and cuts off from both figures an area A B G L, which leaves the effective overplus of force impressed on the piston so as to move machinery, represented in the one case by the area of L G F E, and in the other by L G D C. Numerically, since we found the total force in the two cases to be equivalent to 96 lbs. and 140 lbs. respectively moved through 1 inch, and as the atmospheric resistance is 15 lbs. through 4 inches, or 60 lbs. through 1 inch in both cases, the effective forces are as 140 — 60, or 80, to 96 — 60, or 36; that is to say, the one is more than double the other.

Fig. 148.

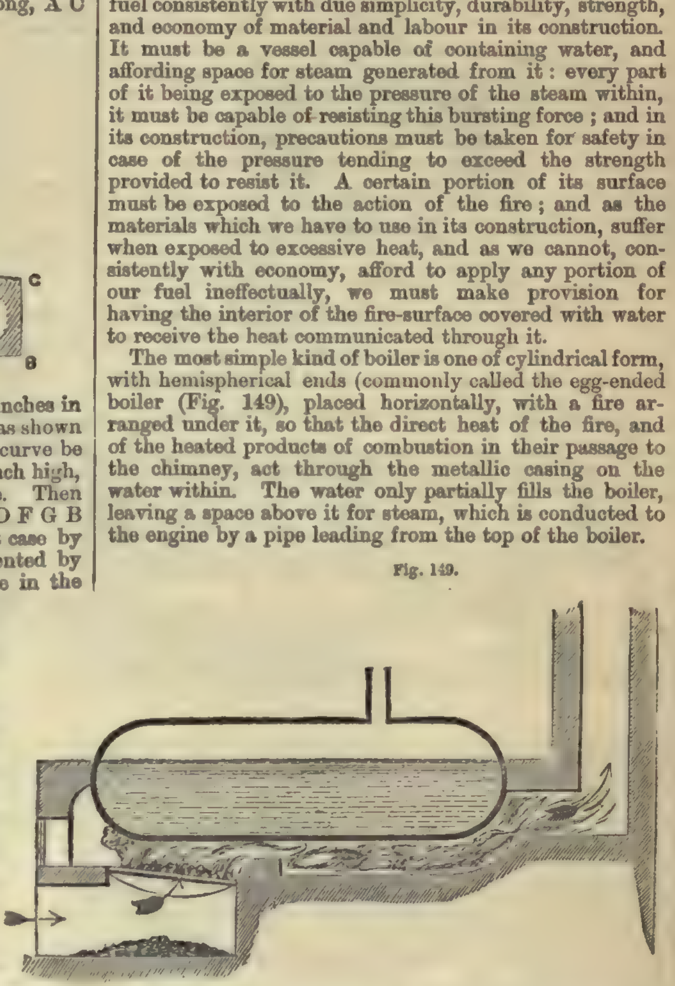


This mode of graphically representing forces is not only of an interesting, it is also of a most useful character. Watt invented an instrument which, being applied to a steam-engine, could draw upon a card a figure such as we have employed, representing the power developed by the action of the steam in the engine. He, however, seemed to consider it only as an interesting toy; but of late years this instrument has been found to be of the greatest utility. It is called the *indicator*, and is capable of not only representing with great accuracy the power developed in the engine to which it is applied, but also of exhibiting defects in design and construction, and of suggesting improvements. We shall have occasion hereafter to enter more particularly into the details of its construction and application.

THE BOILER.—In all steam-engines, the boiler or apparatus for generating the steam is a part of prime importance. In devising a good boiler, the problem is to obtain the greatest quantity of steam, or to boil off the greatest weight of water with the least weight of fuel consistently with due simplicity, durability, strength, and economy of material and labour in its construction. It must be a vessel capable of containing water, and affording space for steam generated from it: every part of it being exposed to the pressure of the steam within, it must be capable of resisting this bursting force; and in its construction, precautions must be taken for safety in case of the pressure tending to exceed the strength provided to resist it. A certain portion of its surface must be exposed to the action of the fire; and as the materials which we have to use in its construction, suffer when exposed to excessive heat, and as we cannot, consistently with economy, afford to apply any portion of our fuel ineffectually, we must make provision for having the interior of the fire-surface covered with water to receive the heat communicated through it.

The most simple kind of boiler is one of cylindrical form, with hemispherical ends (commonly called the egg-ended boiler (Fig. 149), placed horizontally, with a fire arranged under it, so that the direct heat of the fire, and of the heated products of combustion in their passage to the chimney, act through the metallic casing on the water within. The water only partially fills the boiler, leaving a space above it for steam, which is conducted to the engine by a pipe leading from the top of the boiler.

Fig. 149.

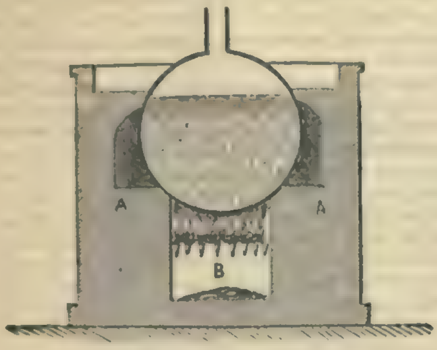


It is found by experiment, and indeed it seems to be a reasonable conclusion, that, within proper limits, having a certain quantity of fuel to dispose of, the larger the surface of water over which the heat developed from combustion is spread, the greater will be the heating effect produced, or the larger will be the quantity of water turned into steam. In fact, it becomes the object of the engineer to allow as little as possible of the heat to escape by the chimney, and consequently to arrange his boiler in such a manner as to make the water absorb the greatest possible quantity of heat, by exposing the largest possible surface to the combustion, and disposing that surface in the best manner.

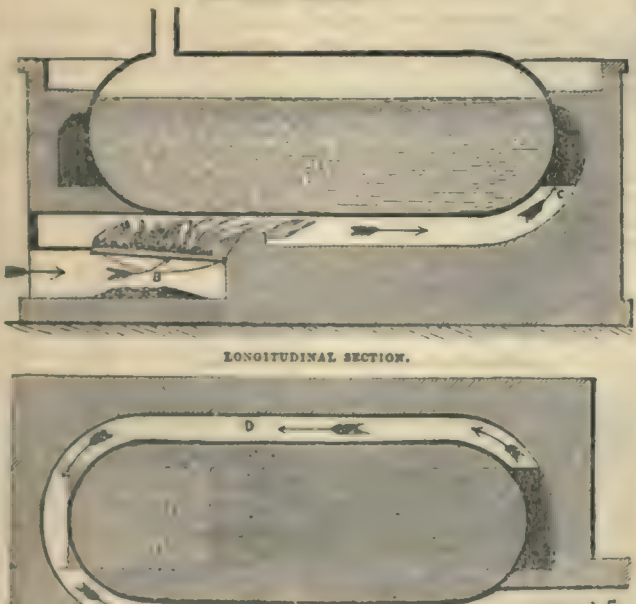
The strongest form in which a vessel can be made, when it is intended that it shall resist internal pressure, is that of a spherical shell. If, then, in the construction of steam-boilers strength alone were studied, the spherical form would be generally adopted. But of all forms of vessels, the spherical is that which has the smallest surface in proportion to its capacity, and it is consequently ill-adapted for the purpose of a boiler where a large amount of heating surface is important. Next to the spherical in point of strength, and superior to it in respect of superficial area, is the cylindrical form, with hemispherical or rounded ends (Fig. 149); and accordingly this form is very generally adopted for steam-boilers.

In order to render available as much as possible of the surface for receiving the heat, the heated products of combustion are not permitted to escape directly from the fire into the chimney, but are carried round the boiler by flues generally in the manner indicated in Fig. 150.

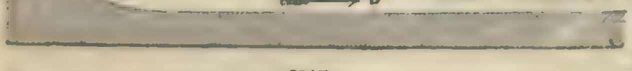
Fig. 150.



TRANSVERSE SECTION.



LONGITUDINAL SECTION.



PLAN.

The boiler is placed on two banks of brick-work A A, between which are fixed the fire-bars B, so that the flame may play on the bottom of the boiler. The products of combustion, heated to a high temperature, pass along under the bottom of the boiler, upwards at the far end C, thence along the side flues D D formed by brick-work, till they finally proceed by any convenient flue or channel E to the chimney. By this arrangement a large portion of the heat contained in the products of combustion is absorbed during their passage along the bottom and side surfaces of the boiler, and is given to the water contained in it; while the brick-work, being a very imperfect conductor of heat, permits very little to escape ineffectively. The power of a boiler arranged in this manner depends upon the extent of fire-grate, or quantity of combustible matter consumed in a given time, and the superficial area of boiler on which the products of combustion play in their course towards the chimney. That there should be some relation between those quantities will be evident from the following considerations. If the quantity of fuel consumed be very great while the flue-surface is small, the products of combustion will not have sufficient opportunity for parting with their heat, and will, therefore, carry up the chimney, and waste, a large amount of heating power, which, by better arrangements, might be made to tell upon the water. If, on the other hand, the fire-grate be too small, while the flue-surface is large, the products of combustion will have parted with their heat before reaching the chimney—a large portion of the flue-surface will thus be rendered useless, the draught (caused by the ascent of heated air in the chimney) will be sluggish, and the combustion slow. We believe that, practically, it will be found advantageous to adopt the following rules as to size of fire-grate and quantity of flue-surface in a boiler, such as we have described—the cylindrical, egg-ended boiler.

To the diameter of the boiler, multiplied by its length, add one-half: the result may be taken as the flue-surface; and this product (in square feet) should be 10 times the horse-power. Thus in a boiler 4 feet 6 inches diameter, and 15 feet long:—

Since 15 feet × 4½ feet = . . . 67½ square feet.
Add one-half . . . . 33¾ „ „

The flue-surface may be taken at 101¼

Or equivalent to 10 horse-power. Again, for every horse-power there should be ¾ths of a square foot of fire-grate. For 10 horse-power there should therefore be 7½ square feet of fire-grate, a surface that might be made up by taking the length of the fire, 3 feet 9 inches, and the width 2 feet, since 3 feet 9 inches × 2 feet = 7½ square feet.

The converse rule for finding the dimensions of a boiler suitable to a given power is the following:—From 10 times the horse-power subtract its ⅓rd part, and the result will be the product of the diameter by the length. Thus, to make a boiler of 10 horse-power:—

Since 10 × 10 = ... 100
Subtract ⅓rd = ... 33⅓

The product of diameter × length = . 66⅔

We are at liberty to take any convenient diameter and length that might make up this product within proper limits. Thus, making the

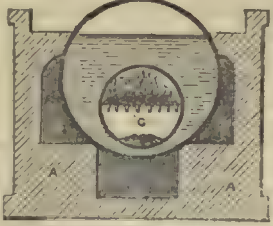
„	6,	„ „	11 2,	„	67 „
„	7,	„ „	9 6,	„	66½ „

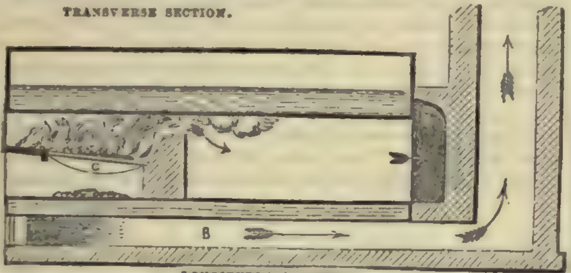
Any of these dimensions may be chosen according to the particular circumstances of the case. Were we to take a diameter smaller than 3 feet, with a greater length than 22 feet, or a diameter greater than 7 feet, with a length less than 9 feet 6 inches, we should find practical difficulties in fixing and working, and lose useful effect from the extreme lengthening or shortening of the flues.

CORNISH BOILER.—When it is desired to obtain greater heating surface within a smaller space, it is found very advantageous to construct the boiler of cylindrical form, with a cylindrical flue or tube passing through the water; so that not only may the exterior surface exposed to the flues receive heat from the products of combustion, but also the interior surface of the tube. When this tube is made of sufficient size to admit the fire within it, as in Fig. 151, the boiler is called a Cornish boiler, from the circumstance of its being first extensively applied with excellent effect in Cornwall. The arrangement of flues for a Cornish boiler is generally similar to that represented in the figure. The boiler rests on two banks of brick-work A A, with a space for the bottom flue B, left between them. The fire-grate is fixed at C, in the front portion of the tube; and the products of combustion pass along the tube, spread at the end E into the two side flues F F, descend at G G to the bottom flue B, and pass thence to the chimney. The quantity of flue-surface in a boiler of this kind exceeds that in the simple cylindrical boiler by nearly the internal surface of the tube. But as the hot products of combustion pass chiefly along the upper side of the tube, and leave its lower side generally covered with a coat of non-conducting soot and ashes, we cannot safely reckon much more than half the surface of the tube as effective heating surface; that is, 1½ time the tube's diameter multiplied by its length.

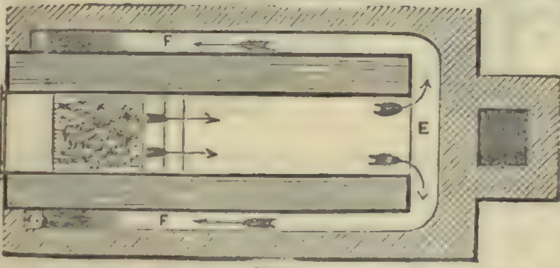
Fig. 151.



TRANSVERSE SECTION.



LONGITUDINAL SECTION.



PLAN.

In order, then, to estimate the power of a Cornish boiler, we should calculate the external surface as before, and add to it the product of 1½ time the diameter of the tube by the length for the total effective surface; allowing 10 square feet for every horse-power.

Or, more simply:—To the external diameter add the diameter of the tube (in feet), multiply by the length, add one-half to the product, and divide by 10 for the horse-power of the boiler.

Example.—A Cornish boiler, 5 feet diameter, and 12 feet long, has a flue-tube 3 feet diameter: required its power.

Diameter of boiler . . . . . 5 feet.
Add diameter of tube . . . . 3 „
8 „
Multiply by length . . . . . 12 „
96 square feet.
Add one-half of 96 = ... 48
Divide by . . . . . . 10) 144
Horse-power of boiler . . . . 14½ nearly.

The converse operation for finding the dimensions of the boiler when the power is given, would be:—From 10 times the power subtract its ⅓rd part; and the remainder gives the product of the length by the sum of the external and internal diameters.

Example.—Thus, for a boiler 14½ horse-power—
Since 10 × 14½ = ... 145
Subtract ⅓rd of 145 . . . . . . 48⅓
97 nearly.

Thus, 97 is the product of the length by the sum of the external and internal diameters.

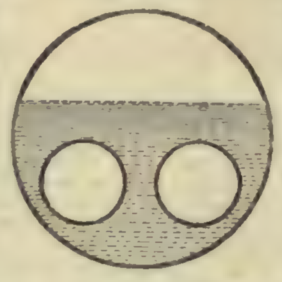
In this case, again, we must consult the circumstances of position for determining the suitable length and diameters. The diameter of the tube should not greatly exceed half that of the boiler, because there should be an ample covering of water over all the heated surfaces. And again, it should not be less than 1 or 2 feet, because it must admit sufficient area of fire-grate without excessive length. The fire-grate in the case given, reckoning $\frac{3}{4}$ths of a square foot per horse-power, should be about 11 square feet; and as a length of fire exceeding 5 or 6 feet would become inconvenient, we must take it at least 2 feet in breadth—that is to say, the diameter of the tube must be 2 feet. The diameter of the boiler might then be 4 feet, and the length would be for these diameters $\frac{97}{2+4} = 16$ feet. Were we to take the diameters as 3 feet for the tube and 5 feet for the boiler, the length would be $\frac{97}{3+5} = 12$ feet.

We believe it will be found practically advantageous to make the length a little more than three times the diameter of the boiler, the diameter of the tube being rather more than half that of the boiler. For 14½ horse-power, according to this proportion, we should have

Diameter of boiler	4 feet 6 inches
Diameter of tube	2 „ 6 „
Length of boiler	14 „ 0 „

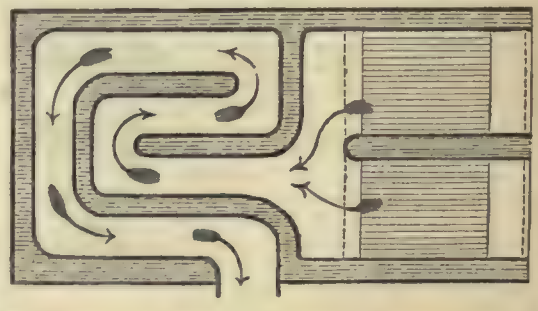
In cases where the dimensions of the boiler are considerable, two or more tubes are introduced, as in Fig. 152. The tubes are always placed as low as possible, allowing 4 to 6 inches between them and the outer casing, in order that their upper and hottest surfaces may be well covered with water, without interfering inconveniently with the steam space above.

Fig. 152.



MARINE AND LOCOMOTIVE BOILERS.—For marine steam-boilers, where brick-work setting would be inconvenient, it is usual to arrange the whole heating-surface within the boiler, by means of flues pervading it in all directions (Fig 153). The water is thus divided into sheets about 6 inches thick; heated on one or both sides by the products of combustion as they pass along the flues. In all such boilers a heating-surface of at least 10 square feet per horse-power, and fire-grate from ½ to $\frac{3}{4}$ths of a square foot per horse-power, should be provided. Nor should the flues be too small in sectional area, nor too much broken up or prolonged, lest the draught or rapidity of movement of air, and consequently of combustion, be interfered with. Of late years, tubular boilers have been very extensively adopted, both for marine and for land engines. These were first employed principally in locomotive engines, as they afforded a means of securing very large flue-surface within a limited

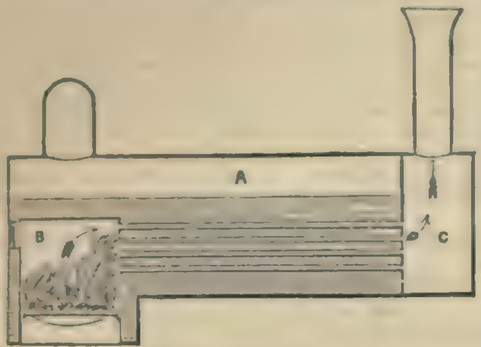
Fig. 153.

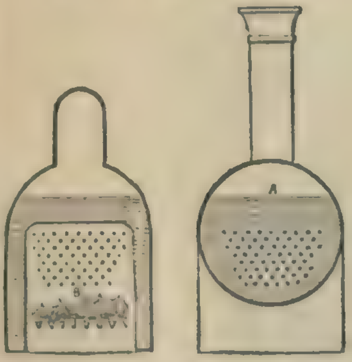


space, and without excessive weight of material. Fig. 154 represents the arrangement of tubes in a locomotive boiler.

The body of the boiler A is cylindrical: at one end B is the fire-box, surrounded by water space; at the other end C is the smoke-box, surmounted by the chimney. In the body are arranged numerous small tubes completely surrounded by water, through which the products of combustion pass in their progress from the fire to the chimney, delivering the greater portion of their heat to the surrounding water. The evaporating power of a boiler of this kind is very great, as we may readily believe on calculating the amount of heating-surface in a boiler of the following dimensions:—

Fig. 154.





Fire-box inside, 3 feet 6 inches × 3 feet 6 inches × 3 feet 6 inches, has 60 square feet actually exposed to the fire, and therefore most valuable as heating-surface. 120 tubes 2½ inches diameter and 10 feet long, give 800 square feet of effective flue surface; the whole, including smoke-box, being contained in a space about 13 feet long, 4 feet 6 inches wide, and 4 feet 6 inches high, and yet being equivalent to 80 or 90 horses' power.

CONSTRUCTION OF BOILERS.—We have now described, generally, the different kinds of boilers used for generating steam. They are, of course, subject to numerous modifications in their details and proportions, according to local circumstances and peculiarities of use and situation. They are generally made of wrought-iron plates, from ¼th inch to ¾ths inch in thickness, according to the magnitude of the work, and the amount of pressure which they are intended to sustain. These plates are made to overlap each other at the edges, and are fastened together by rivets or round pins of iron, passed red-hot through holes provided in the plates, and riveted over so as to form a head. A heavy piece of iron is held against the under side of the rivet-head, and the other end of the rivet is struck repeatedly by heavy hammers, and frequently finished by applying a tool hollowed to the shape of the intended head, and striking the tool by the hammers. The rivet, when the operation is complete, is of the form A (Fig. 155) when finished by smart hammering, called *staff-riveting;* and like B when finished by the tool, being then said to be *button-headed*. As the operation of riveting is performed when the rivet is red-hot, not only is the quality of the rivet not impaired by the hammering, as it would be if hammered when cold, but also the contraction or shrinking of the rivet in its length when it cools draws the edges of the two plates together with great force, and renders the joint impervious to fluid. When it is found by trial that the joints of the plates, or the edges of the rivet-heads, are not quite tight, as manifested by the leakage of water or steam through any of them, a blunt steel chisel or caulking tool is applied to the leaking edge, and struck smartly by a hammer, so as to caulk the joints, or force part of the iron into the crevice.

Fig. 155.

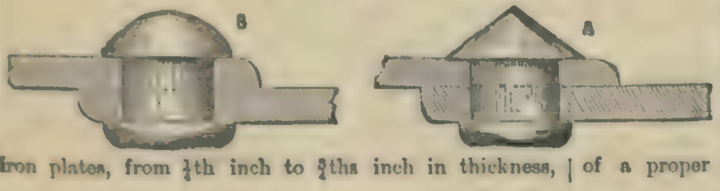


Fig. 156.

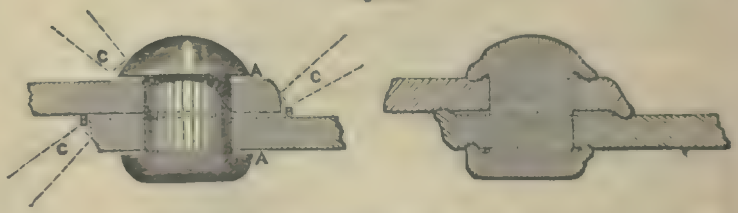
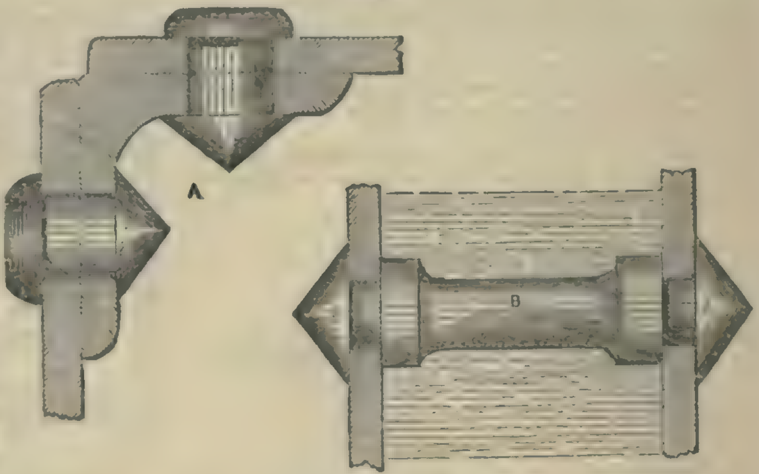


If we suppose, for instance, that an opening exists between the plates at B, and round the rivet-head at A (shown greatly exaggerated in Fig. 156), the caulking tool applied at the points marked C, forces the iron of the plate edges and of the rivet-heads into the interstices, and thus renders the jointing tight. For jointing the plates at the angles, a peculiar kind of iron, called *angle-iron*, indicated in section at A, Fig. 157, is employed; and where there are considerable flat surfaces of plate exposed to bursting, pressure stays, B, are introduced at proper intervals to prevent the plates from being forced asunder.

Fig. 157.



For fixing the tubes of tubular boilers in the plates through which they pass, holes are first bored in the plates of a proper size to fit the tubes tightly; and the tubes being cut of the proper lengths and put in their places, the ends are forced open by means of a conical tool driven by hammering into their mouths. Other methods of fixing tubes and stays are employed; and there are numerous other details of boiler-making of a technical character, upon which we need not enter. The furnace or fire-grate of a boiler is generally made of numerous bars of wrought or cast-iron, laid side by side so as to form a grating, on which the fuel is placed, leaving spaces about ½ inch wide between the bars for the passage of air upwards to support the combustion, and of the ashes or incombustible refuse downwards into the ash-pit. In front of the bars, there is generally placed a dead-plate or surface without openings, to receive the fresh fuel, which, lying there for some time exposed to the radiation of the fire beyond, parts with a portion of its gases, and is partially coked before it is pushed onwards to the fire-grate. The gases are ignited in their passage over the hot fire, and produce flame, which plays on the surfaces of the flues. When the supply of air is deficient, large volumes of these liberated gases, having numerous particles of carbon suspended in them, pass through the flues without ignition, and thence through the chimney as black smoke. When this happens, not only is a large and valuable part of the fuel wasted, but the air is inconveniently polluted. The object of smoke-consuming apparatus is to prevent this evil; and the general principle on which all such apparatus is constructed, is either to manage the production of these gases in such a continuous regular manner, as that sufficient air may be supplied for their combustion when they are sufficiently heated to ignite, or to supply heated air in some part of the flues, so as to turn into flame there, the gases that would otherwise escape unconsumed; or, finally, when the production of the gases is irregular, to supply air to burn them only at the proper times and in suitable proportions.

The chimney of a steam-boiler should be of sufficient area and height to produce a good draught or quick current of the heated products of combustion. When the draught is insufficient, the fresh air supplied to the fire is too small in volume, the combustion is retarded, and the flues are filled with smoke instead of flame. A chimney of 30 or 40 feet in height, and having an area of 1 square foot for 10 horse-power, generally gives a sufficient draught. Where height cannot be obtained, as in locomotive engines, the waste steam is made to rush up the chimney with considerable force, and thus to create an artificial draught. The chimney or flue leading to it is provided with a damper or slide, by which the area of passage may be diminished, and the draught reduced at pleasure. At convenient places in the flues, soot-doors are fixed for giving access to clean them from soot or ashes deposited there.

INCRUSTATION.—As all water supplied to boilers is more or less impure, or contains ingredients that become deposited while the water itself is driven off in the form of vapour, it is essential to provide for the frequent cleansing of boilers. In marine boilers particularly, where sea-water is necessarily employed, the deposit of saline ingredients, none of which are volatile, or pass off with the steam, is very large, and of a very troublesome character. It generally settles in the form of a hard, stony crust upon the interior surface of the boiler; and as this crust is a very bad conductor of heat, not only is there a waste of fuel where it exists, owing to its arresting the passage of the heat from the flues to the water, but there is a positive danger from the circumstance that the interior surfaces of the flues are thus over-heated, and the iron of which they are made becomes rapidly oxidised, scaling off in flakes, losing thickness and strength, and becoming liable to disruption from the pressure within exceeding the strength left to sustain it. As salt-water does not deposit rapidly until it becomes super-saturated with salt, it is usual to permit, frequently, the escape of a considerable quantity of the excessively salt-water in the boiler, and to replace it with new water from the sea, less salt and less liable to deposit. For effecting this object and also for emptying the boiler when required, a pipe and cock, called technically the *blow-off*, is fitted to the lower part of the boiler. This cock should be frequently opened, especially where the water is very dirty or of a saline character, and the worst part of the contents of the boiler, which, being heaviest, lie near the bottom, thus blown out. In order to save the loss of heat occasioned by frequently blowing off the hot impure water from marine boilers, and replacing it by cold, but purer water, an apparatus called the *change-water apparatus* is sometimes employed. It consists of a casing, with numerous small tubes arranged in it as in a tubular boiler. A portion of the contents of the boiler being always permitted to flow through the casing, and thence into the sea, a corresponding quantity of purer water is made to pass through the tubes to the boiler; and the latter is thus made to absorb in its passage through the tubes, a considerable portion of the heat given out by the former, in its passage round them.

The large amount of incrustation in marine boilers, and the consequent ineffective expenditure of fuel, have for many years proved a source of great cost and inconvenience in this application of steam-power. When it is recollected that a steam-vessel has to carry its fuel in a place which might otherwise be available for the stowage of cargo, or that fuel has often to be purchased at distant depôts, where its price is enhanced by the cost and difficulty of transport, it is a wonder that owners should have submitted so long to a large waste of fuel, which might have been avoided. A good many years ago, Mr. Hall introduced a surface-condenser, by which the steam, after working the engine, was recondensed into pure distilled water, and in that condition returned into the boiler to be again converted into steam; and so on, in continual circulation. Notwithstanding the great advantage of this arrangement in saving incrustation and deposit—in avoiding the necessity for blowing-off—in economising fuel, and saving tear and wear of boilers—it is not until very recently that engineers have practically adopted the principle of surface-condensation. As yet, very few engines have been fitted with surface-condensers; but it is probable, that before many years have elapsed, their adoption will become universal. Hereafter we shall have occasion to enter more fully into their construction. We only allude to them, at present, in connection with the subject of boilers, in order to show that the deposit and incrustation, which form the grounds of so many complaints and of so much danger, are by no means necessary evils.

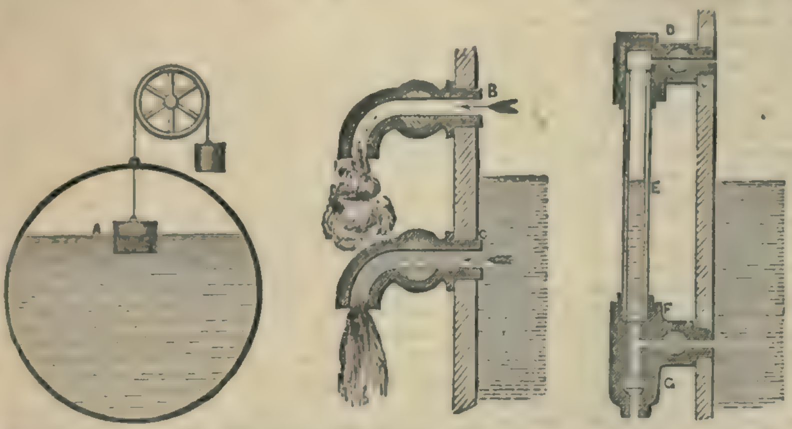
Mud-holes are small holes provided in the lower parts of boilers, and fitted with tight covers, which may be removed, when the boiler is not in use, for the admission of a rake to draw out the mud deposited from the water.

The man-hole, an opening sufficiently large to admit a man, is provided in the upper part of a boiler, and fitted with a tight cover, which may be removed, when the boiler is not in use, for the admission of a man for cleaning or repairs.

In boilers having considerable flue surface, but not great height of steam-room above the water-level, there is always a danger of priming—that is to say, the water in a rapid state of ebullition is often made to boil over, or blow in considerable quantities into the steam-pipes, and thence into the engine, where it is not only useless, but highly detrimental to the action of the machinery. It is usual, therefore, to provide a boiler with a steam-chest, or dome, in its highest part, to give greater space for steam, and greater height for the mouth of the steam-pipe above the surface of the boiling-water. In general, there should not be less than six inches of water above the flues, nor less than three feet of steam-room above the water. In marine boilers, where the water is surged about by the rolling of the vessel, there should be at least double the height named for water and steam. Should the level of the water be so low that the surface of a flue is no longer covered by it, the flue is liable to become over-heated, sometimes to redness; the iron is softened and weakened by the excessive heat, and rapidly deteriorated by oxidation and scaling off. But this is not the only danger of an over-heated flue; for on the water again covering it, the enormous volume of steam suddenly generated produces an excess of pressure, and causes an explosion of the boiler. We believe almost every case of explosion can be traced to some circumstance connected with a deficient supply of water; and, therefore, too much caution cannot be used in watching the condition of the water-level, and providing the proper supply or feed.

BOILER FITTINGS.—In order to ascertain the water-level within the boiler, several kinds of apparatus are employed. The *float* A (Fig. 158) consists of a stone suspended by a wire passing through the top of the boiler, and connected, by a chain led over a pulley, with a counter-balance, sufficient to balance so much of the weight of the float-stone that it shall always lie at the surface of the water. Should the water-level vary, the position of the float-stone, which rises or falls with it, is marked by an index on the pulley.

Fig. 158.



Gauge-cocks B C are two stop-cocks fitted into the face of a boiler, one above and the other below the proper water-level. When these cocks are opened, steam should blow through the upper, and water through the lower one. The objection to gauge-cocks consists in the circumstance that, in order by them to ascertain the level, the attendant must open them.

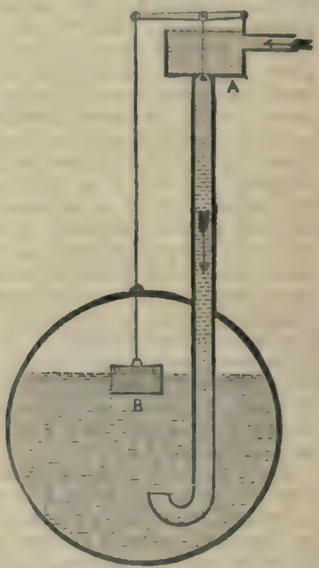
The *glass gauge* consists of two stop-cocks, D and F, fitted in the face of a boiler, one above and the other below the water-line. These cocks are connected by a glass tube E, in which the level of the water is distinctly seen. A stop-cock G is provided at the lower end of the glass tube; and this being occasionally opened, the sediment that may collect in the tube or passages of the cocks is blown out by the pressure within the boiler. Should the glass tube burst, the stop-cocks D and F can be closed until a new tube is fitted, or they can be employed as gauge-cocks.

Occasionally the float is connected with a whistle, in such a manner that when the level of the water becomes too low, it opens a small stop-cock, which permits steam to blow through the whistle, and thus give audible warning of the danger.

In many boilers a precaution is taken against the dangerous consequences of insufficiency of water, by the use of fusible metal plugs. A hole is made in the highest part of the fire-box or flue, which is filled up with a plug or rivet of metal fusible at a temperature not greatly exceeding that of boiling-water. So long as this plug is covered with water, its temperature cannot attain the melting point; but should it be left bare, the heat of the fire playing upon it causes it to melt out, and thus to leave a hole, through which the steam escapes into the flue. Not only does the rush of the escaping steam give warning of the circumstance, but it also relieves the steam-pressure within the boiler, and prevents the explosion which might otherwise result from the over-heating of the flue.

FEED.—In low-pressure boilers, the float occasionally is made to act as a self-feeding apparatus. A (Fig. 159) is a cistern constantly supplied with water, and fitted at bottom with a valve opening downwards into a pipe passing down to nearly the bottom of the boiler; the float B is connected by a wire and lever with the valve, so that when the water-level is too low, the descent of the float causes the valve to open, and thus permits the passage of water from the cistern into the boiler. This arrangement can only be adopted when the pressure of the steam within the boiler does not exceed that of the column of water in the feed-pipe. For high-pressure boilers, the height of cistern and feed-pipe would be inconveniently great to overcome the pressure; accordingly, for these and for marine boilers, the supply of water is effected by means of a force-pump, called the feed-pump, worked by the engine, and regulated by suitable cocks or valves. An apparatus for feeding boilers with water, called an Injector, has also been very successfully applied in many cases. The force of a certain quantity of steam issuing from the boiler by properly arranged channels and valves, is made to cause a proportional quantity of water to enter the boiler.

Fig. 159.



The quantity of water required for a boiler may be generally taken at 1 cubic foot per horse-power per hour; or, as 1 cubic foot contains about 6¼ gallons, and weighs about 63 lbs., we may take 1 lb. of water per minute, or 1 gallon every 10 minutes, as the necessary supply for each horse-power. The actual quantity of water required for generating steam to work an engine of 1 horse-power, depends much upon the construction of the engine, the extent to which the steam is used expansively, the amount of power derived from condensation, or the amount of resistance to the egress of waste steam, if not condensed; but the above estimate is tolerably correct for non-condensing engines worked without much expansion, and is in excess for condensing engines, and such engines as those in which the expansive force of the steam is taken advantage of, so as to produce great effect with small expenditure of steam.

It has been found by experiment, that 1 lb. of ordinary fuel—coal or coke—is capable of turning from 8 to 10 lbs. of water into steam, according to the capabilities of the boiler. Taking the lower estimate, we should reckon that as 63 lbs. of water are required per horse-power per hour, about 8 lbs. of fuel per horse-power per hour would be consumed. In condensing engines, working expansively and under the most advantageous circumstances, the consumption of fuel has been reduced so low as from 2½ lbs. to 3 lbs. per horse-power per hour. In non-condensing engines, when the steam is used to a considerable extent expansively, from 5 lbs. to 7 lbs. of fuel per horse-power per hour is nearly the average consumption.

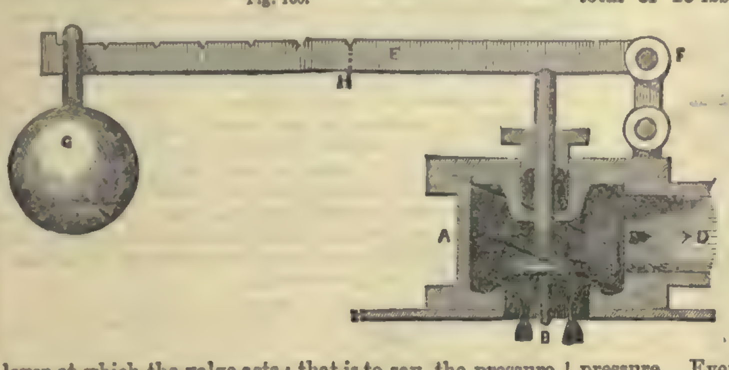
SAFETY-VALVE.—It may be readily conceived, that when water contained in a vessel or boiler of limited strength, is subjected to heat in such a manner as to turn part of it into steam, exerting unlimited pressure, there would be constant risk of explosion, unless some measures were taken for limiting the force of the steam, and preventing its pressure from exceeding that which the boiler could safely sustain. Every boiler is, therefore, fitted with one or more safety-valves, which constitute the most important of the boiler fittings.

The principle of the safety-valve is exceedingly simple. As fluids, and therefore steam, press equally in all directions, any part of the boiler-casing, such as 1 square inch, is subjected to the pressure of the steam. If, then, we make a hole in the upper part of a boiler 1 square inch in area, and cover it with a lid, laying on this lid a weight such as 50 lbs., we can apply heat and generate steam, which, as soon as its pressure exceeds 50 lbs. per square inch, will lift the loaded lid, and permit a portion to escape. Should the generating power of the boiler be moderate, the raising of the lid, and escape of a portion of steam, would prevent the pressure from ever exceeding that due to the weight on the lid; but should the steam be generated more rapidly than it can escape through the hole, the pressure must go on accumulating, until the strain to which it subjects the boiler exceeds the strength of the material of which it is made, and an explosive rupture is the consequence. It is, therefore, important to provide a safety-valve, with an opening of sufficient size to permit the escape of steam as rapidly as it can ever be generated, and to load it with a weight not greater than the pressure which the boiler can safely bear. Boilers are generally tested before use, under a pressure very much greater than that with which they are to be used. For condensing engines, the pressure seldom exceeds 20 lbs. per square inch; for ordinary non-condensing engines, 50 lbs. or 60 lbs. per square inch; and for locomotives, it is as high as 120 lbs. and 150 lbs. per square inch above that of the atmosphere. The area of the safety-valve should not be less than $\frac{1}{4}$th square inch per horse-power.

Fig. 160 represents a safety-valve of the ordinary construction. A is a box fixed over a hole B in the upper surface of the boiler, having a truly-faced seating on which the valve C can rest. The stem of the valve passes through the cover of the box, where there is a gland or stuffing-box to prevent the escape of steam round the stem. A pipe D conducts the steam that passes the valve, when it is lifted, to the chimney or elsewhere. The valve is kept down by a lever E, which works on a pin, or fulcrum, at F, and has a sliding weight suspended from it at any point such as G. The arm of the lever is graduated so that the weight can be placed to give such pressure on the valve as may be required. If we suppose, for example, that the area of the valve-opening is 1 square inch, that the length from the centre of the valve-stem to that of the pin F is 2 inches, and that a weight of 10 lbs. hangs at G, 16 inches from F; then the effect of the weight to press down the stem of the valve is as its weight multiplied by the length of lever at which it acts, divided by the length of lever at which the valve acts; that is to say, the pressure on the valve is $\frac{10 \text{ lbs.} \times 16 \text{ inches}}{2 \text{ inches}} = 80$ lbs. As the area of the valve is 1 square inch, this weight is capable of resisting a steam-pressure of 80 lbs. per square inch within the boiler. If the lever be graduated by divisions each 2 inches in length, each of these will correspond to a pressure of 10 lbs. on the valve; that is to say, the weight at—

16 inches gives a pressure of 80 lbs.
14 „ „ „ 70 „
12 „ „ „ 60 „ and so on.

Fig. 160.



We have not reckoned the effect of the weight of the valve and lever, which should generally be weighed, so that the pressure due to them, exclusive of the weight, may be estimated before graduating the lever. As a practical example, we will suppose that it is required to make a safety-valve of 4 inches diameter, and load it by a weight and lever graduated to steam-pressures varying from 20 lbs. to 50 lbs. per square inch above atmospheric pressure. We will suppose that the weight of the valve and stem is 5 lbs., that a convenient leverage for the valve is 3 inches, and that the whole lever from F to the end is 30 inches, the lever itself being of uniform depth and thickness, and weighing 9 lbs.

The area of the valve (a circle 4 inches in diameter) is $12\frac{1}{2}$ square inches; the effect of the weight of the lever is the same as if it were collected at its middle point H, 15 inches from F, and its

Pressure on the valve is therefore $\frac{9 \text{ lbs.} \times 15 \text{ in.}}{3 \text{ in.}} = 45$ lbs.

To which we add the weight of valve and stem . 5 „

Making a total constant weight on the valve = . 50 „

And as the area of the valve is $12\frac{1}{2}$ lbs., this gives a constant pressure of $\frac{50}{12\frac{1}{2}} = 4$ lbs. per square inch. For a pressure of 50 lbs. per square inch, or a load of $50 \times 12\frac{1}{2} = 625$ lbs. on the valve, the additional load must be 575 lbs. at a leverage of 30 inches against that of the valve at 3 inches; and therefore a weight of $57\frac{1}{2}$ lbs. at the end of the lever gives the required pressure; because $\frac{57\frac{1}{2} \text{ lbs.} \times 30}{3} = 575$ lbs. on the valve. The same weight, to give a pressure of 40 lbs. per square inch, should act on the valve with a force of $12\frac{1}{2} \times 40 - 50 = 450$ lbs; and its distance from F must be about 23·48 inches, because $\frac{57\frac{1}{2} \times 23{\cdot}48 \text{ inches}}{3} = 450$. Now the difference between 30 inches, the leverage for 50 lbs., and 23·48 inches, the leverage for 40 lbs., is 6·52 inches—a division that may be repeated along the lever for 30 and 20 respectively.

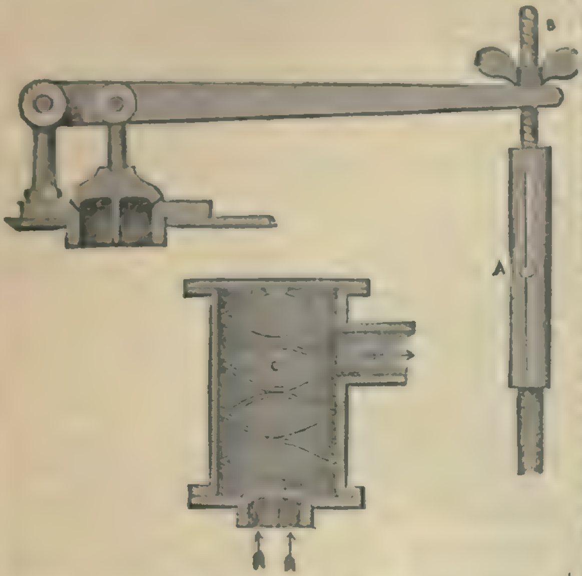
We might attain the same result by another process, thus:—Since the constant pressure due to the weight and valve is 4 lbs. per square inch, the additional pressure to be derived from the weight of $57\frac{1}{2}$ lbs., to make a total of 10 lbs. per square inch, would be 6 lbs. per square inch, or $6 \times 12\frac{1}{2} = 75$ lbs. in all. The leverage of the weight to produce this load would be found from the simple proportion:—

Weight.		Load on valve.		Leverage of valve.		Leverage of weight.
$57\frac{1}{2}$ lbs.	:	75	::	3 in.	:	3·913 in.

Repeating the same process for 50 lbs. pressure per square inch, we should find the leverage of the weight to be 30 inches. The difference of 30 inches and 3·913 inches, viz., 26·087 inches, being divided into 40 equal parts, each 0·652 inches—because 40 is the difference between 50 lbs. and 10 lbs.—would mark the lever for each lb. of pressure. Every 10 lbs. would thus be graduated by intervals of 10 × ·652 = 6·52 inches as before.

In locomotives and boilers where a weight sliding along a lever would be inconvenient, the lever is affixed to a spring-balance A (Fig. 161), graduated to the pressures per square inch due to the spring. By turning a nut B on the stem of the spring-balance, any required pressure can be thrown upon the valve, which is kept down by the spring acting on its lever. Should the pressure within the boiler exceed that to which the balance is adjusted, the valve is opened, and a portion of the steam escapes. The lock-up safety-valve consists of a valve pressed down by a set of strong springs C, the whole enclosed within a box under lock and key. While the engine-driver has command over the spring-balance valve, so as to increase or diminish the load at pleasure, the lock-up valve is inaccessible to him, and opens whenever he has loaded the open valve beyond the pressure to which the lock-up valve has been adjusted; thus serving as a check upon him in case of his working at a dangerous pressure.

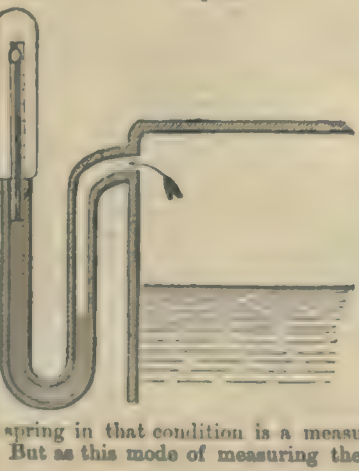
Fig. 161.



In a boiler for an engine working at very low pressures, there is frequently provided a vacuum valve, which is a safety-valve opening inwards, and admitting air into the boiler, in case the pressure within should fall so far below that of the atmosphere without, that there might be danger of collapse.

PRESSURE GAUGE.—The steam-gauge is an apparatus generally fitted to boilers for indicating the pressure of the steam. The safety-valve may be employed for this purpose; for if the weight be adjusted on the lever, or the spring of the balance released, until the valve begins to open and let steam escape, we know that the weight or spring in that condition is a measure of the pressure. But as this mode of measuring the pressure requires personal attendance, it is better to be provided with some self-acting instrument which shall show at a glance the condition of the steam in respect to pressure.

Fig. 162.



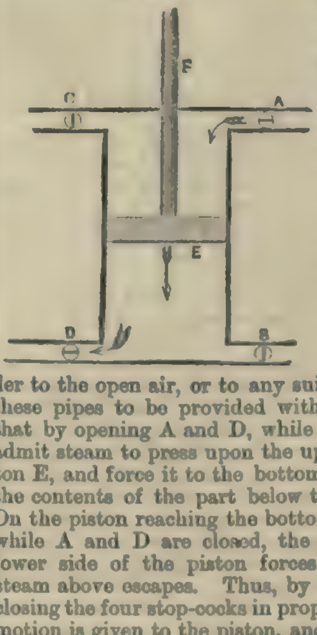
For low-pressure boilers, the mercurial steam-gauge is generally employed (Fig. 162). It consists of an iron pipe bent to a siphon form, connected with the boiler, and containing mercury, on which floats a rod of wood extending above the mouth of the tube, and pointing to divisions on a scale. As 2 cubic inches of mercury weigh very nearly 1 lb., the rise of the wooden index through 1 inch in height, indicates that the mercury in 1 limb of the siphon has risen 1 inch, and fallen 1 inch in the other, making a difference of level of 2 inches, equivalent to a pressure of 1 lb. per square inch in the boiler. Thus every inch on the scale corresponds to 1 lb. pressure per square inch.

For high-pressure boilers, the column of mercury necessary would be inconveniently high, and recourse is therefore had to gauges of other kinds. Among the most effective and ingenious of these may be mentioned that of Bourdon. It consists of a flattened elastic tube of copper or brass, bent into a spiral form. The pressure within the tube tends to bulge it, and uncoil it a little out of the spiral form; and the slight movement thus induced is communicated to an index, which points on a dial-plate to the pressure marked thereon from the result of experiments made for the purpose of determining the proper graduation of the dial.

CYLINDER.—The steam generated in the boiler at such pressure, and in such quantity as may be desired, is conveyed by the steam-pipe to the cylinder, which is a vessel closed at both ends, and fitted with a piston E (Fig. 163), capable of sliding tightly from end to end, and having a rod F passing tightly through one of the end covers, or the cylinder lid. If we suppose A and B two pipes communicating with the boiler, and opening into the cylinder at opposite ends, while two other pipes, C and D, lead from the ends of the cylinder to the open air, or to any suitable place; conceiving these pipes to be provided with stop-cocks, we can see that by opening A and D, while B and C are closed, we admit steam to press upon the upper surface of the piston E, and force it to the bottom of the cylinder, while the contents of the part below the piston escape by D. On the piston reaching the bottom, if we open B and C, while A and D are closed, the pressure acting on the lower side of the piston forces it upwards, while the steam above escapes. Thus, by alternately opening and closing the four stop-cocks in proper order, an alternating motion is given to the piston, and the force is communicated by the rod to any suitable machinery. The amount of force so communicated depends on the size of the piston, or number of square inches in its surface on which the steam-pressure acts, the intensity of that pressure, and the velocity at which the piston is caused to travel. If we suppose, for instance, that the diameter of the cylinder is 1 foot, the circular area of which is 113 square inches, that the pressure of the steam is 20 lbs. per square inch, and that the average speed of the piston is at the rate of 200 feet per minute, the power communicated through the rod is equivalent to

$$\frac{113 \text{ sq. ins.} \times 20 \text{ lbs.} \times 200 \text{ ft.}}{33000} = 13\cdot7 \text{ horse-power.}$$

Fig. 163.



Some of the first steam-engines had cocks arranged as we have described, which demanded the continual attendance of a workman to close or open them at the proper times. But it suggested itself that apparatus connected to the moving parts of the engine might be so adjusted as to perform this operation; and accordingly great ingenuity has been exhibited in contrivances for alternating the flow of steam to and from the opposite ends of the cylinder.

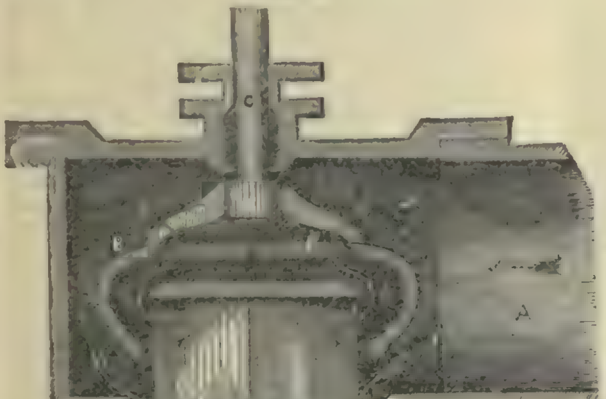
VALVES.—Instead of stop-cocks in the pipes, which are subject to considerable and unequal wear from constant working, and thereby become leaky, valves are often employed, similar to the safety-valve, and worked upwards and downwards by means of levers acting on their stems, which project beyond the steam-tight casing in which they are enclosed. Were these valves made in such a way that the steam pressed on their lower surfaces, and tended to raise them from their seats, it would be difficult to keep them tightly down without very considerable force. If, on the other hand, the pressure of the steam acted on their upper surfaces so as to keep them tightly down, considerable force would be required to lift them so as to permit the steam to pass at the proper times. Moreover, as, in large engines, these valves must be of considerable size to let sufficient steam pass through the openings they cover, and as, for effective working, they must be raised and lowered very rapidly, it becomes important to reduce, as low as possible, the pressure upon them, and thus diminish the force necessary for their movement.

The double-beat valve is a contrivance for covering a large area of steam-passage with a valve subjected to moderate pressure. The steam entering at A (Fig. 164), fills the valve-box, in which an annular or ring-shaped valve B is capable of being pressed upwards or downwards by a rod C passing through the cover of the valve-box. When the valve is down, its upper and lower conical surfaces rest on corresponding seats, to which they are nicely ground; while, the valve being raised, the steam flows between the surfaces into the pipe D. The force necessary to raise such a valve, is that of the steam-pressure on the excess of the area of the lower seating above that of the upper, and may be made much less than that on an ordinary valve of equivalent size. We shall suppose, for example, that a valve of 10 inches diameter is subjected to a pressure of 20 lbs. on the square inch. The force to lift it would be

(circ. area of 10 ins. diam. =) 78½ sq. ins. × 20 = 1570 lbs.;

and the height through which it must be lifted to give the full passage for steam round it, is 2½ inches; for 2½ × (circumf. of 10 ins. diam. = 31½) = 78½ sq. ins., the area of a circle 10 ins. in diameter. But were we to use a double-beat valve, having its lower seating 10½ ins. in diameter, and its upper 9 ins. in diameter, the area of the one being 86½ sq. ins. and that of the other 63½, the pressure on the difference, 23 sq. ins., is 23 × 20 = 460 lbs., little more than one-fourth of that on the single-seated valve. Again, the height through which the double-beat valve must be raised is only half that required for the single valve; because, when it is raised, passage is provided for the steam both above and below. Thus, to work the double-beat valve, only ⅐th or ⅛th part of the force requisite for the single-seated valve is required.

Fig. 164.



Wherever valves are used, especially in large engines, or under great pressures, for alternating the flow of steam, recourse is had to the double-beat valve, or some expedient of a similar character, by which considerable size of passage may be secured without having to lift a great weight, or move it through a great distance.

SLIDE.—But the frequent raising and lowering of any set of valves, however well balanced, would, in quickly-moving engines, be accompanied with noise, and would prove very inconvenient, on account of the complication of machinery required for the purpose, and the greater amount of wear and tear resulting from its use. To avoid these evils, the *slide* has been contrived; and it is almost universally employed for alternating the flow of steam to or from the ends of the cylinder, except in engines moving very slowly. There are various kinds of slides in use, but they are nearly all contrived on similar principles, with such differences in the details of construction as the peculiar views of makers, or the circumstances of their position, suggest. The most simple kind is called the D-*slide*, from the circumstance of its form resembling that of the letter D.

Fig. 165.

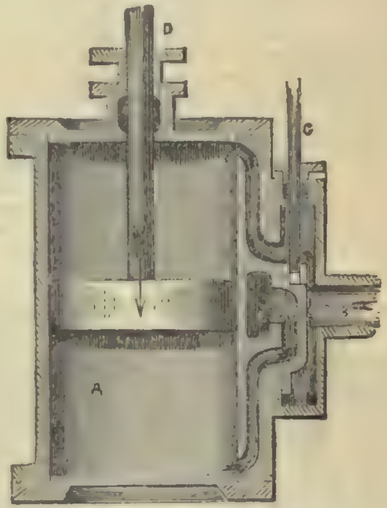


Fig. 166.

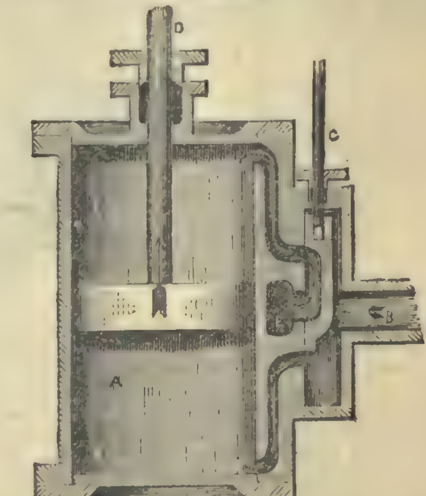
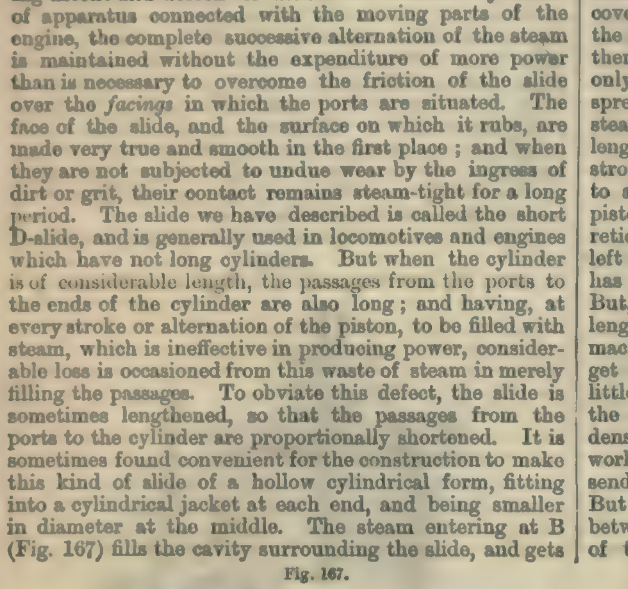


Figs. 165 and 166 represent two longitudinal sections of a cylinder fitted with a D-slide. The steam enters by a pipe B from the boiler into a cavity called the *slide-*

jacket, on the opposite side of which are three openings, the upper and lower, called the *ports*, communicating by tubes or passages with the upper and lower ends of the cylinder respectively; and the middle one, or exhaust channel, communicating by a cavity E with an opening at the side, by which steam can escape. These three openings are partially covered by a hollowed plate of metal, the *D-slide*, which, as its name implies, can be made to slide up or down by means of a rod C passing tightly through the jacket. The hollowed part of the D-slide is made to embrace the middle exhaust-passage and either of the ports, so as to let steam escape from the cylinder, while it leaves the other port open for the ingress of steam to the cylinder; and as for every ascent and descent of the piston in the cylinder, a corresponding ascent and descent of the slide is effected by means of apparatus connected with the moving parts of the engine, the complete successive alternation of the steam is maintained without the expenditure of more power than is necessary to overcome the friction of the slide over the *facings* in which the ports are situated. The face of the slide, and the surface on which it rubs, are made very true and smooth in the first place; and when they are not subjected to undue wear by the ingress of dirt or grit, their contact remains steam-tight for a long period. The slide we have described is called the short D-slide, and is generally used in locomotives and engines which have not long cylinders. But when the cylinder is of considerable length, the passages from the ports to the ends of the cylinder are also long; and having, at every stroke or alternation of the piston, to be filled with steam, which is ineffective in producing power, considerable loss is occasioned from this waste of steam in merely filling the passages. To obviate this defect, the slide is sometimes lengthened, so that the passages from the ports to the cylinder are proportionally shortened. It is sometimes found convenient for the construction to make this kind of slide of a hollow cylindrical form, fitting into a cylindrical jacket at each end, and being smaller in diameter at the middle. The steam entering at B (Fig. 167) fills the cavity surrounding the slide, and gets access to the cylinder by the upper or lower port as the slide is moved upwards or downwards, while the steam passes from either of these ports into the cavities at the upper or lower ends which communicate through the tubular body of the slide, and from one of which the waste-pipe C conveys the steam which has done its work.

Fig. 167.



We might mention many other varieties of slides; but all being constructed on similar principles to those we have described, we need not discuss them in detail. We will now proceed to describe the practical construction of a cylinder and piston suitable for a non-condensing engine.

CYLINDER AND PISTON.—Referring to Figs. 165 and 166, which give a general view of the cylinder and slide, we have to inquire into the proportions of the parts, and the details of their construction, in such a manner as to be economical, durable, and efficient.

The cylinder is made of cast-iron, bored in a suitable lathe, so that the interior is as nearly as possible perfectly cylindrical. The covers are also of cast-iron, having a projecting part turned to fit into the ends of the cylinder, to which they are secured by bolts and nuts. The mouths of the cylinder are generally bored somewhat larger than the rest, so that if, after some years' wear, it become necessary to bore out the cylinder afresh, thereby making its diameter a little larger, the same covers may still fit it. The flanges or projecting rims of the cylinder, and the faces of the covers which lie against them, are turned very true; and if well smoothed, require only a little thin flour-paste, or white and red lead paint, spread over them, to render the joints impervious to steam when the bolts are screwed tightly up. The length of the cylinder is determined by the length of stroke or movement of the piston: it should be such as to allow from ¼th to ½ an inch clearance between the piston and the cover at each end of the stroke. Theoretically, the less clearance the better, because any space left between the piston and cover at the end of the stroke, has to be filled at every stroke with steam uselessly. But, practically, it may be difficult to determine the length of stroke with perfect accuracy; the wear of the machinery may alter it a little, and water or dirt may get into the cylinder, so that it is necessary to allow a little space, such as we have named, for clearance. When the steam first enters a cold cylinder it becomes condensed into water; and not unfrequently, during the working of the engine, the boiler primes or boils over, sending water along with the steam into the cylinder. But as water is practically incompressible, its presence between the piston and the cylinder-covers at each end of the stroke, would be quite as detrimental as the presence of a mass of iron or any hard material, unless an exit were provided for it; for the sudden approach of the piston would be arrested by the water, and either the cover would be forced off, or the parts connecting the piston to the rest of the machinery would give way. Accordingly, cylinders are often fitted with relief-valves—small safety-valves loaded by weights or springs, and communicating with each end of the cylinder—so that whenever, by the presence of water, the pressure becomes increased to a dangerous extent, the valve is opened, and permits the water to escape. In the absence of relief-valves, *pet-cocks* or small stop-cocks are fitted for the same purpose. On first admitting steam to the cylinder, these are left open to permit the escape of the water arising from condensation; and during the working of the engine, they may generally be left a little open, especially when the presence of water is manifested by a sharp blow, heard when the piston strikes upon it. The thickness of the cylinder depends on its diameter, and the pressure to which it is subjected; and the strength of the flanges, covers, and bolts and nuts, must be determined on the same ground. For such details it is difficult to give precise rules, as experience and study of well-proportioned works can alone give the power of determining them.

The piston is constructed in various ways, one of which, being simple and effective, we will describe:—The body of the piston consists of a disc and boss A (Figs. 168 and 169), the outer edge of the disc fitting the cylinder, and the boss having a central conical hole, in which the piston-rod B is secured by means of a key, or thin bar of iron slightly tapered in width, driven through a slot or opening in the boss and rod, so as to tighten the conical end of the rod in the corresponding conical hole. To the body of the piston is secured by screws, a cover C fitting the cylinder, and leaving between

Fig. 168.

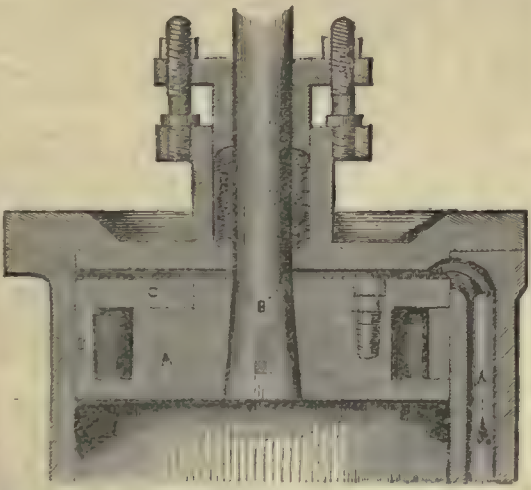


Fig. 169.

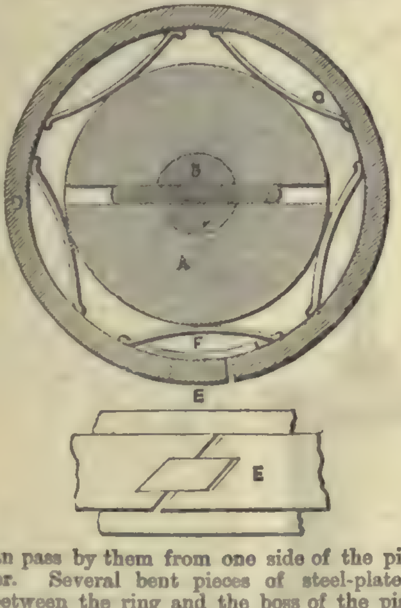
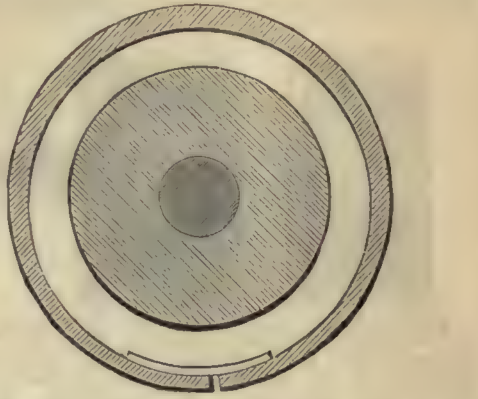


it and the edge of the disc below, a groove which contains the packing ring D. This ring is made to fit the cylinder, and is cut obliquely across at some point of its circumference E, a parallelogram-shaped hole being cut out of the middle, and filled with a piece of metal truly fitted to it. By thus cutting the ring across at E, it is permitted to expand in diameter ; and the slits made at E are covered by a plate F inside the ring so that no steam can pass by them from one side of the piston to the other. Several bent pieces of steel-plate G are placed between the ring and the boss of the piston, so as to push the circumference of the ring outwards.

As the inside of the cylinder and the edges of the piston and its cover become worn by constant rubbing, the packing-ring is made to expand, and still to work tightly in the cylinder, without permitting the flow of steam past the piston. Sometimes, for small pistons, the packing-ring is merely made thicker at the side opposite its slit ; and being at first slightly larger than the cylinder, so that it must be compressed when pushed into it, its own elasticity makes it expand to fit the cylinder even after considerable wear, without the necessity for steel springs within it (Fig. 170).

The piston-rod, in passing through the cylinder cover, is surrounded by a cavity called a stuffing-box, and filled with soft twisted hemp and tallow, called *packing*, which is compressed in the cavity by means of a *gland*, forced down upon it by tightening screws. By the use of this packing, while the rod travels upwards and downwards, steam cannot pass round it ; for even if the rod be worn somewhat irregularly, the elasticity of the packing serves to prevent the leakage of steam. Occasionally vulcanised india-rubber is employed for the purpose of packing.

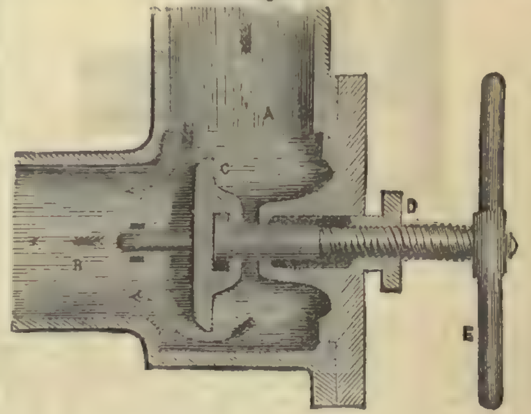
Fig. 170.



The slide-rod, and, indeed, all rods about an engine for moving valves or parts within cavities containing steam or water, have to pass through packing of this kind.

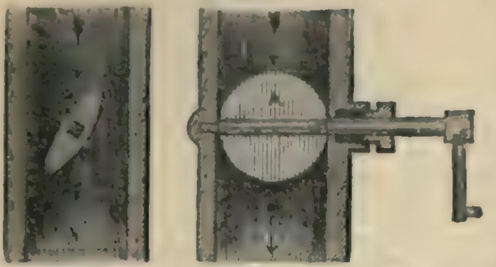
SHUT-OFF AND THROTTLE VALVES.—For opening or closing the communication between the boiler and the cylinder, so as to admit steam from the one to the other, to diminish the quantity or entirely arrest it, a stop-cock is generally employed for small engines, and for larger ones a *shut-off valve*. The stop-cock, being sufficiently well-known, we need not describe. The *shut-off* or *stop-valve* is generally made as indicated in Fig. 171. The steam-pipe A communicates with the valve-box, having a pipe B proceeding from it. The mouth of this pipe is fitted with a conical edging or seating, to which a conical-edged valve C is nicely fitted. Through a stuffing-box D in the cover of the valve-box, passes a screwed rod, connected by a free joint to the valve C ; when the rod is turned round by a handle E, so as to screw it inwards through the gland D, the valve is pressed firmly down on its seating, and thus all communication from A to B is cut off. By unscrewing the rod, the valve is raised from its seating as much as may be required for the passage of steam.

Fig. 171.



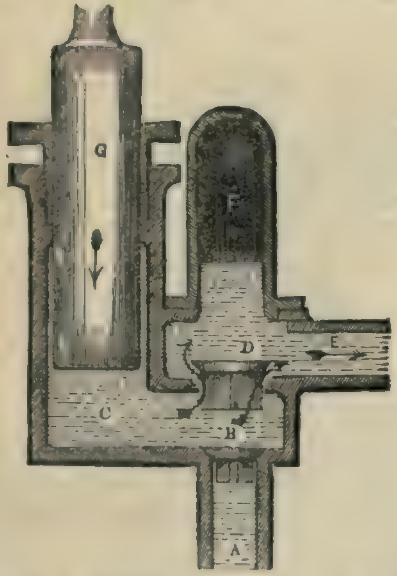
The *throttle-valve* is for the purpose of choking or throttling the passage of steam in a pipe, so as to regulate the quantity passing through it in a certain time, without perfectly arresting it. It consists of a disc A (Fig. 172) mounted on a rod passing across the pipe through a stuffing-box at one side. On turning the disc *edgeways* towards the current, the steam is allowed to pass ; but when it is turned *across* the pipe, none can pass except such a small quantity as can leak round the edges of the disc. This valve is almost universally applied to engines which are fitted with a governor, to which it is attached by means of proper connecting rods; and by its means the speed of the engine is regulated with great nicety, as more or less steam is permitted to pass the valve.

Fig. 172.



FEED-PUMP.—The feed-pump of an engine is for the purpose of supplying the boiler with water to take the place of that which is boiled off, and passes away in the form of steam, after working the engine. It consists of a barrel C (Fig. 173), in the upper part of which a plunger G is worked alternately upwards and downwards through a stuffing-box. At the lower end of the barrel is a valve-box, containing a suction-valve B, covering a pipe A by which the water is drawn from a convenient reservoir, and a discharge-valve D, past which the water has to flow in its progress to the boiler by the feed-pipe E. When the plunger is raised, the valve D being kept down in its seat by the pressure of water in the boiler (equivalent to that of the steam) communicated through the feed-pipe E, the vacuum left by the rise of the plunger is filled by water entering from A and raising the valve B for its passage. On the descent of the plunger, the water being forced out of the barrel, presses down the valve B, but raises the valve D, and flows onwards to the boiler. At some convenient part of the feed-pipe E there is always fitted a stop-cock, or shut-off valve, for completely cutting off communication between the pump and the boiler in case of the valves being deranged. But water being almost totally incompressible, it would be extremely hazardous to close this communication while the pump is in action; for in that case the barrel must be burst open, or some part of the machinery that works the pump must be broken. It is, therefore, usual to provide also a relief-valve, constructed exactly like a safety-valve on the feed-pipe, to permit the efflux of the water when its ordinary passage is closed. The cover F of the feed-valve box should be capable of being readily moved to give access to the valves; and it is often made of considerable size, hollowed out to contain air, which is compressed by the influx of water during the descent of the plunger, and reacts to force the water onwards to the boiler while the plunger ascends. In all cases, indeed, where water under considerable pressure is exposed to the recurring action of a propelling force, as in the feed-pump, an air-vessel should be provided to act as a spring, relieving the blow on the water, and regulating its motion to a gradual flow instead of a sudden movement.

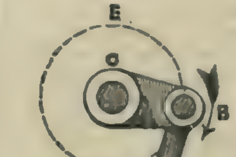
Fig. 173.



CRANK AND CONNECTING-ROD.—Having now described the *cylinder* in which, and the *piston* on which, the steam acts to put the machinery in motion—the *slide* by which the alternation of the course of the steam is effected—the *throttle-valve* by which its quantity is regulated—and the *feed-pump* by which the necessary supply of water is maintained in the boiler; we have to inquire how the reciprocating motion of the piston is converted into the rotary movement required for driving machinery, and how this rotary movement produces the reciprocating motion of the slide and feed-pump, and governs the action of the throttle-valve.

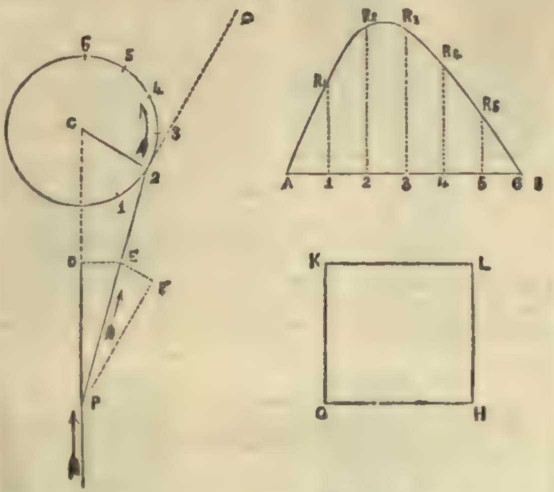
To the end A (Fig. 174) of the piston-rod there is jointed the connecting-rod A B, having an eye at B working on the *crank-pin*, or pin fixed to the *crank*—an arm B C projecting from the main shaft or spindle C. The crank-pin can move round in a circle, the diameter of which is exactly equal to the length of stroke, or distance through which the piston travels in the cylinder. As the piston descends from F to G, making the down-stroke, the crank is caused to revolve from E round to D, one half-revolution. Again, while the piston ascends from G to F, making the upstroke, the crank revolves from D round to E, another half-revolution. Each revolution, then, of the crank requires a double stroke of the piston; and to effect it, the upper and lower portions of the cylinder have each to be filled and emptied of steam; or, as their capacities are equal, the cylinder has for each revolution to be twice filled and emptied. It is obvious that, at every different point of its revolution, the crank is acted on by a different force, owing to the varying obliquity of the connecting-rod. At the two extreme points, D and E, where the crank is in a line with the connecting-rod, the effect of the piston to cause it to revolve is reduced to nothing; for it merely pushes or pulls it against the central shaft. These points are technically called the *dead centres*, because there the force of the piston is dead or ineffective. But to make up for the total want of action at those points, we find that at some other points the effect of the force passing through the connecting-rod to turn the crank, is greater than the pressure on the piston, in consequence of the obliquity of its action.

Fig. 174.



Again, the piston, during a revolution or double stroke, passes through a distance equivalent to twice the diameter of the crank-circle; while the crank-pin passes over the circumference of that circle, more than 3 times its diameter. The influence of the pressure on the piston to turn the crank may be best conceived by a graphical delineation of the force in the following manner:—If we divide the circle described by the crank-pin round the centre C into any number of equal parts (Fig. 175), and draw a straight line A B equal to the half-circumference divided into corresponding parts, A B represents the distance through which the crank-pin moves during half a revolution, developed into a straight line. If at any point, such as 2, we draw a line 2 C representing the crank, and a line 2 P representing the connecting-rod, and draw Q 2 touching the circle at 2, and therefore representing the direction in which the crank-pin is moving at the point 2, while the line P C represents the direction of the piston, we may take any length P D in that line representing the force of the piston (as, for instance, if the pressure on the piston were 5 tons, we might take P D = 5 inches), draw D E perpendicular to P D, P F parallel to Q 2, and E F perpendicular to P F, or parallel to C 2. Then, on the principle of resolved forces, the length of P E represents the force transmitted through the connecting-rod, and P F the force tending to turn the crank, while D E measures the side thrust on the piston-rod, and E F the longitudinal strain on the crank, pushing the shaft against its bearings. If, now, at the point 2 in the line A B we erect a perpendicular 2 R_2 equal in length to P F, and at the points 1, 3, 4, &c., erect others deduced by the same kind of construction, we can trace a curve through their summits, the height or ordinate of which at any point measures the force turning the crank-pin at the corresponding point of its circumference; and therefore the area or space enclosed between the curve and its base A B, which may be considered to be made up of an indefinite number of these ordinates, measures the total force expended on the crank during a half-revolution. If, now, we take a line G H equal to the diameter of the crank-circle or the stroke of the piston, and, dividing it into any number of equal parts, erect ordinates each equal to P D, and therefore representing the constant force of the piston, the area of the rectangular figure G H K L thus formed will, in like manner, measure the total force of the piston during one stroke. It will be found that the area of this figure is exactly equal to that of the curvilinear figure, as might be predicted from the knowledge of the *universal* mechanical principle, that by no combination of machinery can we create or annihilate force; and that consequently, whatever power the piston during its straight stroke impressed upon the crank, is found in the crank during its circular movement. By altering the length of the connecting-rod, as compared with that of the crank, we alter the figure of the *force-curve*, but we do not change its area; and whether the connecting-rod be long or short, the power conveyed through it during the half-revolution is the same. The other half-revolution being effected under similar circumstances, would give a *force-curve* precisely like that of the former.

Fig. 175.

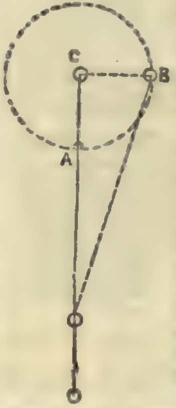


In this investigation we have observed that the oblique action of the connecting-rod causes a lateral thrust on the piston-rod, measured by the line D E. It will be found, that the longer the connecting-rod, the less will this lateral thrust be; and as it is a force not only useless to the machinery, but positively prejudicial, tending to bend the piston-rod or force it out of its straight path, it is advantageous to reduce it to as small a quantity as possible, and to provide means for counteracting its influence. For this reason, a long connecting-rod, three or four times the length of the crank radius at least, should be employed, and the end of the piston-rod should be made to move in guides so as to prevent it from being deflected.

As the piston at the dead centres has no influence in causing the crank to revolve, it is necessary to provide some means of making up for this deficiency. On the crank shaft there is fixed a large heavy wheel, which revolves with it, and acts as a reservoir of force to carry the crank round the dead centres, and otherwise to equalise the movement. A large mass of matter, such as the fly-wheel, weighing sometimes many tons, cannot be put in motion at a high velocity without the expenditure of great force; but when it is in motion it requires as great force to arrest it. In the motion of a crank connected with a fly-wheel, while the crank is receiving its most advantageous impulse from the piston at such points as 2, 3 or 4, it communicates some of its overplus to the fly-wheel, which is there stored up in the form of momentum or active power, to be given out upon the crank and any machinery connected with it, when, at the points 1 and 6, it is receiving no power from the piston.

In cases where a fly-wheel, on account of its weight and bulk, cannot be applied—as in marine and locomotive engines—the engine is made in duplicate, with two cylinders, pistons, connecting-rods, and cranks, both of the cranks being fixed on one shaft at right angles to each other. While the one crank is on its dead centre, as C A (Fig. 176), and receiving no rotatory impulse; the other crank C B is nearly at its best position for receiving the force of its piston.

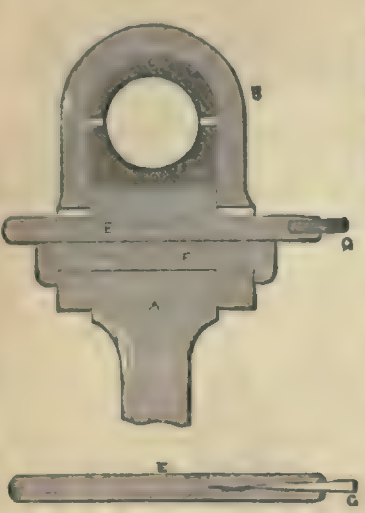
Fig. 176.



As the whole power of an engine has to pass through its connecting-rod, the joints which connect it with the piston-rod and the crank require to be made of great strength, and with precautions against friction and wear. The pins of the crank and piston-rod, on which these joints work, are made of wrought-iron or steel, for the sake of strength; and as the friction of like metals upon each other is found to exceed that of different metals, the eyes at the ends of the connecting-rod are lined or *bushed* with brass, gun-metal, or some soft metal, such as tin alloyed with copper. The special construction of those eyes depends upon circumstances, different engineers having preferences for different forms.

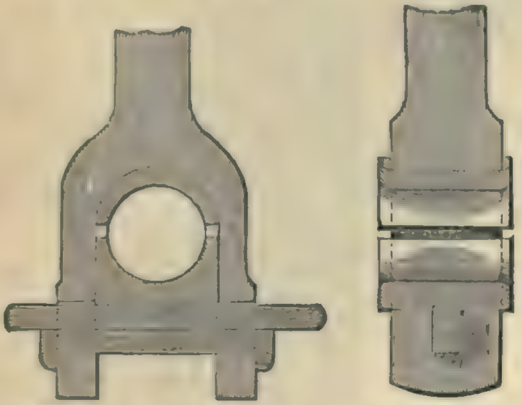
In Fig. 177 is represented what is called the *strap-eye.* The end A of the connecting-rod is squared, so that a wrought-iron strap B, bent to horse-shoe form, can slide on to it. Between the arch of the strap and the flat end of the rod are inserted the upper brass C and the lower brass D, generally made of gun-metal, sometimes lined with soft metal. The brasses have projecting lips or flanges at each side to prevent them from moving sideways within the eye. Through the sides of the strap and the head of the connecting-rod is cut a slot, into which are fitted two pieces of iron, the *key* E and the *gib* F, each slightly tapered, so that when the key is driven gently into its place by a hammer, it acts as a wedge, pulling the strap down, and thereby tightening the brasses on the pin to which they are fitted. A little space is left between the edges of the brasses to permit their closer approach as they or the pin become worn in the hole; and the slot for receiving the gib and the key is extended upwards in the strap and downwards in the connecting-rod, to permit the key to be driven. Lest the key should be shaken loose by the motion of the machinery, it is often split open at the small end, and a wedge G is driven in to spread it laterally.

Fig. 177.



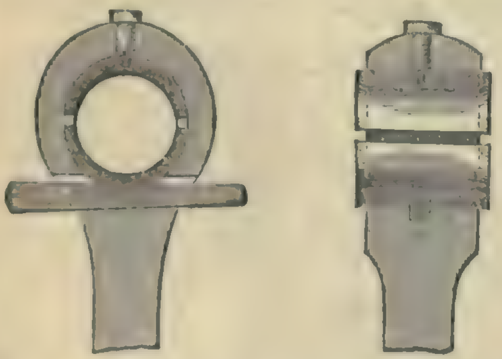
The fork-end (Fig. 178) is made by forming the end of the connecting-rod like a fork, fitting it with gun-metal bushes, and tightening them by means of a gib and key.

Fig. 178.



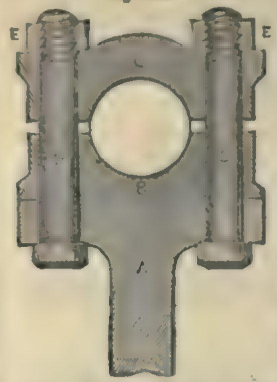
The bushed-eye (Fig. 179) is formed by shaping the end of the rod into an eye, in which gun-metal bushes are fitted, capable of being tightened by a key passing through a slot in the rod, and bearing against the lower bush, which is notched to receive it.

Fig. 179.



Sometimes the eyes are made as represented in Fig. 180. The end of the rod A is spread out to form a flat face, on which are fitted two brasses made with a hole to fit the pin, and secured by means of bolts and nuts D, E, passing through holes in the end of the rod, and in the brasses fitted accurately to receive them.

Fig. 180.



Such are the modes principally used in forming the eyes of connecting-rods, or of any joints through which considerable strain has to be communicated.

The crank A (Fig 181), is made, sometimes, of cast-iron for stationary engines, but, generally, for marine engines, of wrought iron, having a hole fitted to B the round end of the shaft, on which it is fixed, and prevented from turning by a key C, or tapered piece of iron, driven tightly into a slit, formed partly in the crank and partly in the shaft. Generally, the round hole in the crank is made slightly smaller in diameter than the round end of the shaft; the crank is heated so as to expand it, and permit it to be driven on the shaft; and as it cools it tends to contract, and thereby becomes very firmly bound on to the shaft, the end of which is riveted or hammered over the hole. The crank-pin D is made to fit truly into a hole in the crank, in which it is sometimes secured by a key or pin driven through it transversely. The distance E F, between the centre line or axis of the shaft and that of the pin, is called the *throw* of the crank, and it is exactly half the length of the *stroke* of the piston. For locomotive engines, and, indeed, for many of the largest marine engines, where double cranks are required, it is usual to forge both cranks and the shaft in one piece, as indicated in Fig. 182. By this means great strength and simplicity are secured, and all the risk of the loosening of parts, put together by keys or otherwise, is avoided.

Fig. 181.

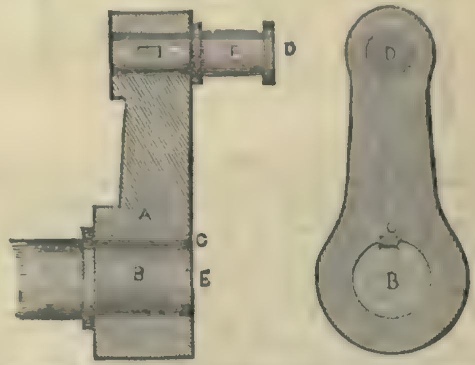


Fig. 182.

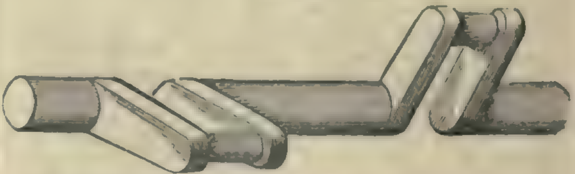
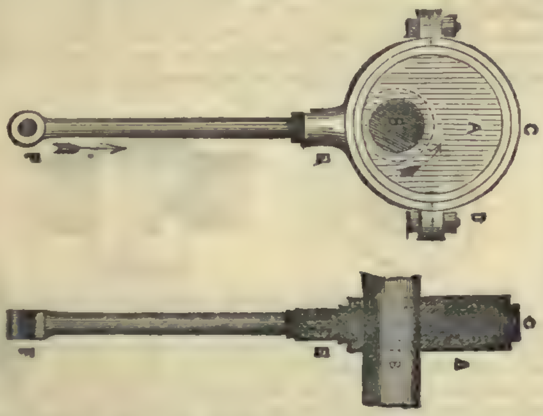


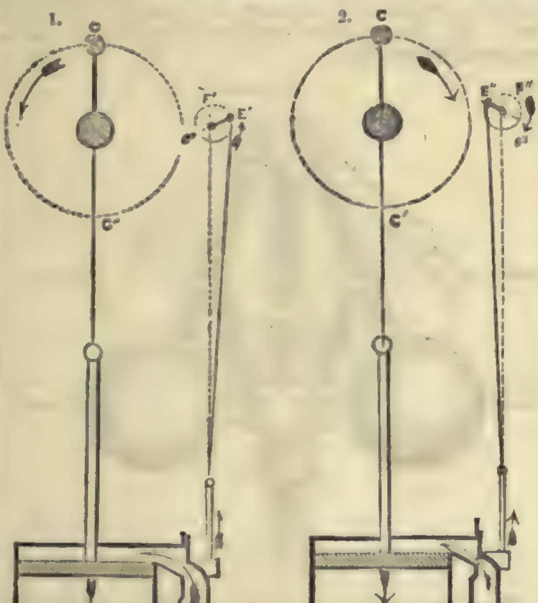
ECCENTRIC.—As, by means of a crank, the reciprocating motion of a piston is converted into a continuous rotary motion of the shaft, so the continuous revolution of the shaft may, by means of a crank, be converted into a reciprocating movement for the slide or feed-pump; but for this purpose, instead of a crank, an eccentric is generally employed. It consists of a circular disc A (Fig. 183), having a hole B, *not* in its centre, through which the shaft passes. Round the disc is fitted a ring C, generally made in halves, secured to each other by bolts and nuts at D; and to one side of the ring is attached the eccentric-rod E F. The eccentric disc, or *sheave*, being firmly fixed on the shaft, is caused to revolve with the latter, and its centre is thus made to describe a circle round the centre of the shaft. The whole sheave thus becomes a crank-pin of extended diameter; and as it can slip freely round within the ring, the end F of the eccentric-rod is caused to move upwards and downwards, during every revolution, through a distance equal to the diameter of the circle through which the centre of the sheave revolves. The radius of this circle is called the *throw* of the eccentric; and its diameter, or the distance through which F is caused to move during a half-revolution, is called the *stroke* of the eccentric-rod.

Fig. 183.



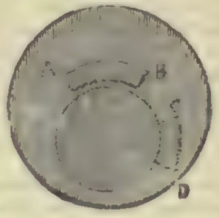
The setting of the eccentric upon the shaft, or the fixing of its position with respect to that of the crank, is a matter of nice adjustment for causing an engine to act well, as we shall endeavour to describe. Let A (Fig. 184) represent the outline of a cylinder and piston, with the ports at one side, and a long D-slide D fitted to them; C the circle in which the crank-pin revolves, and E that in which the centre of the eccentric revolves in connection with it. We suppose the piston at the top stroke, and the crank-pin at C.

Fig. 184.



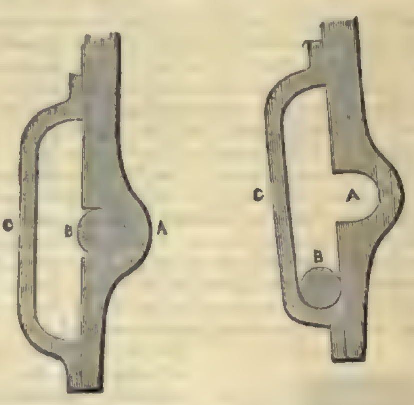
If it be intended that the crank shall revolve in the direction of the arrow in 1, the eccentric revolving in the same direction, the slide should be just opening to admit steam above the piston, and to permit its exit from below it. The centre of the eccentric must, therefore, be at some such position as E′—so that, as it continues to revolve, it may continue to open the slide to steam above and to eduction below for some time, and then be ready at e′ when the crank reaches C′ to reverse the movement. Again, if the rotation of the crank be in the opposite direction, as in 2, the eccentric centre must for the like reason be at E″, a point on the side of the vertical central line opposite to that occupied by E′. In an engine always moving in one direction, the eccentric can be fixed on the shaft in such a manner as to give the proper movement to the slide; but when it is desired that the engine should move in the opposite direction, some expedient must be devised for altering the position of the eccentric on the shaft through an angle measured by twice E′ F′, or E″ F″, so as to throw its centre as much to one side as it was to the other side of the crank-pin. The simplest mode of effecting this object is to make the eccentric sheave loose on the shaft, with a piece A B (Fig. 185) projecting from its face, and a piece, or stop, C D projecting from the shaft. When the shaft moves in one direction, the eccentric remains at rest until the end C of the stop comes against B, when it is caused to revolve with the shaft. But, if the shaft rotate in the opposite direction, it leaves the eccentric behind, until D comes round to A, when it is again caused to revolve, but having its centre changed with respect to any fixed point on the shaft, by a quantity determined by the extent of slip before the opposite edges of the stops come in contact.

Fig. 185.



When this arrangement is adopted, the end of the eccentric-rod is generally made of the form indicated in Fig. 186, having what is called a *gab* or round-bottomed notch A fitted to the pin of the slide-rod B.

Fig. 186.



When the eccentric-rod is pushed or drawn aside, so as to relieve the slide-rod pin from the gab, the slide can be moved upwards or downwards by hand, independently of any motion of the eccentric-rod, and the movement of the steam above or below the piston thus changed at pleasure. C is a guard or stop to prevent the withdrawal of the rod too far from the pin. The slide-rod is generally made capable of being worked by a lever conveniently situated for the hand of the attendant. When he wishes to reverse the motion of the engine, he quickly withdraws the gab from the slide-rod pin, and by means of the hand-lever moves the slide in the direction opposite to that in which it was formerly moved by the eccentric. He thus throws the steam-pressure on the opposite side of the piston—if it were formerly ascending, it begins to descend, and conversely—the movement of the crank and shaft is thus reversed; the stop that drives the eccentric is brought round to the opposite side; and when, after a few alternations of the slide by hand, the reversal of the engine is fairly established, the gab of the eccentric-rod is permitted again to drop over the slide-rod pin, and the contrary motion continues.

When there are two engines working together, such as marine or locomotive engines, the number of operations required for reversal makes it a rather difficult matter. There are two slides, two eccentrics, and two sets of hand-levers; both gabs have to be thrown out of gear, and both levers worked for a time by hand; while great care is demanded on the part of the attendant, lest he work them in such a way as to neutralise each other, or oppose the reversing effect which he desires to produce. To overcome these difficulties, an ingenious arrangement, called the *link motion*, has been introduced in marine and locomotive engines. For each of the engines there are two eccentrics fixed side by side on the shaft, and their rods are jointed to an arc A (Fig. 187) with a circular slot in it, in which the pin B of the slide-rod can freely slide. The two eccentrics are fixed on the shaft in such positions that one is adapted for the motion of the shaft in one direction, while the other suits its motion in the opposite direction. When the rod of the one is nearly in a direct line with the slide-rod, it gives it its reciprocating motion, while the other merely causes the arc to oscillate without affecting the motion of the slide; but when the arc and rods are pulled aside, so as to bring the slide-pin under the other eccentric rod, its motion is given to the slide, and the engine is thus reversed. With such an apparatus, then, one simple movement of a hand-lever, connected with the arcs of both engines, causes their immediate reversal. But this is not the only advantage of the link motion. It will be readily seen that the middle point A of the arc being brought round to the slide-rod pin, the latter will be left nearly at rest; for the opposite ends of the arc being moved nearly in opposite directions by the eccentrics, will merely oscillate round A, as a fulcrum or centre. By bringing the arc to this position the engines are stopped, because the slide being at rest, admits no alternation of steam above or below the piston. Again, by shifting the arc so as to bring the pin to any point on either side of A, more or less movement of the slide in either direction is produced at pleasure, and thus the quantity of steam passing through the ports into the cylinder may be varied, and consequently the speed of the engine, according as the slide is caused to expose a greater or less amount of opening at the ports for its admission.

Fig. 187.

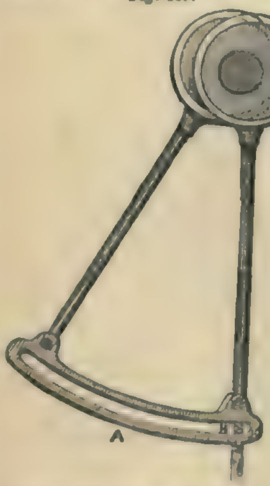


Fig. 188.

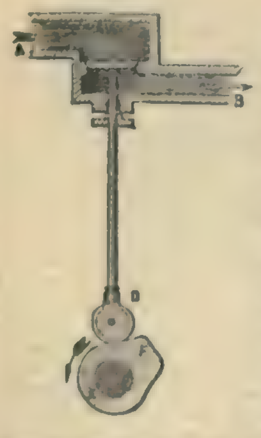
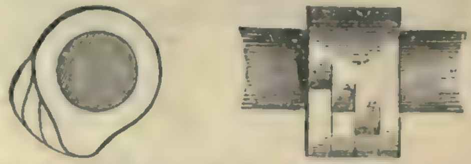


CAMS.—When valves are used instead of the slide, for alternating the flow of steam to the cylinder, it is not unusual to move them by apparatus called *cams.* A (Fig. 188) is a pipe leading from the boiler, B a port to the cylinder, and C a valve, either simple or of the double-beat kind, closing the passage from A to B. The valve-rod CD, passing through a stuffing-box in the cover of the valve-box, terminates in a roller D, which bears upon a cam F fixed on a shaft E, caused to rotate by the engine. This cam is a disc partly circular, and with part of it, F, projecting to a greater distance from the centre. As long as the roller D bears upon the circular portion, the valve C remains down upon its seat; but as the projecting part of the cam is brought by its revolution under the roller, the valve-rod is pushed up, and the valve lifted to permit the passage of the steam. By varying the extent of the projecting part, the valve can be kept open during a greater or less portion of a revolution of E. When it is desirable to vary this period, the cam is sometimes made with numerous steps of various extents, on any of which the roller may be made to bear at pleasure (Fig. 189).

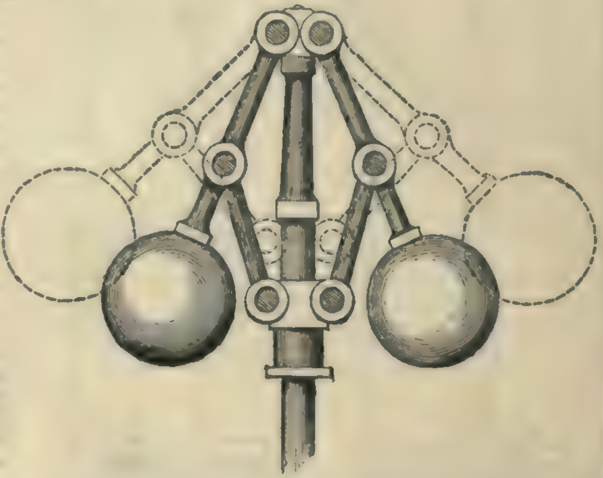
Fig. 189.



For engines revolving slowly, this mode of working valves is very valuable, as it gives the power of admitting steam to the cylinder during a less or greater part of a stroke, and thereby of taking advantage of its expansive power within the cylinder. But when the rate of revolution is rather rapid, it is difficult to make the cam and roller capable of working without noisy and injurious blows, resulting from their rapid alternations.

GOVERNOR.—In stationary engines, which are subjected to continual variations of work, and yet are required to move with great regularity, it is essential to provide some means of governing the speed. The most simple and efficacious apparatus for this purpose is the conical pendulum or governor, invented by Watt (Fig. 190). We have already described it in general terms as applied to windmills.

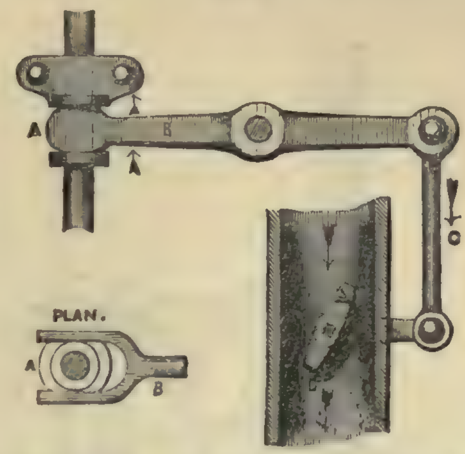
Fig. 190



For steam-engines it is used in a similar manner. The vertical spindle is put in motion by the engine, and revolves quickly or slowly, according to the velocity of the engine. When it revolves rapidly, the balls fly outwards, and raise the grooved brass which slides on the spindle A (Fig. 191), and thus moves a forked lever B, which, by proper rods and levers C, causes the throttle-valve D to turn round in the steam-pipe, and check the passage of the steam to the cylinder. When the engine revolves slowly, on the other hand, the balls fall in, the brass sinks, and the throttle-valve is presented edgeways to the steam, and permits a more free passage.

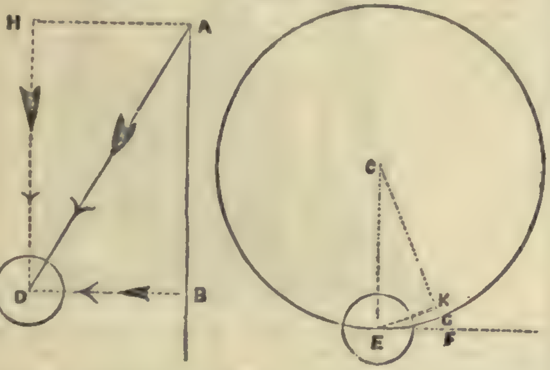
As, in the pendulum of a clock, the length from the point of suspension to the bob must be regulated to beat seconds, or half seconds, or any other intervals that may be required; so in the conical pendulum or governor,

Fig. 191.



the length of the arms that carry the balls must be regulated by the speed at which they revolve. In discussing this question, we need only consider one ball, as each is regulated by the same law, and they are generally made in duplicate for the sake of balancing the apparatus, and to give it symmetry. The force which tends to throw the ball outwards from the vertical spindle, is the centrifugal force of its revolution, or its tendency in obedience to the first law of motion to proceed in the straight line E F (Fig. 192), touching the

Fig. 192.



circle in which it revolves, rather than to be continually diverted from its straight to a circular path. The force which opposes the centrifugal force, and causes the ball to be continually deflected from the straight line, is the weight of the ball tending to push it close home to the vertical spindle. If we take any position of the ball, such as D, A B being the vertical spindle, and complete the parallelogram of forces A B D H, while the line D H or A B represents in quantity and direction the weight of the ball, drawing it down, and D B or A H the centrifugal force pushing it outwards, A D represents the resultant of those two forces as a tension on the rod by which the ball is suspended. If we know the velocity with which the ball moves in its path, and the radius of that path, we can estimate its centrifugal force in comparison with its weight, and can make the limb A D of such a length that these two forces shall be properly proportioned for a certain velocity.*

The length of the arm of the governor, measured from the point of suspension to the centre of the ball, may be found from the following rule:—

Divide 200 by the number of revolutions per minute, and multiply the quotient by itself for the length in inches.

Example.—Required the length of a governor arm suited to 50 revolutions per minute:

$$\frac{200}{50} = 4, \text{ and } 4 \times 4 = 16 \text{ inches.}$$

To find the speed suited to a governor of a given length of arm.

Divide 200 by the square root of the length (in inches), and the quotient will be the number of revolutions per minute.

Example.—Required the proper speed for a governor having an arm 16 inches long.

The square root of 16 is 4, and $\frac{200}{4} = 50$ revolutions per minute.

The rods and levers connecting the governor with the throttle-valve should be capable of adjustment, and it is useful to have an adjusting counterbalance to the centrifugal force of the balls, by changing which, the regulated speed of the engine can be varied at pleasure. Although the governor we have described is a most valuable accession to an engine, yet it is not a perfect regulator; for its very mode of action implies that the velocity of the engine must have undergone a change, before the governor can have begun to act on the throttle-valve. But within certain limits, the variation in speed of an engine thus regulated is inconsiderable, and there is no appa-

---

* E G being part of the circular path, which may be taken as small as we please, and E K perpendicular on C F, F K is nearly bisected in G, and E K is nearly equal to E F, and K F nearly parallel to C E. Also $CE : EF :: EK : KF = \frac{EK \cdot EF}{CE}$, or nearly $\frac{EF^2}{CE}$.

A body projected from E with such a velocity as would in a small period $\triangle t$ cause it to describe E F, if acted on during that period by a constant deflecting force parallel to C E, giving it during $\triangle t$ a velocity which would cause it to describe uniformly F K in the time $\triangle t$, would be deflected through F G, the half of F K in the time $\triangle t$.

If f = the deflecting force (measured by the velocity acquired in one second), $f \triangle t^2$ is the space traversed during $\triangle t$ at the velocity acquired during $\triangle t$, and if v be the velocity per second of the body in E F, and therefore $EF = v \triangle t$, and $r = CE$, the radius (measured in inches),

$$f \triangle t^2 = FK = \frac{EF^2}{CE} = \frac{v^2 \triangle t^2}{r} \therefore f = \frac{v^2}{r}$$

Taking n = the number of revolutions per minute, $\frac{n}{60}$ = number per second, and $2 \pi r$ = the circumference traversed in each revolution, $\therefore v = \frac{2 \pi r n}{60} = \frac{r n}{9{\cdot}545}$

Hence, $f = \frac{r^2 n^2}{(9{\cdot}545)^2 r}, = \frac{r n^2}{91{\cdot}1 \text{ \&c.}}$ very nearly.

The force of gravity is measured by a velocity of $32\frac{1}{2}$ feet or 385 inches acquired per second, and taking w = the weight of the body, $f : w :: \frac{r n^2}{91} : 385$

$$\therefore f = \frac{w r n^2}{91{\cdot}1 \text{ in.} \times 385} = \frac{w r n^2}{35344} \text{ very nearly.}$$

Now, as f is represented by B D, while w is measured by A B, and as $BD = r$

$$AB : BD :: w : f :: w \cdot \frac{w r n^2}{35344}$$

$$\text{or } AB = \frac{35344 \, BD}{n^2 \quad BD} = \frac{35344}{n^2} = \left(\frac{188}{n}\right)^2$$

It is convenient in practice to make the angle B A D about 30° when the governor is at its average speed, when $AD = 2 DB$; and as $AD^2 = AB^2 + DB^2$, we find

$$AD = \frac{2}{\sqrt{3}} \left(\frac{188}{n}\right)^2 = \left(\frac{200}{n}\right)^2 \text{ very nearly.}$$

ratus so simple and durable, that is capable of maintaining like regularity.

Fig. 193.

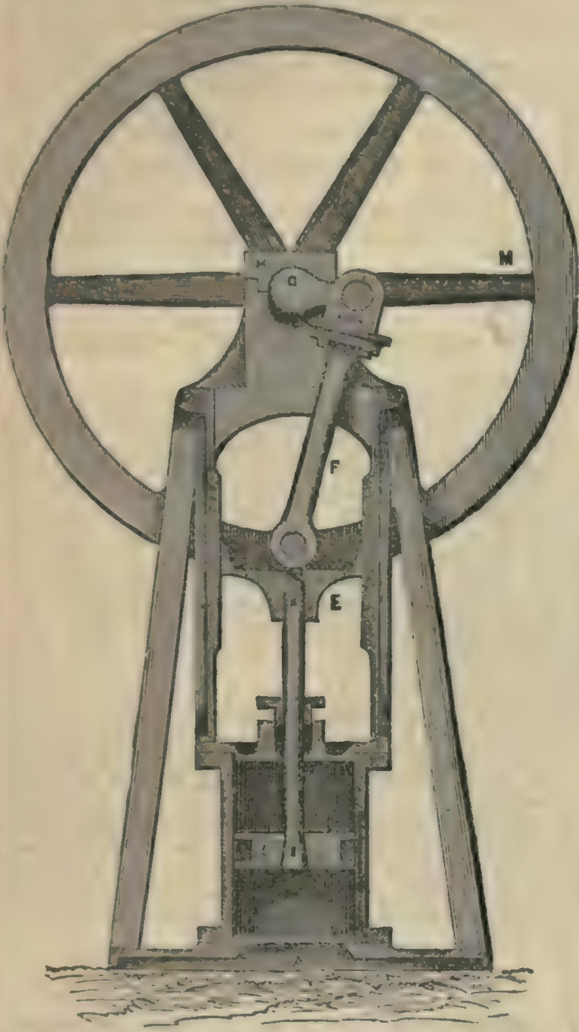


Fig. 195.

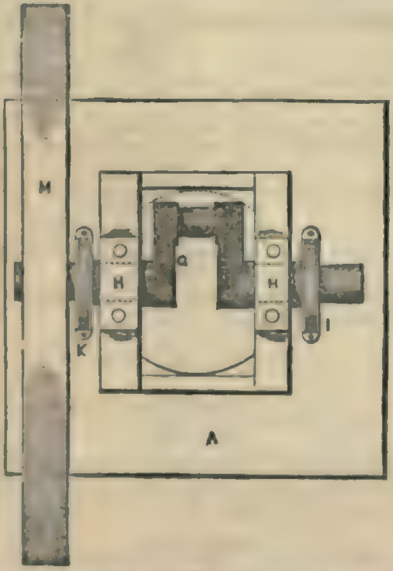
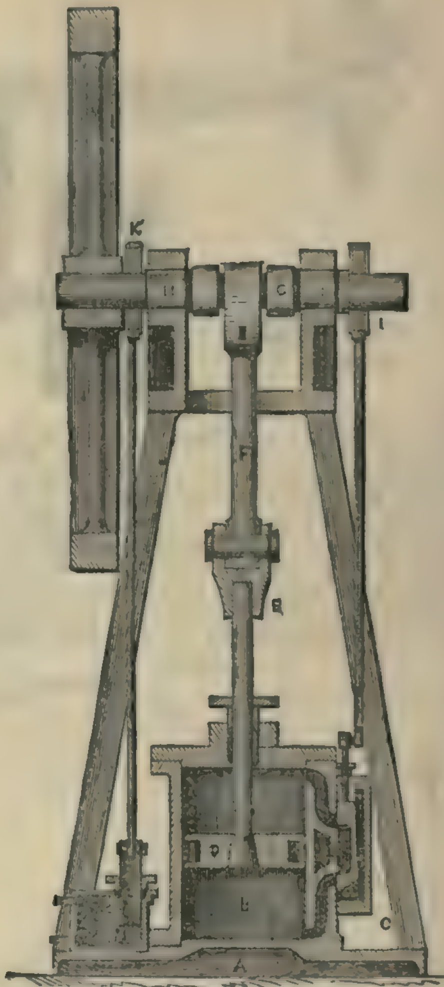


194.



Another kind of governor has been applied, not without success. The lever of the throttle valve is connected by a rod with a small piston working in a cylinder; the engine puts in motion a small pump, forcing into this cylinder air or water, which escapes from it by an aperture, the size of which can be regulated at pleasure. If the speed of the engine increase, the small cylinder is filled more rapidly than it can empty itself, and the piston thus raised closes the throttle-valve. Should the engine move more slowly, the small cylinder becomes emptied more rapidly than it is filled by the pump; and the piston descending, opens the throttle-valve so as to admit more steam to the main cylinder.

Other contrivances for governing the speed of engines have been applied with success. Among them we may mention the chronometric governor, of which our limited space does not permit us to give a detailed description.

Having now described separately the principal parts of which a non-condensing engine consists, we will discuss some of the modes in which these parts can be most conveniently arranged.

DIRECT-ACTING ENGINES.—Figs. 193 and 194 are sections, transverse to each other, of a vertical, direct-acting non-condensing engine; and Fig. 195 a plan of the same. A is the foundation-plate, forming the bottom of the cylinder B, which is secured to it by bolts and nuts. C, the slide and steam passages. D, the piston and rod, terminating in a cross-head E, which works between guides, and to which is jointed the connecting-rod F. G, the crank; and H H, the bearings in which the crank-shaft revolves. I, the eccentric and rod for working the slide; and K, an eccentric for working the feed-pump L. M, the fly-wheel. This engine is

of very simple construction, and has no parts that are unnecessary to the efficient working.

The annexed plate represents a horizontal direct-acting non-condensing engine; and as this form of engine has of late years been very extensively used, we think its details may be studied with great advantage. The principal objects attained by adopting the horizontal arrangement are these:—

The framing (marked V V on the plate) is of a very simple character, and can generally be cast all in one piece.

The whole strain caused by the alternate pulling and pushing of the piston in giving motion to the crank, is thrown rectilineally on the framing, which can be readily made strong enough to bear it, and which, being subjected to no racking strain, is laid upon a bed of masonry, and secured in its place by a few bolts.

The whole machinery of the engine being spread out as it were under the eye, is visible and accessible in every part for cleaning, oiling, and repairs, and is in itself so simple that great economy of construction is secured, along with efficiency and durability.

The plate gives an external side elevation, in which—A is the cylinder surmounted by the slide jacket, B; C is the piston rod, which, attached at one end to the piston inside the cylinder, passes through a stuffing-box, O, in the cylinder cover, and terminates in a cross-head and pin, D, on which is jointed the connecting rod, E, by means of a strap-joint, as shown in the plate, or any other of the joints already described, that may be found most suitable. As the connecting rod, by its oblique action on the crank, throws a considerable lateral strain on the head of the piston-rod, tending to push it upwards or downwards, out of its direct line of action,* the cross-head, D, of the piston is made to slide between guides, N N, which are nicely smoothed and kept well lubricated.

F is the crank fixed on the main shaft, and to which the connecting-rod, E, is jointed by a strap-joint. The shaft revolves in bearings, one of which is fixed on the engine frame, and is generally made oblique (as indicated by the dotted lines on the plate), because the action of the piston being in the horizontal line, if the bearing were jointed horizontally, the strain would be thrown on the joints of the bushes instead of their solid bodies. The outer end of the shaft revolves in a bearing or plummer-block, which is fixed on a wall or other suitable masonry at the side of the engine. The fly-wheel, H, is fixed on the shaft, and revolves with it. A small crank, I, is mounted on a small shaft, J, concentric with the main shaft, in order to give motion to the governor-spindle, G, and to the eccentric, K, which regulate the supply of steam to the cylinder.

The governor and eccentric gear are connected by an ingenious arrangement, which we will endeavour to describe. From the eccentric, K, extends a rod, L, to the joint, M, of a lever, which vibrates on a pin, *n*. This lever contains a slit (which is part of a circular arc), in which slides a pin, *s*. A rod, *t u*, extends from this pin to the extremity of a lever, which vibrates on a spindle, *v*, and which has its other extremity, *w*, connected by a rod, *w x*, to the slide-rod. The slide-rod moves rectilineally through a guide, *y*, and through a stuffing-box, *z*, and puts the slide into alternating motion within the jacket, B, so as to admit steam to the opposite ends of the cylinder, and permit its egress from these ends successively.

The governor, which is mounted on a vertical spindle, G, is put in motion through bevil gearing, driven by the small spindle, J. The governor-balls, *e e*, are attached to equal rods, which work on pins mounted on the head of the governor-spindle, *d*. From these rods two bent rods extend downwards, and are jointed to a tubular boss, *f*, which slides upwards or downwards on the governor-spindle, according as the balls fly out from or fall in towards its axis. This boss, *f*, has a groove cut into it, which receives the ends of a forked lever, *g*, mounted on a fixed pin, *h*. A lever at right angles to this, terminating in a pin, *k*, communicates motion by the rod, *l*, to the extremity of another lever, *m*, which is mounted on the same pin, *n*, with the slotted lever, M, already described. From each side of the central pin, *n*, arms extend to *o* and *p*, the one suspending a weight, *q*, balancing the rod, *t u*, which is suspended at *r*, by a small vertical rod from the other extremity, *p*, of the double-ended lever. In order to understand the action of this apparatus in governing the engine, we shall first suppose that it is going at its proper speed, so that the governor-balls, *e e*, maintain their mean distance from the axis, G, neither flying out from it, as they would do if they revolved too fast, nor falling into it if they revolved too slowly. Under these circumstances, the eccentric-rod, M, works directly on the pin, *s*, and through it, and the rod, *t u*, and lever, *u v w*, on the slide-rod, *x*, giving the slide its mean amount of stroke backwards and forwards, so as alternately to uncover the steam ports to the extent necessary for the admission of such a quantity of steam into the cylinder as is required for working the engine at the speed to which it is timed. Let us now suppose that some additional work is thrown on the engine, more than the steam allowed to it is capable of performing. The first and immediate result of this is a reduction of speed.

The governor-balls, *e e*, no longer maintained in their position by their former centrifugal force, sink inwards towards the axis G; the tubular boss, *f*, is thus caused to slide down the axis, the bell crank lever, *g h k*, pushes the rod, *l*, towards the cylinder, and thereby throws the double-ended lever, *m o p*, into the position represented on the diagram (Fig. 2). The effect of this movement, by dropping the point *r*, is to let the pin, *s*, slide down the circular slot of the lever to a point farther from its centre, *n*. As the eccentric-rod, L, maintains the same amount of stroke as before, the pin, *s*, being removed farther from the fulcrum, *n*, of the lever, receives a more extensive vibration, which it gives to the slide-lever and rod, and the slide itself is thus caused to move over a larger extent of the facings within the jacket, B, and so to open the steam ports more widely, and admit into the cylinder the increased amount of steam required for the increased work thrown on the engine. If, on the other hand, work were thrown off the engine, the speed would increase, the governor-balls would fly outwards, their operation on the slotted lever would be reversed (as marked by the dotted lines in Fig. 2), and the stroke of the slide and supply of steam would be proportionally diminished, to suit the reduced work which the engine might have to perform.

P is the steam-pipe leading from the boiler to the cylinder; R the shut-off valve for stopping the passage of the steam, or regulating the quantity supplied; S a short piece of connecting-pipe, which may be removed by undoing the bolts, by which it is connected to the valve and to the slide-jacket, so that room may be afforded for lifting the slide-jacket itself off the cylinder without disturbing the steam-pipes, when it may be necessary to repair the slide or adjust the facings on which it works. The eduction passage is carried by a tubular jacket T round the cylinder to a convenient place, U, below the framing, whence the waste steam may be conducted away. The feed-pump X is placed in an excavation made to receive the lower portion of the fly-wheel. It is worked by an eccentric from the main shaft acting through the rod W, and draws by the pipe Z its supply of water, which, after passing through valves situated in the lower part of the pump X, is forced through the pipe Y to the boiler, and supplies the feed required for the generation of steam to work the engine.

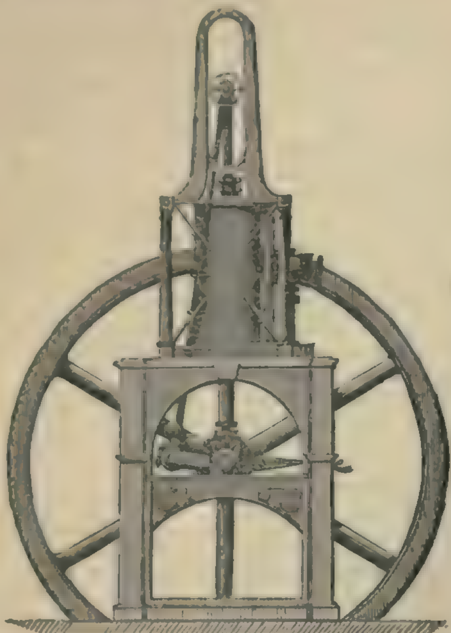
Figs. 196 and 197 are views of what is called a table-engine. The cylinder is elevated on a table; the piston-rod terminates in a cross-head, having a roller at each end working in a guide, and a connecting-rod descending on each side of the cylinder to a shaft made with two cranks below, working in bearings, and carrying a fly-wheel and eccentrics for the slide and feed-pump. The governor is driven by bevil gearing from the crank-shaft.

---

* See *ante*, p. 859.

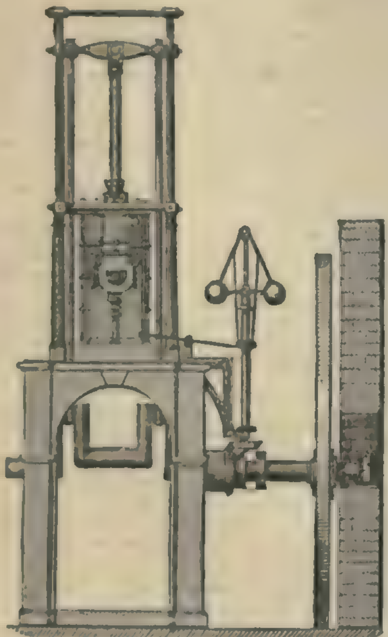
In the locomotive engine, the action is precisely similar to that of the direct-acting vertical engine, although the cylinder is laid horizontally, and the framing is combined in such a manner with the boiler, as to secure strength and lightness.

Fig. 196.



The three annexed plates represent respectively a side elevation, a plan, and a partial front elevation and section of Crampton's Locomotive. We omit a special description of these, because the drawings, if carefully examined, are sufficiently explanatory of the uses and connections of the various parts. Other locomotives differ somewhat in the details, both as to arrangement and proportions, but all embody the same principles of construction.

Fig. 197.



Of late years portable or locomoble engines have attained great importance, and likewise traction engines, or engines suited for travelling and drawing heavy loads on common roads. All these have so many features in common with the locomotive—such as tubular boilers, and cylinders placed horizontally, or at a slight angle to the horizon—that their construction may be readily understood without special drawings or description being necessary to illustrate it. Before quitting this portion of our subject, we may also refer to a particular form of engine, which has been largely adopted where economy of weight and of space is desirable :—we mean oscillating engines. At first these were made on a small scale suited for such boats as those which ply on the Thames ; but of late years they have been employed on a very large scale, and with success. The paddle-engines of the *Great Eastern* are of this kind, and many other large vessels are now fitted with engines of like construction. The cylinder of an oscillating engine, instead of being fixed firmly on its bed, is provided with trunnions at each side, about midway in its length, somewhat like a cannon, and these trunnions are fitted into bearings formed in the framing, in such a manner that the cylinder is free to oscillate upon them as on pivots. The piston-rod which passes through a long and strong stuffing-box on the cylinder cover, is made of larger diameter than usual, for the sake of giving it great strength transversely ; and it is jointed directly on to the crank without any intervening connecting-rod. As the crank-pin travels round in a circle, it carries with it the top end of the piston-rod, not only in a direction upwards and downwards (co-incident with the axis of the cylinder), but also from side to side (or transversely to the axis). The motion of the piston, from end to end of the cylinder, accords with the one direction of the crank's motion, and the oscillation of the cylinder on its trunnions allows for the other. As the steam has to be admitted to the oscillating cylinder, and has also to escape from it after having done its work, the trunnions are made hollow, and form passages for the steam to and from a jacket or steam space provided on the cylinder, whence it passes by suitable parts, commanded by a slide, to and from the opposite ends of the cylinder successively. For several years after the invention of this arrangement, it remained comparatively idle, because of the mechanical difficulties that were experienced in properly working the slide on an oscillating cylinder, itself oscillating with it. At length an ingenious arrangement for overcoming these difficulties suggested itself, and shortly afterwards the use of oscillating cylinders became very general on the small scale, and gradually came to be adopted for the very largest marine engines.

ESTIMATION OF POWER.—In estimating the power of a non-condensing engine, we have to ascertain the pressure on the surface of the piston causing it to move, and the distance passed over by it under this pressure in a given time, or the velocity with which the pressure acts. The product of the pressure by the velocity gives the power ; and if the former be taken in lbs., and the latter in feet per minute, we have to divide their product by 33,000 to reduce it to the standard of horse-power. For example, if the piston move over 200 feet every minute under an average pressure of 1,650 lbs. on its whole surface, the effect is the same as if 1650 × 200 = 330,000 lbs. moved over 1 foot per minute ; and as 1 horse-power is reckoned equivalent to 33,000 lbs. moved over 1 foot per minute, the power in the case assumed is $\frac{330000}{33000} = 10$ horse-power.

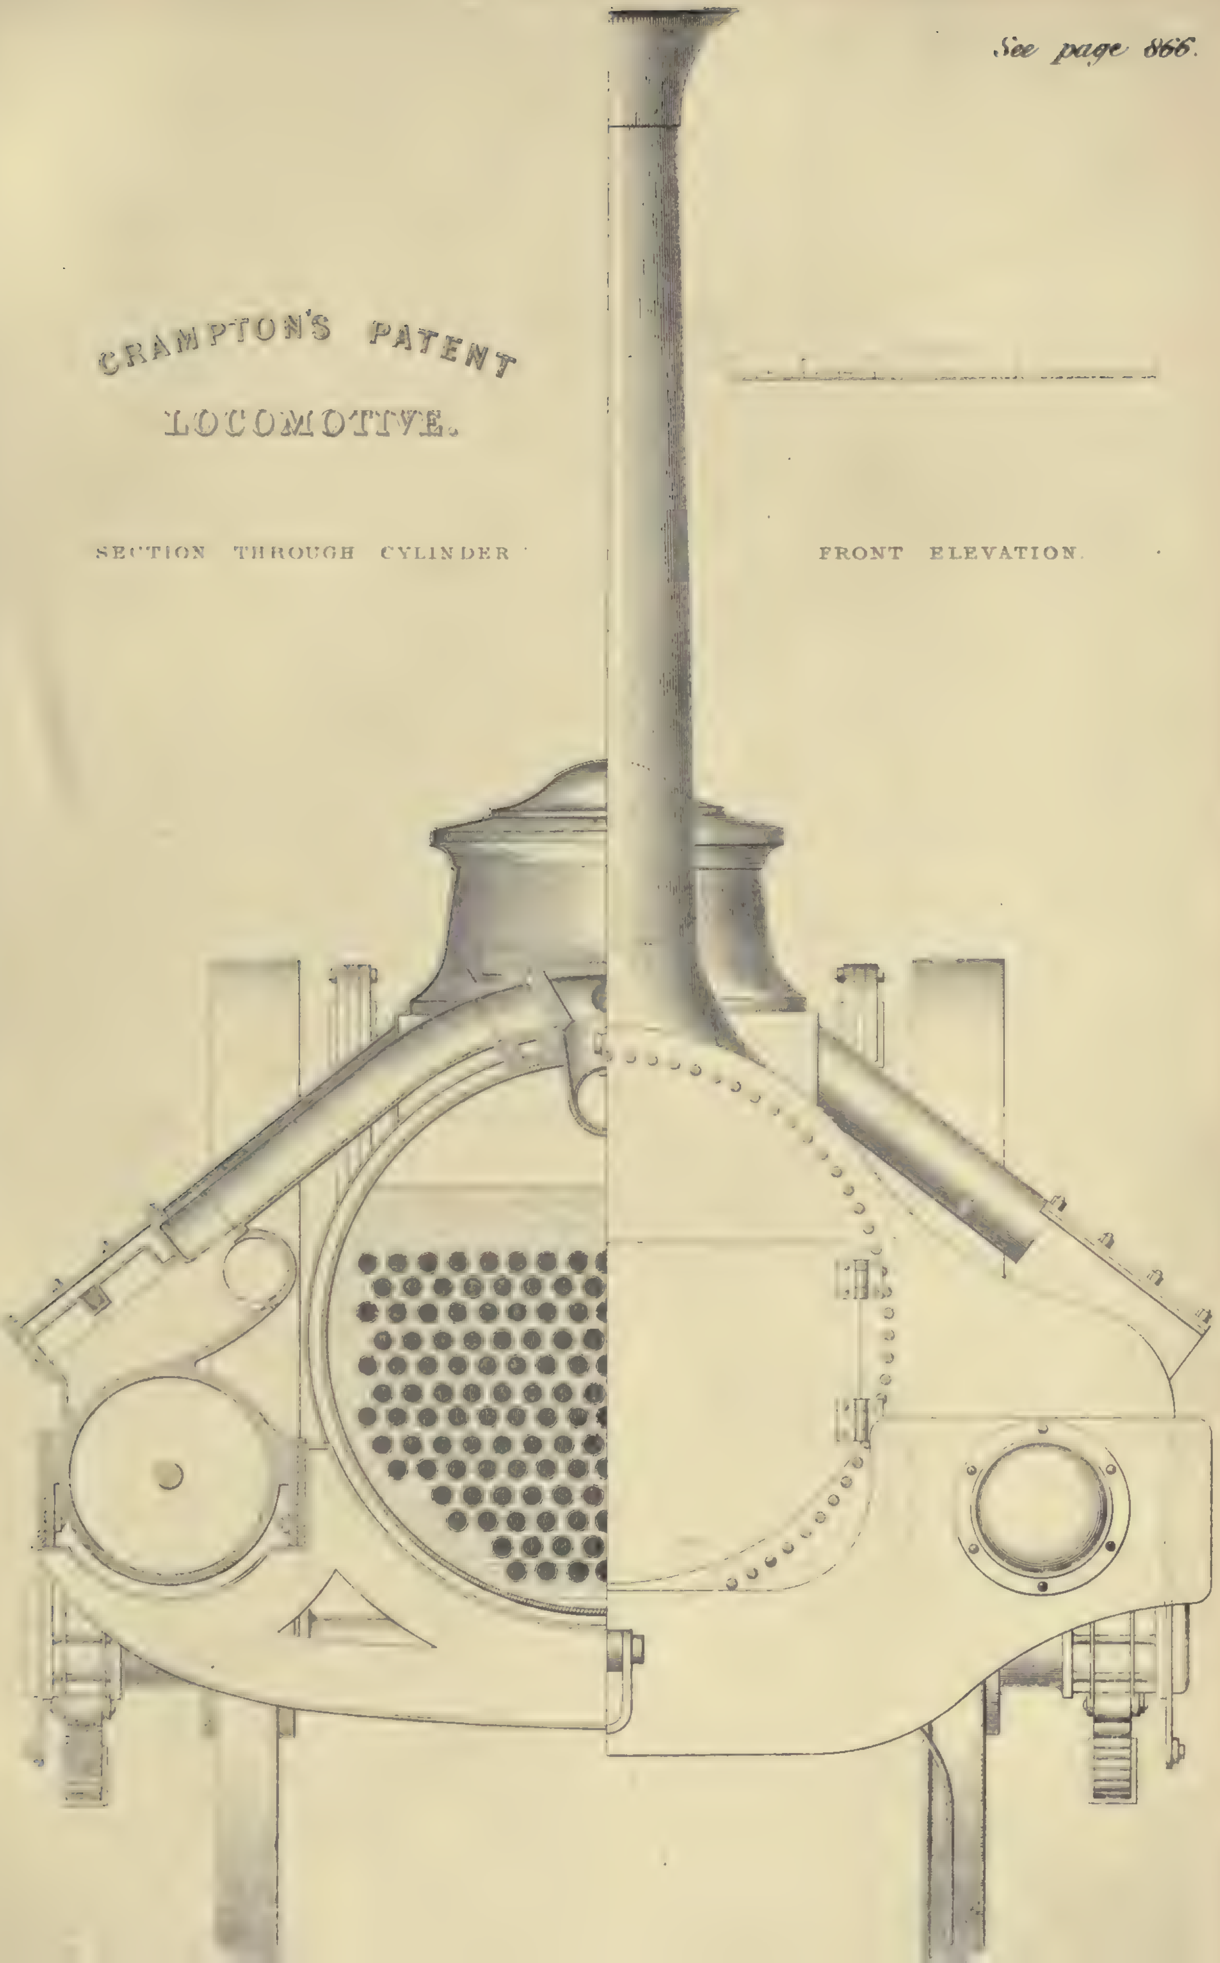
But in estimating the pressure on the piston, we are not entitled to assume it as that of the steam in the boiler, as measured by a steam-gauge. In the first place, there is always some length of pipe between the boiler and the cylinder, and the steam passing through this pipe loses some portion of its heat. Referring to the table of temperatures and corresponding pressures, we can see that the reduction, by a very few degrees of the former, produces a very considerable diminution of the latter. While it is usual to cover the steam-pipe with felt, or some such non-conducting casing, in order to prevent a loss of this kind as far as possible ; yet with

See page 866.

CRAMPTON'S PATENT LOCOMOTIVE.

SECTION THROUGH CYLINDER

FRONT ELEVATION.



every precaution, there is a diminution of pressure to the extent of several pounds per square inch, especially when the initial pressure is considerable.[*] Moreover, before the steam enters the cylinder, it has to pass the throttle-valve, which may be partially closed by the governor, and the steam is thus, as it were, *wire-drawn*, or made thinner, less dense, and consequently capable of pressing with less force on the piston. Were the piston at rest, however small might be the passage for the steam, yet, like water finding its level, its pressure would very quickly become uniform throughout every cavity to which it might have access. But as the piston is in motion, the steam has to flow along the pipe and passages with sufficient rapidity to follow up the piston in its progress; and if its course be arrested or impeded, that portion of it beyond the impediment must necessarily be of less density than that before it. Again, as the alternate flow of the steam above and below the piston is controlled by means of valves or a slide, the apertures covered by them cannot be opened or closed instantaneously, and there must, therefore, be at every alternation, moments of transition, during which the passages are throttled and the steam wire-drawn. When the slide is moved by an eccentric, the opening and closing of the ports is gradual, and the amount of passage open for the steam is continually changing. If the slide and eccentric be so adjusted that the upper port is just beginning to open when the piston is at the top, it continues to open for some time during the descent of the piston, until it attains its extreme width. It then begins to close; and some time before the piston reaches the bottom it must be closed by the slide, which has moved onwards a sufficient distance to be ready for opening the bottom port to admit the steam below the piston. The slide and eccentric are generally so adjusted that each port is closed when the piston has passed through $\frac{2}{3}$rds of its stroke. During the remaining $\frac{1}{3}$rd of the stroke, the pressure on the piston must therefore gradually diminish, for no fresh steam being admitted into the cylinder, that which is already in it becomes expanded in volume, and proportionally diminished in density and pressure. Moreover, when the double eccentric and link motion are employed to work the slide, or when a special valve is provided for cutting off or arresting the ingress of steam to the cylinder at an earlier period of the stroke than that which is determined from the motion of the slide alone, the engine is said to be worked expansively, and the gradual diminution of pressure during the stroke becomes still more marked.

Again, after the piston has completed its stroke, the cylinder being filled with steam of such final pressure as may result from the causes we have named, has to empty itself on the return of the piston, through the ports and waste-pipes. To move the steam through these passages demands some force, which acts as a back pressure or resistance on the piston, and thereby diminishes its effective working force.

Having in view, then, all these causes of change in the steam-pressure during each stroke of the piston, it becomes important to ascertain what is the mean or average pressure throughout, which may be reckoned as the working pressure, or the actual force applied to each part of the surface of the piston to move it against the resistance of the machinery on which it acts.

THE INDICATOR.—The *indicator*, to which we have already referred as having been invented by Watt (see p. 847), is a simple and beautiful instrument, by which this element of power can be ascertained with the greatest accuracy. A (Fig. 198), is a small cylinder open at top, fitted with a piston, and communicating by a pipe and stop-cock, with either the upper or lower part of the main cylinder. The piston is pressed down into the cylinder by a nicely adjusted spiral spring, and a pencil B is fixed to the piston-rod. C is a roller, round which a piece of paper is wound; on the axis of this roller is fitted a pulley D, connected by a string with some of the moving parts of the engine. The roller is also fitted with a spring, like the mainspring of a watch, in such a manner that, after being pulled round in one direction by the motion of the engine communicated through the string, it is made to recoil by the spring. If we suppose the stop-cock closed, the piston, being pressed on by the spring and the atmosphere, will remain at the bottom of the cylinder; and the pencil being stationary at its lowest point E, while the roller is made to rotate backwards and forwards, will describe a line on the paper which would appear straight on its being unfolded from the roller. But if, while the roller continues its motion, the stop-cock be opened, then the piston will be subjected to the pressure of steam in the main cylinder, and will be forced upwards in opposition to the pressure of the spring and of the atmosphere, and the pencil will trace a line on the paper, varying in height as the piston rises and falls. But farther, if the spiral spring be so adjusted that we know exactly how many pounds will compress it an inch, and if we know the area of the piston, we can, exactly, measure the amount of pressure on it by the height to which the pencil is raised above the neutral line E, where it remains when subjected to no upward pressure. And thus the position of the pencil on the paper, or the mark left by it at any point, furnishes the measure of the pressure on the main piston of the engine at the corresponding point of its stroke. On unfolding the paper from the roller, we should find a figure (Fig. 199) described on it by the pencil, which, when properly analysed, gives us the means of reckoning the varying pressure on the piston, and often points out defects in some of the adjustments, and suggests modes of remedying them.

Fig. 198.

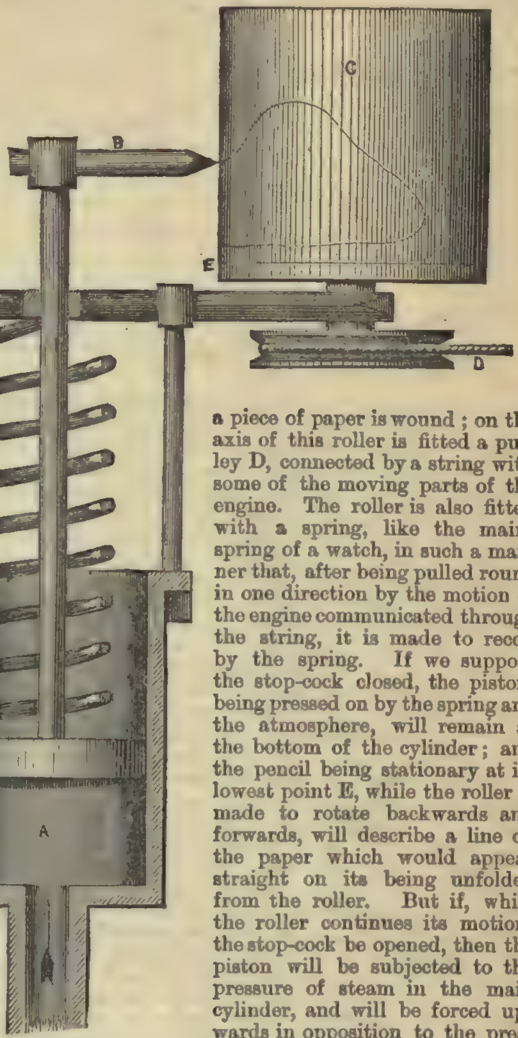


Fig. 199.

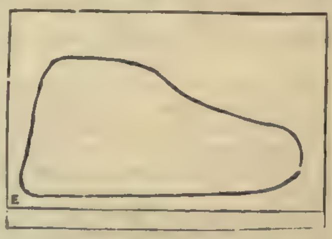
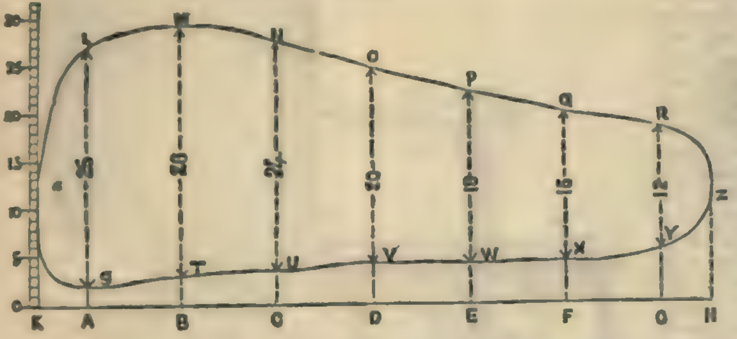


---

[*] We shall afterwards have occasion to describe the means of remedying this evil by super-heating the steam before it passes to the cylinder.

If we suppose that the area of the indicator-piston is 1 square inch, and that the spring is adjusted so that it requires a force of 10 lbs. to compress it 1 inch in length, or 1 lb. to compress it $\frac{1}{10}$th of an inch, we can form a scale of tenths of inches, and apply it to the indicator diagram at a number of points, A, B, C, &c. (Fig. 200), equally distant; and measuring off the lengths of ordinates A L, B M, &c., drawn through these points, we can thus estimate the pressures acting on the piston of the indicator-cylinder at equidistant points of the stroke through which the paper is made to travel. These pressures correspond exactly, per square inch, with those to which the main piston of the engine is subjected during its stroke, because the small cylinder of the indicator communicates freely with the cylinder of the engine. If we suppose the indicator to be fixed at the top of the cylinder, the upper part of the curve *a*, L, M, &c., R, Z, is that traced during the descent of the piston when the steam is pressing on it. The lower part of the curve Z, Y, &c., S *a*, is that traced during the ascent of the piston when the steam is escaping from the cylinder. Were the indicator fixed to the bottom of the cylinder, we should get corresponding curves for the steam-pressures there. Generally, when the eccentric-slide and its levers are properly adjusted, these figures are very nearly alike; and, if so, the upper part of the curve may be taken as that traced by the active pressure either above or below the piston, while the lower part of the curve may be taken as representing the corresponding resistance of steam during its egress from the cylinder. Now, as the total height C N of any ordinate, measures the total pressure on one side of the piston when it is at the point of its stroke corresponding to C; and as the part C U of the same ordinate represents the resisting pressure on the opposite side of the piston at the same point of its stroke; the difference U N, or the part of the ordinate intercepted between the upper and lower limbs of the curve, measures the effective pressure on the piston clear of all resistance. The same applies to all the ordinates; and, as we may suppose, the whole curved space made up of numerous equal, narrow, vertical strips, each measured in height by an ordinate, we may reckon the area of the figure contained within the curve as an expression of the power developed by the piston during its stroke. Or, having taken a considerable number of these pressure-ordinates, and found their average, we may consider this the mean effective pressure on the piston. For example, the average of those marked in the figure, found by adding them into one sum, and dividing it by their number, is $\frac{140}{7} = 20$ lbs., the mean effective pressure on every square inch of the piston. In taking the average in this way, the most correct method is to take the first and last ordinates, A L and G R, at distances, K A, H G, from the respective ends of the stroke *a* and Z, half of A B or B C the distance which separates the other ordinates.

Fig. 200.



If we suppose the engine from which this figure was taken had a cylinder 12 inches in diameter, a stroke of 15 inches, and that the crank made 80 revolutions per minute, we can readily calculate the effective power of the engine thus:—Each revolution of the crank requires an up-stroke and a down-stroke of the piston, or a travel through twice 15 inches, viz., 2½ feet; and as 80 revolutions are made per minute, the piston travels over 80 × 2½ = 200 feet per minute. Again, the area of the piston 12 inches diameter is 113 square inches, and as this is pressed on with an average load of 20 lbs. on every square inch, the total pressure on it is 113 × 20 = 2260 lbs. We have, therefore, 2260 lbs. moved over 200 feet per minute, equivalent to 2260 × 200 = 452000 lbs. moved over 1 foot per minute, which give $\frac{452000}{33000} = 13\frac{3}{4}$ horse-power nearly.

The complete rule for finding the power may therefore be thus stated:—Measure the ordinates (at least 6 or 8 in number) contained within the indicator figure, sum them up, and divide by their number for the mean pressure; multiply the area of the piston (in square inches) by the mean pressure (in lbs. per square inch) by twice the length of stroke (in feet) and by the number of revolutions per minute, and divide the product by 33,000 for the horse-power.

Example.—On the indicator being applied to an engine, having a cylinder 30 inches diameter, a stroke of 4 feet, and making 27 revolutions per minute, 8 ordinates of the figure were found to be respectively 34, 34, 34, 33, 24, 18, 14, and 9: required the power of the engine.

Sum of 8 ordinates = 200, which, divided by their number 8, gives 25 lbs. as the mean pressure.

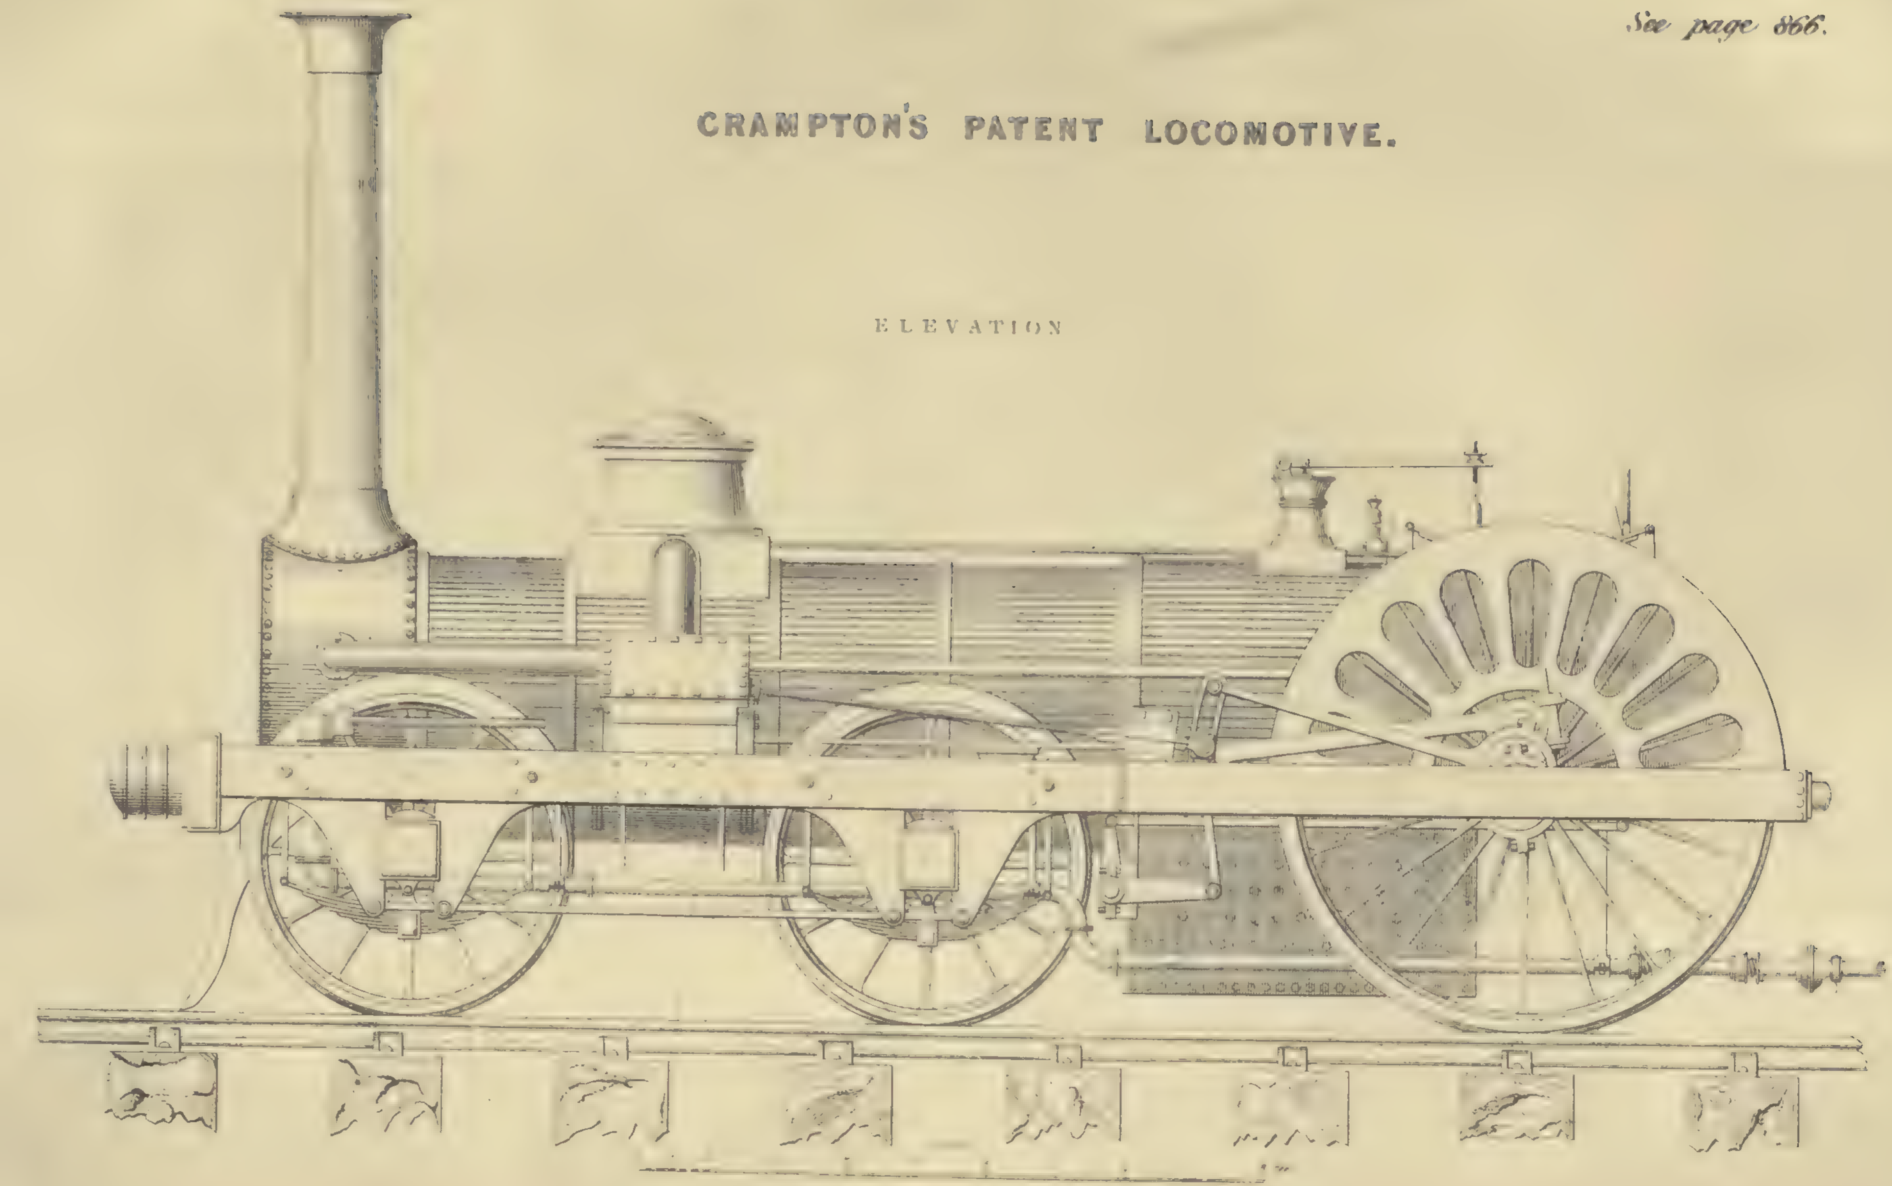
Area of cylinder, 30 ins. diameter =	707 square inches.
Multiply by mean pressure . .	25 lbs.
Total mean pressure on piston .	17675 lbs.
Double the stroke . . .	8 feet.
	141400
Number of revolutions . .	27 per minute.
Divide by	33000) 3817800
Horse-power	115¾ nearly.

But in making these calculations, it must not be forgotten that we only reckon the force with which the piston moves. In communicating this force to the crank-shaft, and thence to the machinery driven by the engine, there are losses from friction and other causes for which some allowance must be made. The piston rubs along the surface of the cylinder; its rod rubs through the stuffing-box; so with the slide. The end of the piston-rod rubs on the guides, which save it from yielding to the oblique action of the connecting-rod; the connecting-rod eyes rub on their pins, the crank-shaft rubs in its bearings, the eccentric and its rod also present rubbing surfaces, the fly-wheel encounters considerable resistance of the air to its rotation, and the feed-pump demands power for its working. All these resistances vary with the conditions of the rubbing surfaces, the accuracy or inaccuracy of their fitting, their state of lubrication, and other circumstances; so that it is difficult to state any constant deduction to be made from the calculated power on account of them. An engine in a very good state should thus waste not more than $\frac{1}{10}$th to $\frac{1}{8}$th of its power; while one in a bad state may lose as much as $\frac{1}{3}$rd. It may generally be fair to reckon the loss at $\frac{1}{5}$th or $\frac{1}{4}$th of the calculated power. Thus, in the example given, the calculated power being 115¾, we take the real power about 90, deducting rather more than $\frac{1}{5}$th for losses.

The indicator figure is not only a measure of power, it is also a picture of defects, and may often furnish useful hints as to the proper mode of improving the action of the engine. If A B (Fig. 201) represent the stroke, *See page 866.*

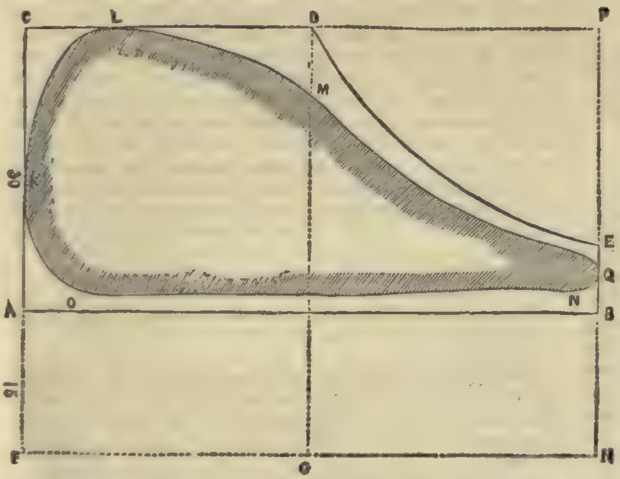
CRAMPTON'S PATENT LOCOMOTIVE.

ELEVATION



F H a line drawn at a distance A F below equal to 15 lbs., and if we suppose steam at 30 lbs. above atmospheric pressure is admitted to the cylinder during half the stroke, then suddenly cut off, we draw A C = 30 lbs., C D half the stroke; take E midway in P H, and fill in the hyperbolic curve D E. Then will the figure A C D E B represent the best possible effect that could be got under the conditions given; for the straight line A C represents the sudden rise of the pressure from that of the atmosphere to 30 lbs. above it at the beginning of the stroke; the straight line C D represents the continuance of that pressure during half the stroke; the curve D E indicates the gradual reduction of pressure, as the steam enclosed in the cylinder expands to fill its increasing capacity; the point E midway in P H marks the pressure at the end of the stroke, half that at the beginning or middle, because the capacity of the cylinder at the end has been doubled, while the quantity of steam within it has remained constant. The straight line E B marks the sudden fall of the final pressure to that of the atmosphere when the exit port is opened; and the straight line B A represents the constant resistance of the atmosphere to the issue of the steam during the return stroke of the piston. Such might be the theoretical figure. The practical figure inscribed within it must necessarily fall short, in some respects, of that which is theoretically perfect. For instance, at the beginning of the stroke, the port opening not suddenly, but gradually, produces a curved line from K to L, the piston having travelled some distance before the full pressure is attained; the gradual closing of the port or expansion valve, and some diminution of pressure from the cooling of the steam, or from leakage past the piston, are indicated by the inclined line L M. The cooling varies the expansion curve M Q from the true hyperbola, and the gradual opening of the exit port causes a curved turn from Q to N instead of a sudden drop E B. The line N O above the line of atmospheric pressure B A, indicates some additional resistance to the issue of the steam dependent on limited area, or bad form of opening, or leakage from the steam side of the piston, and the turn at O K marks the gradual closing of the exit port, and opening of the inlet port for the succeeding stroke. A careful analysis of a figure produced by an engine not working satisfactorily, will thus point out causes of loss, and suggest means of remedying them, by widening the ports, readjusting the eccentric and slide, clothing the cylinder to prevent cooling, and such other arrangements as may be found advantageous. In the hands of an experienced engineer, indicator diagrams become highly suggestive of merits and defects, and often furnish more information as to the economical working of an engine or the reverse, than continued observation of its structure and action could supply.

Fig. 201.



CALCULATION OF POWER.—In estimating the power of a non-condensing engine without reference to its indicator figure, we may generally make a very near approximation to the truth by the following mode of reckoning. We assume the engine to be in fair working order, and fitted with an ordinary slide, cutting off the steam at about $\frac{2}{3}$rds of the stroke; that the steam-pipe is not of great length, and well clothed with non-conducting material; that the ports are well-proportioned, and the piston and slide tight. We farther suppose the piston to travel at the velocity of 200 feet per minute, which is found to be practically a fair working rate; and that a horse-power, to be effective, after all allowances for friction, &c., should be estimated at 44,000 lbs. moved 1 foot per minute, or 220 lbs. moved 200 feet per minute. We observe the pressure in the boiler, and deduct from it $\frac{1}{4}$th for loss by cooling in the steam-pipe and expansion in the cylinder, and 2 lbs. for resistance to exit and other losses, the remainder being reckoned as the mean effective pressure. Multiplying this by the area of the piston, and dividing by 220, we get a fair estimate of the power.

Example.—An engine having a cylinder 30 inches in diameter, is worked at a pressure of 36 lbs. in the boiler: required its power.

From pressure in boiler . . .		36 lbs.
Deduct one-fourth for cooling, &c.	9 lbs.	
And for back pressure . .	2 lbs.	—11 ,,
Mean effective pressure		25
Multiply by area of 30 inches . .		707
Divide by		220)17675
Horse-power		80

In general it is the business of engineers to provide engines of certain powers without special reference to the pressure at which they should be worked. By employing very high pressures, the size, weight, and cost of an engine are certainly reduced; but, on the other hand, some danger is incurred, and the tear and wear are considerable. By using very low pressures, again, the cylinder must be large, the engine is generally cumbrous and heavy, and little advantage can be taken of the expansive power of the steam. We consider a boiler pressure of 40 to 50 lbs. to be a fair average on which to estimate the engine-power; and would suggest the following rules for calculating the power of a given engine, and the diameter of cylinder necessary to produce a given power.

1. To find the power of an engine when the diameter of the cylinder is given.

Rule.—Divide the diameter (in inches) by 3, and square it for the horse-power.

Example.—Required the power of an engine having a cylinder 15 inches in diameter.

$$\frac{15}{3} = 5, \text{ and } 5 \times 5 = 25 \text{ horse-power.}$$

2. To find the diameter of cylinder necessary for a given power.

Rule.—Multiply the square root of the power by 3; the product is the diameter of the cylinder in inches.

Example.—What should be the diameter of a cylinder for 100 horse-power?

Square root of 100 = 10, and 3 × 10 = 30 inches.

The length of stroke must depend on the number of revolutions made by the crank in a given time. It is convenient to assume that the piston, in engines going at a fair average speed, shall travel over 200 feet per minute. Sometimes it moves at the rate of 250, and even exceeding 300 feet per minute; but, upon the whole, 200 is a convenient and economical speed. This is the product of twice the stroke by the number of revolutions; and hence its half, 100, is the product of the stroke by the number of revolutions. If, then, either the length of stroke or the number of revolutions be given, the other may readily be thus found:—

1. Given the length of stroke to find the speed.

Rule.—Divide 100 by the stroke (in feet), the quotient is the number of revolutions per minute.

Example.—What is the speed of an engine having 2 ft. 6 ins. stroke?

$$\frac{100}{2\frac{1}{2}\text{ feet}} = 40 \text{ revolutions per minute.}$$

2. Given the speed to find the stroke.

Rule.—Divide 100 by the number of revolutions per minute, the quotient is the length of stroke in feet.

Example.—What must be the stroke of an engine making 35 revolutions per minute?

$$\frac{100}{35} = 2{\cdot}86 \text{ feet, or about 2 ft. 10 ins.}$$

STEAM PASSAGES.—The dimensions of the steam passages should be proportioned to the area of the cylinder; for while the piston travels at its quickest speed, increasing rapidly the space to be filled with steam, the passages should admit the steam with sufficient velocity to sustain the pressure on the retreating piston. It is found, practically, that the area of the steam-pipe may be advantageously $\frac{1}{36}$th of that of the cylinder, or the diameter of the one $\frac{1}{6}$th of that of the other. Thus, for an engine having a cylinder 30 ins. diameter, the steam-pipe should be 5 ins. diameter. When it is intended that the piston should travel more rapidly than the average rate of 200 feet per minute, the steam-pipe should be proportionally large. In such cases, its diameter may be advantageously reckoned at $\frac{1}{5}$th of the diameter of the cylinder. The ports which admit the steam into the cylinder should always present an area of passage considerably greater than that of the steam-pipe, for during a great part of every stroke they are partially closed by the slide. The exhaust-pipe, which conveys the steam from the cylinder, should be larger than the steam-pipe; for the waste steam should be permitted to become rapidly expanded in volume, in order that its back pressure on the piston may be diminished as much as possible.

FEED-PUMP.—The size of the feed-pump should always be greatly in excess of that which is absolutely required for supplying the amount of water boiled off in steam for the engine. Occasionally, the valves of the pump leak; there may be leaks in the boiler; some of the water may pass over in priming; and a good deal may be wasted in blowing off. The pump should, therefore, be capable of supplying at least 3 times as much water as is actually due to the steam supplied to the cylinder. The pump is generally arranged so as to make one stroke for each revolution of the engine, or each double stroke of the piston. If, then, we take a case where the diameter of the cylinder is 30 inches, the stroke 4 feet, and the average pressure 30 lbs. above that of the atmosphere—that is to say, the steam at 3 atmospheres—we find that, during each revolution, the cylinder, twice filled with steam, uses a volume of about 68,000 cubic inches. Steam at 1 atmosphere of pressure being about 1,600 times the volume of water, its volume at 3 atmospheres is $\frac{1}{3}$rd of that, or about 533 times that of water. The water necessary to generate 68,000 cubic inches of steam at 30 lbs. pressure, therefore, amounts to 128 cubic inches; and as the feed-pump should be capable of supplying thrice this quantity, it must deliver at each stroke 384 cubic inches. Should we make the stroke of the pump 2 feet, half that of the piston, its area must be $\frac{384}{24} = 16$ square inches, or its diameter $4\frac{1}{2}$ inches.

As a general rule, for the dimensions of the feed-pump in non-condensing engines, we may offer the following:—

Multiply the square of the diameter of the cylinder (in inches) by the length of stroke (in feet), divide by 90, and the quotient is the product of the square of the diameter (in inches) of the pump, by its length of stroke (in feet).

Example.—Required the size of the feed-pump for an engine having a cylinder 30 inches diameter, and a stroke of 4 feet.

$$\frac{30 \times 30 \times 4}{90} = 40,$$ the product of diameter squared by stroke. If we take the stroke of the pump 2 feet, then $\frac{40}{2} = 20$ is the square of the diameter, or the diameter is about $4\frac{1}{2}$ inches, because $4\frac{1}{2} \times 4\frac{1}{2} \times 2 = 40$ nearly.

Many treatises on the steam-engine give rules for the dimensions of all the principal parts of an engine. We think, however, that these rules are not, in many cases, practically available, because a difference in general design and arrangement, or in average pressure and speed, occasions very considerable variations in the proportions of the parts. Careful study of well-made engines, and actual experience in their construction and working, form the true sources of information as to their due proportions.

CHAPTER VI.

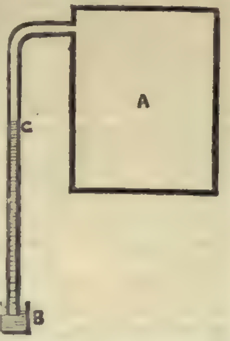
THE STEAM-ENGINE—(*Continued*).

Contents.—CONDENSING ENGINES—SAVERY'S—NEWCOMEN'S—WATT'S IMPROVEMENTS—CONDENSER AND AIR-PUMP—INJECTION—SURFACE CONDENSER—PARALLEL MOTION—BEAM ENGINE—MARINE ENGINE, PADDLE, SCREW—COMBINED ENGINES—ROTARY ENGINES—SUPER-HEATING STEAM—APPLICATIONS OF STEAM POWER—PUMPING—DRIVING MACHINERY—LOCOMOTION—PROPULSION OF VESSELS.

THE *Condensing Engine*, in all main points, resembles the non-condensing engine; but it requires some additional parts, in order that the vacuum produced by condensing the steam may be employed as a source of additional power. If we suppose that the steam, on leaving the bottom of the cylinder, instead of flowing out into the atmosphere, which resists its egress with a pressure of 15 lbs. per square inch, were conducted into a vessel totally void of air or steam, this resisting force would be entirely removed, and the effect of the steam pressing on the upper side of the piston, would be increased by that quantity. If the vacuum in the vessel were not perfect—that is to say, if there were contained in it some rare fluid, such as air or steam, or a mixture of both, greatly attenuated, and capable of pressing with a force of only 2 or 3 lbs. on the square inch—the pressure of the steam on the piston would be increased by a quantity 2 or 3 lbs. less than 15 lbs. per square inch. Generally, if we reckon the pressure of steam in the boiler as its absolute pressure, not its excess over the atmosphere, and deduct the pressure of fluid in the vacuum vessel, the difference will be the effective pressure on the piston. Thus, with steam in the cylinder exerting a pressure of 10 lbs. above that of the atmosphere, or having an absolute pressure of 25 lbs. per square inch, while the vacuum vessel contains a fluid pressing with a force of 2 lbs. per square inch, the effective pressure on the piston is 25 − 2 = 23 lbs. per square inch. The condition of the fluid in the vacuum vessel, as to pressure, is generally measured by a barometer.

The upper part of the vessel A (Fig. 202) is connected with a glass tube C, about 30 inches long, dipping into a cup of mercury B. Were the space in A an absolute vacuum, the atmospheric pressure on the surface of the mercury in the cup would force the mercury up the tube to the height of about 30 inches, because a column of mercury 30 inches in height, presses with a force of 15 lbs. on the square inch. But if A contained fluid pressing with 2 lbs. per square inch, the mercury would attain a height of only 26 inches; because the pressure of a column 26 inches high is 13 lbs., and the additional 2 lbs. of fluid pressure make up 15 lbs., the atmospheric pressure.

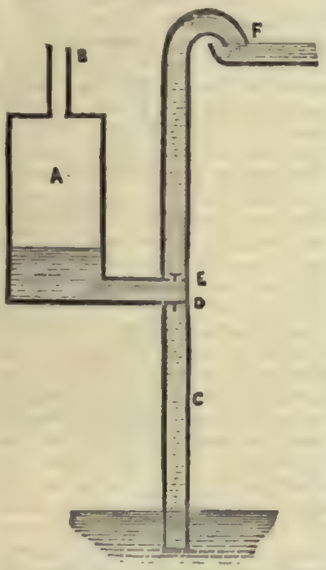
Fig. 202.



If, then, we know the pressure of steam in the cylinder (above that of the atmosphere), and the height of the mercurial column in the barometer, we can find the effective pressure on the piston by adding the steam pressure to half the height (in inches) of the column.

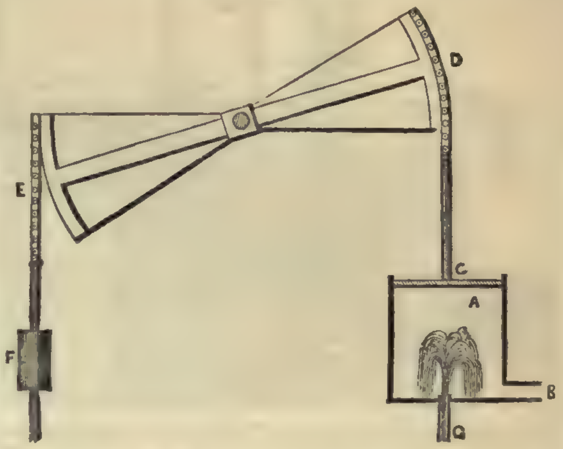
SAVERY'S AND NEWCOMEN'S ENGINES.—It is remarkable that some of the earliest efforts made for obtaining power from steam, were directed to the construction of apparatus in which its condensation, as well as its elasticity, should afford the force required. At the end of the 17th century, Captain Thomas Savery succeeded in constructing an engine for raising water by means of steam. A vessel, A (Fig. 203), connected by a steam-pipe and cock B, with a suitable boiler, communicated with a vertical water-pipe C, in which were fitted two valves, D and E, opening upwards. Steam being admitted into A, forced out the air contained in it by the upper part of the water-pipe, and occupied its place. The steam-cock B being closed, and a stream of cold water made to pour over A, the steam within it became condensed, and formed a partial vacuum; the pressure of the atmosphere acting on the water at the bottom of C, forced it up the pipe through the valve D, and into A, so as to fill the void space. The steam-cock being again opened, the pressure of steam on the water in A forced it through the valve E and up the pipe. The vessel A was thus successively filled and emptied by the alternate closing and opening of the steam-cock, and the water raised through the height of the pipe C.

Fig. 203.



A few years afterwards, Thomas Newcomen applied steam to give motion to a piston in a cylinder. The cylinder A (Fig. 204) communicated by a pipe and cock B with a boiler generating steam at low (or nearly atmospheric) pressure. A piston C, fitting the cylinder, was connected by a chain with one end of a beam or lever D, to the other end of which, E, was attached a pump-rod with a heavy weight F. The ends of the beam were made arcs of circles, so that while the chains were wound on them or unwound from them, the piston and pump-rod might move in straight lines. Steam being admitted into the cylinder below the piston, so as to balance the atmospheric pressure on its upper surface, the weight F caused it to ascend; and when it reached the top, the steam-cock was closed, and a water-cock G was opened to admit a jet of water into the midst of the steam. The coldness of the water rapidly condensed the steam, and formed a partial vacuum below the piston, and the atmospheric pressure forced it down to the bottom, raising the weight F. The water-cock being now closed, and the steam-cock opened, the ascent of the piston was repeated.

Fig. 204.



WATT'S IMPROVEMENTS.—Numerous inventors contributed to the improvement of Newcomen's engine; and about the beginning of the 18th century it had become a practically useful, but not economical apparatus for pumping. The principal objection to the use of this, as well as of Savery's engine, consisted in the circumstance that the alternated flow of cold water into the steam-cylinder cooled it down, and greatly diminished the force of the steam as it entered, a great portion of its heat being ineffectively expended on the cold metal of the cylinder. It was reserved for the illustrious James Watt, shortly after the middle of the last century, to introduce those improvements in the arrangement and construction of the steam-engine, which have rendered it the most useful and economical of all known sources of power. His principal improvement on Newcomen's engine was the use of a separate vessel for condensing the steam, with an air-pump for removing the water of condensation, and the air liberated from the water. But his ingenuity was likewise devoted to the improvement of every detail of arrangement and construction; and, having found the steam-engine in many respects rude, ineffective, and costly in its working, he left it an apparatus, as nearly perfect as any human work can be. Since his time, changes have been made in the arrangements of the parts to suit peculiar circumstances of operation, and new forms have been devised for particular purposes; but in all their leading features, the steam-engines of the present day are essentially the products of Watt's fertile genius.

The condensing engine, as improved by Watt, is of two kinds:—

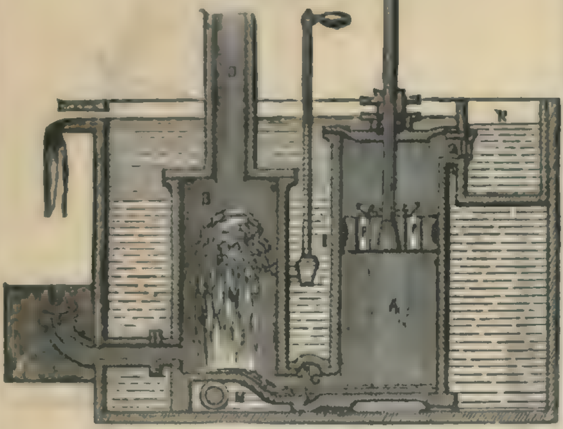
Single-acting, where the steam is permitted to press on one side of the piston only, so as to cause it to make a single stroke; the return stroke being effected by a counterbalance weight.

Double-acting, where the steam presses alternately on each side of the piston, and its reciprocating movement is converted, by a crank, into rotary motion.

The single-acting engine is well suited for such an operation as pumping, where the reciprocating movement of the pump-bucket corresponds with that of the piston. The double-acting engine, again, is adapted for driving machinery. In both these kinds of engine, where the steam is condensed, there are required a condenser and an air-pump, which we will now describe.

CONDENSER AND AIR-PUMP.—The condenser is a vessel B (Fig. 205), generally made of about $\frac{1}{8}$th of the capacity of the steam-cylinder, with which it communicates by the pipe D. The steam, after acting on the piston, instead of escaping into the atmosphere as in non-condensing engines, flows by this pipe into the condenser, which is placed in a cistern of cold water, and has a pipe and cock, I, for the admission of a jet of cold water to condense the steam. This jet is called the *injection*, and its quantity is regulated by means of the cock, worked by a rod passing upwards, with a handle in some place convenient for the attendant. The bottom of the condenser communicates by a passage, having a valve G, with the air-pump A. The bucket or piston P of the air-pump is fitted with valves opening upwards, and is moved upwards and downwards by a rod connected with some reciprocating part of the engine, and passing through a stuffing-box in the air-pump cover. Near the top of the air-pump there is a passage Q, fitted with a discharge valve opening into the *hot-well* K, from which the feed-water is pumped to the boiler, the overplus or waste being discharged by a waste-pipe. The cistern in which the condenser and air-pump are placed, is kept constantly filled with cold water by a pump called the *cold-water pump*, supplying it by a pipe N at the bottom, while the heated water overflows by a suitable waste-pipe. While the steam from the cylinder flows into the cold condenser, and meets the cold water diffused through it by the injection jet, it becomes condensed into water, and falls with the injection-water to the bottom, occupying very little volume compared with that which it occupied while in the state of steam, and leaving the space of the condenser as a partial vacuum. But water always contains a quantity of air mingled with it, which passes over with the steam from the boiler to the cylinder, and thence to the condenser, and the injection-water also parts with a portion of the air it contains, so that after a time the condenser would become filled with the air so liberated, and with the water of injection and condensation, unless means were taken to remove them.

Fig. 205.



As the air-pump bucket descends, the discharge-valve Q being closed, no air or water can enter from above to fill the space left void by the descent of the bucket, but the air and water from the condenser pass through the valves G and P, and enter this space from below. On the ascent of the bucket, the bucket-valves P being closed by the pressure of air and water above them, the contents of the pump are discharged through the valves Q into the hot well. Thus by the alternate descent and ascent of the air-pump bucket, when its capacity and the amount of injection are properly proportioned, almost a perfect vacuum is maintained in the condenser; and the effective pressure of the steam on every square inch of the piston is increased by nearly 15 lbs. above that which it would be, were the steam permitted to escape uncondensed into the atmosphere.

The condenser is generally fitted with a *blow-valve* H, which comes into play on starting the engine thus. The engine having been stopped, the condenser and air-pump may have become quite filled with water through the injection-cock; and on starting the engine again, no vacuum could be produced while they are thus *water-logged*. But by opening a small valve called the *blow-through valve*, a communication is made between the steam-pipe from the boiler, and the eduction-pipe leading from the cylinder to the condenser. The pressure of the steam in the boiler is thus brought to bear on the water in the condenser, and forces it out by the *blow-valve* H, the steam occupying its place. On shutting the blow-through valve and opening the injection-cock, the steam in the condenser is condensed, and a vacuum formed, so that the engine may be started. As long as there is even a partial vacuum in the condenser, the atmospheric pressure on the blow-valve keeps it closed.

The bottom-valve, bucket-valves, and discharge-valves of the air-pump, are frequently made of vulcanised caoutchouc sheet, cut into discs and laid over gratings. Water or air forced through the perforations in the gratings, raises the flexible discs of caoutchouc, and passes round their edges; but neither air nor water can return, for the atmospheric pressure forces the caoutchouc discs firmly down on the gratings, and thereby effectually closes their openings.

INJECTION.—It is a peculiar property of all vapours, that, besides their sensible heat, or the temperature to which they raise the thermometer, they contain a great amount of latent heat, not measured by the thermometer, but by its effect, when the condition of the vapour is changed. The latent heat of steam, when its temperature or sensible heat is 212°, is estimated to be about 1,000°. This does not mean that the latent heat could raise a thermometer 1,000°, but simply that a pound of steam at 212° being condensed by its mixture with 1,000 lbs. of water at any temperature, such as 60°, could raise the temperature of the whole mass of water 1°. In other words, if it were found that the combustion of a certain weight of fuel could raise the temperature of a given mass of water from 211° to 212°, it would require 1,000 times that quantity of fuel to convert the water into steam, having still the sensible temperature of 212°. This great latent heat is something essential to the condition of water in a state of vapour; for as soon as any portion of it is removed, by bringing the steam into contact with a cold substance, a part of the steam is immediately condensed into water; and the remainder, expanding to fill the space thus left void, loses density and pressure as it gains volume. In estimating the quantity of injection-water necessary for condensing the steam of an engine, we must therefore bear in mind that it is not alone the sensible temperature, but also the latent heat of the steam which we have to absorb by the cold water injected. Let us assume that 1 cubic foot of water, having been converted into steam in the boiler, and having acted on the piston in the cylinder, flows into the condenser at a temperature of 212°, and containing 1,000° of latent heat, and that it there mingles with a quantity of water at 62°, sufficient to condense it and produce an ultimate temperature of 112° throughout the mixture. The total heat of the steam being 1,212°, has to be reduced to 112°—that is, the steam has to lose 1,100° of temperature; the injection-water entering at 62°, and being raised to 112°, has to gain 50°. The quantity of injection-water must therefore be 22 cubic feet; for 22 cubic feet raised 50°, are equivalent to 1 cubic foot reduced 1,100°, because $22 \times 50 = 1100$.

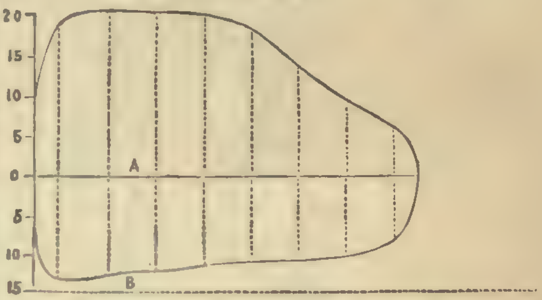
The temperatures we have assumed are such as would frequently occur in practice; and generally it will be found that the quantity of injection-water required for an engine is from 15 to 25 times the quantity required for feed.

The capacity of the air-pump is generally $\frac{1}{8}$th of that of the cylinder, the stroke being usually $\frac{1}{2}$, and the diameter $\frac{1}{2}$ that of the cylinder. The power necessary to work the air-pump of a condensing engine is about $\frac{1}{10}$th of the total power.

SURFACE-CONDENSER.—Condensation by injection, such as has been described above, is the system that has been almost universally adopted since Newcomen applied in his engine. We have already (see p. 851) alluded to another mode of condensation, by means of cold surfaces, which now begins to be adopted, and which, from the great advantages attending its use, will probably soon entirely supersede the *injection* method. On considering the mode in which a jet of cold water admitted into a vessel containing steam acts upon it, we readily see that the water, entering with considerable force through an aperture (usually fitted with a rose), presents to the steam a very great and minutely subdivided surface. Thus every minute particle of the water is at once surrounded by an atmosphere of steam, from which it abstracts so much heat, that the steam is almost immediately reduced to its liquid condition as soon as it comes in contact with the water: as a mode of condensing, then, rapidly and effectually, probably no better arrangement could be desired. But, after condensation, the injection-water, which, as we have seen, amounts to 15 or 20 times the quantity of water produced from the steam, forms the principal part of the water fed from the hot well to the boiler. If, therefore, the injection-water be impure, as it generally is; and still more, if it be salt, as it always is at sea, the boiler is fed with the impure water, and is thus subjected to all the evils of deposit and incrustation, to which we have before alluded. The quantity of water actually required for feeding the boiler, is precisely the quantity derived from the condensation of the steam, with a small allowance for unavoidable losses by leakages. If, then, the steam could be rapidly and effectually condensed without mixing it with impure water, it would itself supply almost enough water for feed, and that of the purest possible quality, because it would be distilled. There appears to be no mode of obtaining the rapidity of condensation required for the efficient working of an engine, except that of exposing the steam to a very extended cold surface, just as it is exposed to the minutely subdivided surface of the water of injection, but without mingling with it. The new condensers, called *surface-condensers*, are therefore constructed generally like tubular boilers. A box or casing, like the body of a boiler, has a great number of very small tubes passing from end to end, and tightly jointed, so that no communication can take place between the interiors of the tubes and the space through which they pass. In some condensers, cold water is made to flow through the tubes, while the steam from the cylinder is admitted to the box, and plays round the outside of the tubes in the spaces surrounding them. In other condensers the steam is made to pass through the tubes, which are surrounded by cold water supplied to the box in which they are contained. There are numerous modifications of form and arrangement of parts, and varieties in the modes of constructing the casing and of jointing the tubes to it, of causing the water to circulate, and in other details. But in all surface-condensers the general principle is the same—namely, that of exposing a very large cold surface to the steam, and of subdividing the steam so that every minute portion of its bulk is brought rapidly into contact with the cooling surface. In the best condensers of this kind now in use, a vacuum is obtained quite as good as was formerly obtained by the injection method; and, although an increased quantity of cold water may be demanded for keeping the surface cold, yet this is readily attainable at sea, and in most situations where condensing engines are employed. The very leakages are provided against by supplying for the loss of feed from this cause, by distilled water procured from a small supplementary boiler, so that scarcely a particle of impurity can enter the main boiler, and all the evils of deposit, incrustation and priming over of viscid water, are effectually remedied. As water, before attaining its boiling point, parts with the air which it may have held in solution, the condensed steam contains no air, and thus the vacuum in the surface-condenser is maintained by the use of a much smaller pump. With the ordinary condenser, worked by injection, the pump is properly called an *air-pump*, because a large portion of its capacity is at every stroke filled by the attenuated air given off from the steam and from the water of injection. But with the surface-condenser, the function of the pump is almost exclusively confined to the removal of condensed water, the quantity of air evolved from the distilled water in the condenser being so small as to be almost inappreciable. The size of the air-pump is thus considerably reduced when surface-condensation is adopted, and less of the engine power is consequently absorbed in working it.

The indicator applied to a condensing engine produces a figure similar to those we have already discussed. But as during one stroke of the piston the communication to the condenser is open, the pencil traces a line below that of atmospheric pressure. Thus if A (Fig. 206) be the line of atmospheric pressure, another line B, drawn at the pressure of 15 lbs. below A, would be the line of absolute vacuum, or of no pressure. The lower limb of the figure would more nearly approach this line, the more perfect the vacuum in the condenser. The area of the figure represents the power during a stroke; and the mean effective pressure is found by taking the average of the lengths of numerous ordinates drawn within the figure as before.*

Fig. 206.



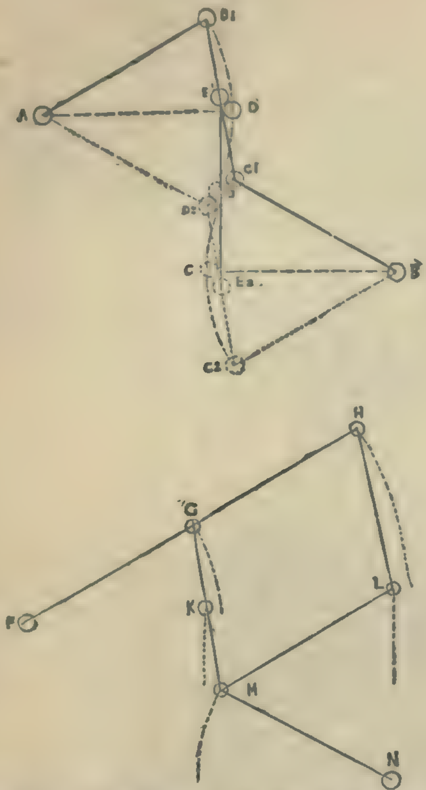
PARALLEL MOTION.—Non-condensing engines are generally of the form called *beam-engines*. The piston-rod does not act directly on the crank in the case of the double-acting engine, nor on the pump in the case of the single-acting engine, but on one end of a lever or beam, working on central bearings, from the other end of which the crank or pump is worked by a connecting-rod. By jointed rods connected with pins on the beam, the air-pump is worked with half the stroke of the piston; the feed-pump and the cold-water pump are also worked with their proper strokes. As the piston-rod, and also the air-pump rod, pass through stuffing-boxes in the cylinder and air-pump covers respectively, and must therefore move in straight lines, while the parts of the beam to which they are connected vibrate in circular arcs, some arrangement is required for controlling the motion of the rods so that it shall not partake of the circular vibration. This could be effected by making them slide between rectilineal guides, but not without considerable friction and some difficulty in arranging the guides in a suitable manner. We are indebted to Watt for a simple and elegant manner of effecting this object by the apparatus called the *parallel motion*.

If A D_1 and B C_1 (Fig. 207) be two equal levers vibrating in circular arcs D_1 D D_2, C_1 C C_2 respectively, their extremities being connected by a rod D_1 C_1, it will be found that E, the middle point of this rod, moves from E_1 to E_2 in a line which is very nearly straight. Again, if F G, one of these levers, be prolonged to H so as to be doubled in length, and a parallelogram G H M L be formed of jointed rods so that F K and L are always in one straight line, then K being controlled so as to move in a straight line or nearly so, L will also move in nearly a straight line. Applying this principle to the beam of an engine, K is the point to which the air-pump rod is connected, and L that to which the piston-rod is connected; G M and H L are called *parallel motion links*, and M N, the subsidiary lever which controls the movement of K, is called the *radius rod*. In the case of single-acting engines, where the end of the beam opposite to that worked by the piston works a pump, a parallel motion is also fitted there to give rectilineal motion to the pump-rod.

---

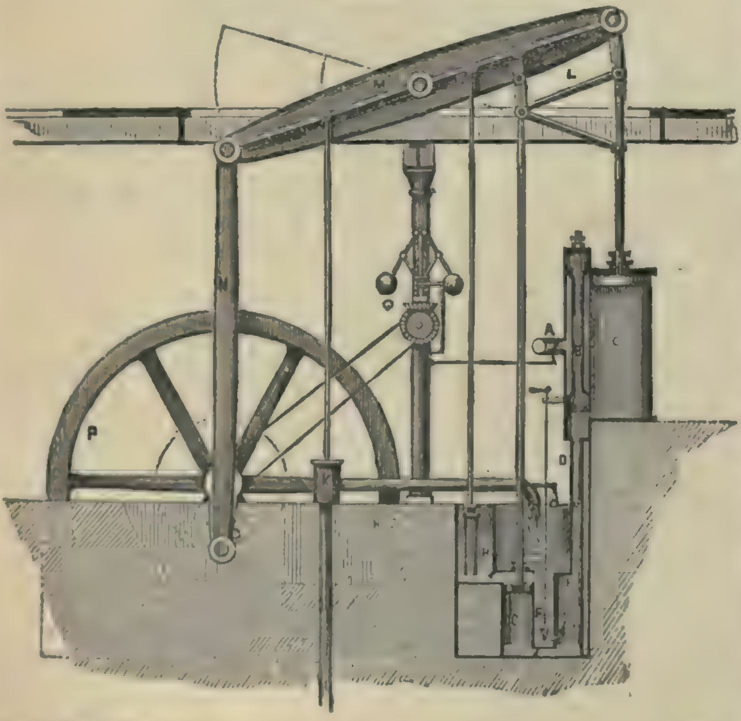
* See *ante*, p. 863.

Fig. 207.



BEAM ENGINES.—In marine engines, where it is desirable to keep the weight as low as possible, the arrangement of beam is different. Instead of one beam above the cylinder and crank, two beams are fitted below, one on each side of the cylinder, and the parallel motion employed in that case is somewhat different from that which we have described, although the principles embodied are very similar.

Fig. 208.



The alternate movements of the steam to and from the opposite ends of the cylinder, are effected in condensing engines in the same manner as non-condensing engines, by a slide worked by an eccentric, or by valves worked by cams. In single-acting engines valves are generally employed, and they are worked by levers struck by pins or tappets fixed to the air-pump rod, as it ascends and descends along with the piston.

The single-acting beam-engine is almost exclusively employed for pumping. The form of engine most commonly used for this purpose is what is called the Cornish engine, because at the mines in Cornwall these engines have been employed with great economy and efficiency for draining to great depths.

The steam is admitted above the piston at considerable pressure, and the supply is cut off when the piston has performed a small part of its down stroke, so that the rest of its stroke is effected by the expansion of the steam. When the piston has reached the bottom of the cylinder, the steam is permitted to pass from its upper to its lower side, so that it does not press it in either direction; but the weight of the pump-rods at the other end of the beam, loaded, if necessary, with additional weight, causes the piston again to ascend to the top of the cylinder. The steam is again admitted above the piston, while that which is below it flows into the condenser; and thus the alternation is continued, the valves which control the movements of the steam being worked by levers and tappets from the air-pump rod.

Fig. 208 represents a double-acting condensing beam-engine working a crank. Here the weight of the piston and air-pump bucket, and their rods at one end of the beam, is balanced by that of the connecting-rod at the other end, and the steam is alternately admitted by the slide to the upper and lower sides of the piston, and thence to the condenser, so that each end of the beam is alternately pushed upwards and pulled downwards by the pressure on the piston. A the steam-pipe from the boiler, supplying steam to the slide-jacket or space round the slide B. C the cylinder fitted with piston, and piston-rod connected to one end of the beam M by the parallel motion L. E the condenser, communicating with the slide-jacket by the eduction pipe D. F the injection-cock, admitting water into the condenser by a jet from the cold cistern in which it is placed. G the air-pump, worked by a rod from the parallel motion, and discharging into the hot well H, in which is placed the feed-pump, worked by a rod from the beam, so as to draw water from the hot well, and propel it by a feed-pipe to the boiler. K the cold-water pump, worked by a rod from the beam, drawing water from a well or stream, and supplying the cold cistern for condensation. N the connecting-rod, worked from one end of the beam, and giving rotary motion to the crank O. P the fly-wheel, fixed on the crank-shaft, and revolving with it, with the necessary momentum for bringing the crank over the dead centres, or highest and lowest points of its revolution, where the connecting-rod is ineffective to turn it. Q the governor, caused to revolve by a strap or band, and suitable gearing connecting it with the crank-shaft. The steam-pipe A is fitted with a throttle-valve connected with the governor by levers and rods, so that the velocity of the engine is controlled by the throttling of the steam, as already described.*

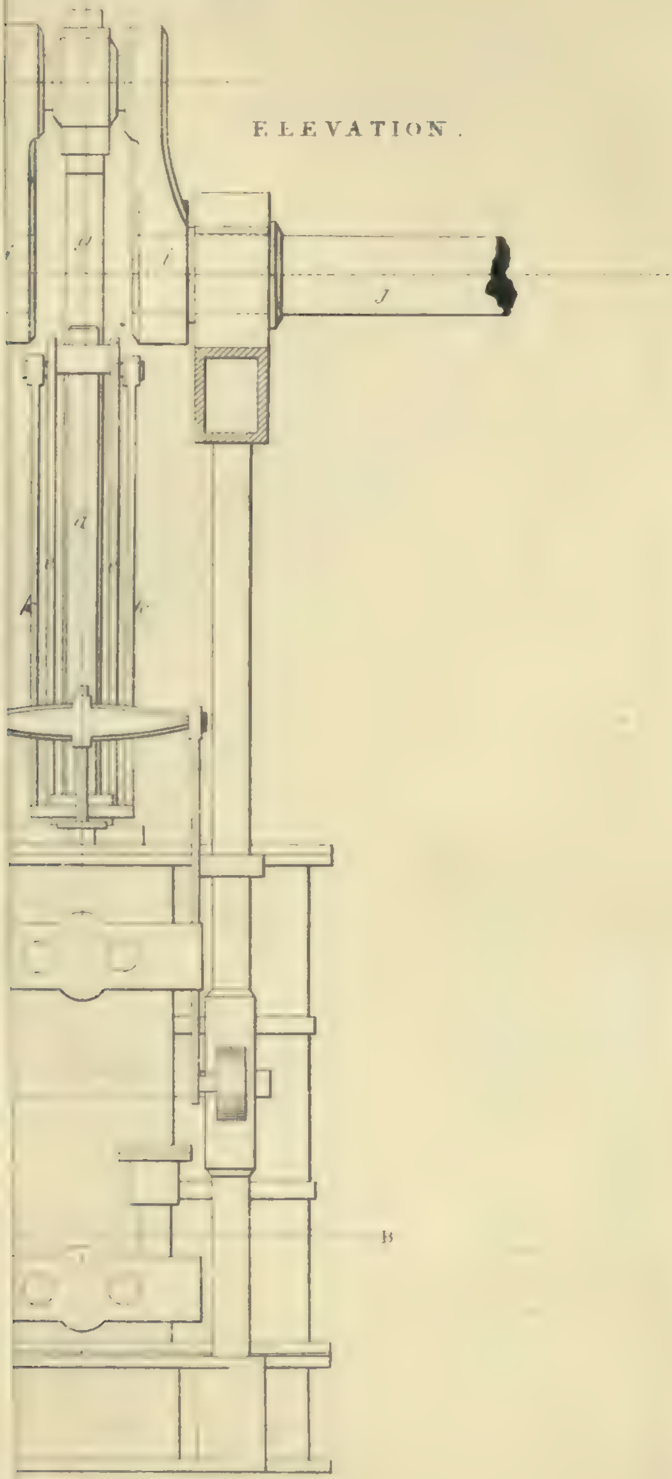

Fig. 209.

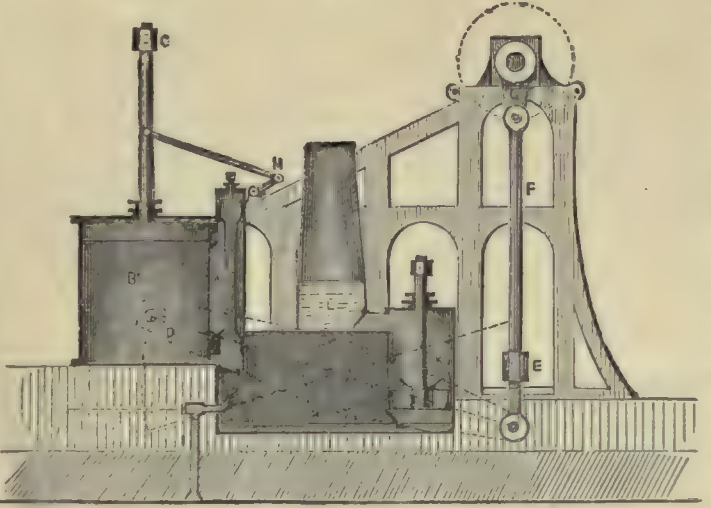


MARINE ENGINE.—Fig. 209 represents the arrangement of a condensing marine engine suited for driving paddle-wheels. A the slide-jacket supplied with steam from the boiler. B the cylinder fitted with piston and rod. C the piston cross-head, from the ends of which, side rods descend on each side of the cylinder to the extremities of two side beams D. H the condenser, supplied with injection-water, by the injection-pipe and cock I, passing through the ship's bottom. K the air-pump, worked by side rods from pins in the side beams D, and discharging into the cistern-head L, whence the supply of water for feed is drawn, and from which a discharge-pipe conveys the waste water through the ship's side into the sea. E the cross-head of connecting-rod, connected by side rods at each end to the beams D. F the connecting-rod, causing the revolution of the crank G, on the shaft of which are fixed the paddle-wheels. M is a parallel motion for constraining the cross-head C to move in a straight line. The feed-pump is generally placed on one side of the air-pump, and a bilge-pump (for emptying the bottom of the vessel of water leaking into it) on the other, both being worked by the cross-head which moves the air-pump bucket. The general arrangement of the marine engine is such as to keep the principal weight at as low a level as possible, lest the stability of the vessel should be endangered by too much weight above the floating line. These engines are generally in duplicate, placed side by side longitudinally in the vessel, the crank-shafts working the paddle-wheels being laid transversely.*

A great variety of arrangement has been adopted in marine paddle-engines, so as to secure compactness, simplicity, and lightness, consistently with the great strength required to sustain the shocks to which sea-going vessels are subjected. Among these arrangements we may instance the oscillating engine, to which we have already alluded (page 866), and a remarkably compact engine, called the Annular Cylinder Engine, represented in the annexed plate. In this engine, the cylinder *a* contains an inner cylinder *b*, open at top and bottom, and the piston *c* is of a ring or annular form, working tightly between the inner and outer cylinders. Two piston-rods *d d*, passing through stuffing-boxes in the cylinder cover, are firmly fixed to the opposite ends of a cross-head *e*, which is double, having two thicknesses with a space between them. The lower part of this cross-head extends downwards into the inner cylinder *b*, in which it is fitted to slide. To a pin *f* in this sliding part the connecting-rod *g* is jointed, and also to the crank-pin *h*; *i* is the crank fixed on the main paddle-shaft, which revolves in bearings in strong framing, secured to the wooden beams that extend across the vessel, and tied to the cylinder and foundation-plate by strong wrought-iron bolts or columns. It may be readily seen from the drawing that this arrangement permits the use of a long connecting-rod well guided at its lower end *f*, and a stroke of piston of considerable length, even when the height allowed for the engine is very limited, as is usually the case in vessels, especially such as are of light draught of water. The condenser is the box or hollow foundation on which the engine stands, and *m* is the air-pump, which is worked by a small double beam *l*, mounted on the framing, and receiving its motion from rods *j*, connected to the lower part of the cross-head at *f*. The feed and bilge-pumps are fixed at each side of the air-pump *m*, and are worked by rods connected to the same cross-head as that which works the air-pump rod, to which they serve as guides. The alternations of the steam to and from the opposite ends of the annular cylinder are effected by a long hollow D slide, which is worked by an eccentric from the main shaft. For stopping, starting, or reversing the engines, the eccentric-rod, having a gab end, as described (page 861), is thrown out of gear by a small lever, and the slide worked by a cross-handle, so as to make the required change of direction in the movement of the piston; and on this being effected the gab of the eccentric is again dropped into gear, and the motion of the engine continues.

The conditions of a marine engine suited for driving a screw-propeller, differ considerably from those of the engines we have hitherto described. The shaft of the screw-propeller is necessarily at a low level, and lies longitudinally in the vessel to which it is fitted, and it must be made to revolve at considerable velocity. When this system of propulsion was first tried, it was usual to employ ordinary marine engines placed transversely in the vessel, and to fit on their shaft a large cog-wheel, driving a pinion on the shaft of the screw-propeller below it. By this arrangement the low level of the latter was secured, as well as its high velocity; but the weight, bulk, shake, and noise of the toothed gearing were found objectionable. Screw-propeller engines are generally made now with very short stroke, so that the number of strokes made in a given time is much greater than in ordinary engines of equivalent power. The cylinders are arranged horizontally; and the piston-rods act on the cranks placed at a low level, without the intervention of side-beams.

The annexed plate represents the transverse section of a screw-steamer, with the engine placed in the lower part of its hold: *g* is the cylinder placed horizontally, and supplied with steam from the boiler by the steam-pipe *m*. The piston-rod *f* works a cross-head, which moves in horizontal guides, and acts by the connecting-rod *e* directly on the crank-shaft *d*, which is extended horizontally to the stern of the vessel, and projects through a stuffing-box into the water near the stern-post, carrying on it the screw-propeller, indicated by the dotted circle *s*. For working the air-pumps of screw engines, several different arrangements are employed. In some cases the air-pumps are placed horizontally, like the cylinders, on the opposite side of the vessel, and worked directly by the piston-rods, which are extended in length for that purpose. In the plate, another method of working the air-pumps is represented. A second or counter-shaft *i* is worked by gearing *c* from the main-shaft *d*; and this second shaft, by means of cranks and connecting-rods *j*, works the pistons of vertical air-pumps *l*. In order to secure, in a height so limited, a greater length of connecting-rod, and at the same time to furnish a guide to resist the transverse strain resulting from the obliquity of its action, the piston of the air-pump is made with a trunk or tubular rod *k*, which passes through a stuffing box in the pump-cover; and the lower end of the connecting-rod *j* is jointed within this trunk. The water discharged from the air-pump passes by a pipe *n* into a cistern, whence a portion is drawn by the feed-pump for the supply of the boiler, the rest escaping by the discharge-pipe *o*, which is carried through the side of the vessel above the level of the external water: *p* is the hand-lever, by which the engine-driver stops, starts, or reverses; it is connected by a rod *q* and bell-crank lever, with the link motion already described (page 862). When the lever *p* is held in its middle position by a catch dropping into a notch on an arc against which it slides, the engines remain at rest; when it is raised upwards, or depressed to either of the extreme notches, the engines work at full speed, either ahead or astern; and when it is set at either of the intermediate notches, they work at half speed, or are *eased* in either direction.

---

* See *ante*, p. 859.

Many other forms of engine for screw-propulsion might be described; but as they all, more or less, display the same general features, we do not think it necessary, in our limited space, to enter on a full description of their details.

COMBINED ENGINES are those which embody the principles of both the condensing and non-condensing engines. In these, a small cylinder and large cylinder are placed side by side, and their piston-rods are connected so as to work together. High-pressure steam admitted to the small cylinder, works its piston as in a non-condensing engine; but, instead of being permitted to escape into the atmosphere, is conveyed to the larger cylinder, in which it expands to greater volume but lower pressure, and acts on a greater area of piston. Thence the expanded steam flows into a condenser, as in the ordinary condensing engine.

This arrangement gives the opportunity of securing a large amount of useful effect from the steam, and thereby economising fuel in the boiler. If we suppose, for example, that steam with an absolute pressure of 75 lbs. is admitted into the smaller cylinder during $\frac{1}{4}$th of the stroke, and allowed to expand during the remainder of the stroke, its final pressure, allowing for a little loss by cooling, will be about 18 lbs., and the mean pressure throughout the stroke will be about 42 lbs. The steam at 18 lbs. being now admitted into the larger cylinder during $\frac{1}{2}$ the stroke, will have a final pressure of about 8 lbs., and a mean pressure of about 13 lbs. throughout the stroke. The back pressure of rarefied air and vapour in the condenser may average 2 lbs. throughout the stroke, and the mean effective pressure on the larger piston would then be $13-2=11$ lbs., while that on the smaller is $42-13=29$ lbs. per square inch. Now, if the area of the small piston be to that of the large in the proportion of 11 to 29, the total mean pressure on each will be alike; and the power of the engine will be double that of either, with an expenditure of steam at 75 lbs. pressure, or 60 lbs. above that of the atmosphere, only sufficient to fill $\frac{1}{4}$th of the capacity of the smaller cylinder. By cutting off at an earlier period of the stroke, and using a still larger second cylinder, still greater economy of steam may be attained.

In determining the power of a condensing engine, it is necessary to know the pressure of the steam employed, the amount of vacuum produced in the condenser, the size and velocity of the piston, and the various losses of force occasioned by the friction of the machinery, and the resistance of the air-pump, feed-pump, and cold-water-pump. Assuming that, generally, the speed of the piston is about 200 feet per minute, and that the pressure in the boiler does not exceed 5 or 6 lbs. per square inch above that of the atmosphere, we may take the following rule as to power:—

Given the diameter of the cylinder to find the power.

Rule.—From the diameter (in inches) subtract 6, square the remainder, and divide by 20 for the power.

Example.—What is the power of a condensing engine having a cylinder 54 inches diameter?

$$54-6=48, \text{ and } \frac{48\times48}{20}=115 \text{ horse-power.}$$

Given the power to find the diameter of the cylinder.

Rule.—To the square root of 20 times the power add 6, for the diameter in inches.

Example.—Required the diameter of cylinder for 115 horse-power.

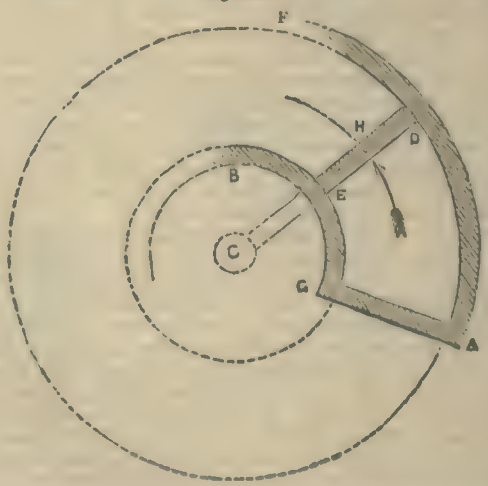
$20\times115=2300$, square-root $=48$ nearly, and $48+6=54$ inches.

These, however, merely furnish rough guesses at the power of any engine. The proper method of ascertaining the real power is to apply the indicator, when the engine is only moving itself, so as to ascertain the power necessary to overcome the friction and resistance of its working parts; and to deduct this quantity, with some allowance for additional strain, from the power indicated when the engine is in full work. No definite rule can be offered for estimating these allowances, as varieties in construction and workmanship introduce great differences among experimental results. In general, it is safe to reckon not more than $\frac{3}{4}$ths of the indicated power as really effective to move machinery, the remaining $\frac{1}{4}$th being absorbed in friction and moving the pumps.

ROTARY ENGINES.—In all steam-engines, except those that are single acting, a good deal of mechanism is necessary in order to convert the reciprocating rectilineal motion of the piston into the continuous circular motion of the crank. It has, therefore, been a great object with many mechanics to devise a rotary engine, or one in which the steam pressure shall at once give the required rotary motion, without the intervening machinery of connecting-rod, beam, parallel motion, and crank. Many of the arrangements devised for this purpose present great ingenuity, and it is not improbable that some may prove ultimately successful; but hitherto no rotary engine has proved so far satisfactory as to warrant its adoption in the place of those already in use.

A singular error regarding rotary steam-engines has crept into some of the best books on the subject; and as it is calculated to discourage inventors who may apply themselves to devising engines of this kind, we will endeavour to point it out. It is asserted that steam applied to give direct rotary motion to a piston is less effective, or loses part of the power which it would produce if applied to move a piston in a straight line. If we suppose E D (Fig. 210) to be a piston fitted to an annular cylindrical vessel B G A F, so that it may be moved round the centre C by the pressure of steam admitted behind it, we have to ascertain whether a certain quantity of steam applied to a piston thus arranged, will generate as much power as it would produce when applied to a piston in the ordinary way. Some authors (among them Tredgold, in his large work on the steam-engine) say that "the quantities of steam being equal, the power of rotary action will be less than that of rectilineal action;" and this fallacy is but too generally admitted among engineers. That it is a fallacy may be very easily shown by a practical example. Let us sup-

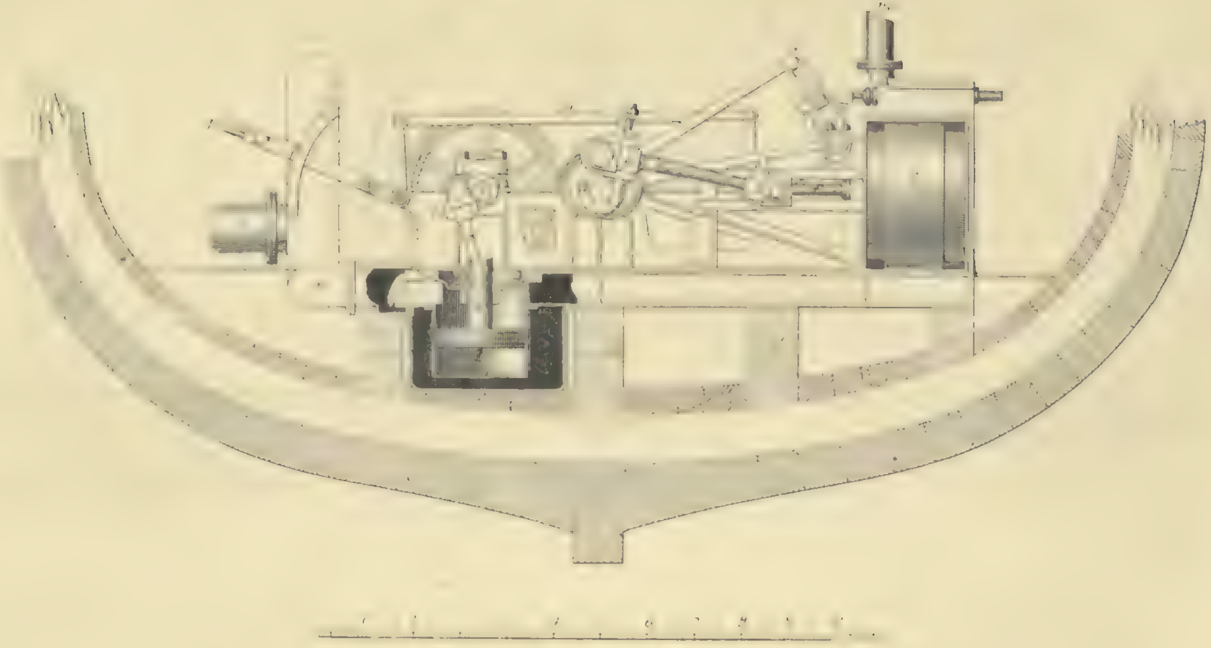
Fig. 210.



See page. 875

MARINE ENGINE.

SCREW PROPELLER



pose that the piston D E measures 10 inches each way, and therefore presents a surface of 100 square inches, and that it is acted on by steam having a pressure of 20 lbs. per square inch; so that the total pressure on its surface is 100 × 20 = 2000 lbs. Now, considering C D as the arm of a lever, of which a portion E D is loaded with pressures distributed uniformly over it, we know that their combined effect to turn the lever round its fulcrum C is the same as if the whole pressure were collected into one force at H, the centre of gravity of the part D E. We have, therefore, effectively a lever or arm of the length C H, pushed round C by a force of 2,000 lbs. applied at H. If we take C E = 9 inches, then as E H = 5 inches ($\frac{1}{2}$ of 10 inches), C H = 14 inches; and during one revolution, H passes over a distance equivalent to the circumference of a circle having a radius of 14 inches—that is to say, over 88 inches, or $7\frac{1}{3}$ feet. Hence, the work done during a revolution is 2000 lbs. × $7\frac{1}{3}$ feet = 14667 lbs. moved over 1 foot. Also the quantity of steam required to fill the annular space passed through by the piston is thus found, C E being 9 inches, and C D being 19 inches:—

Area of outer circle (38 inches dia.) =	1134·12 sq. ins.
Area of inner circle (18 inches dia.) =	254·47 ,,
Area of annular space (difference) .	879·65 ,,
Multiply by breadth	10 inches.
Volume of annular space . .	8796·5 cubic ins.

Were we to apply this quantity of steam in an ordinary cylinder, whatever be its dimensions, we should produce equivalent power. Let us, for example, take a cylinder 1 foot diameter, having an area of piston 113·1 square inches, subjected to a pressure of 113·1 square inches × 20 lbs. = 2262 lbs., moving through a stroke of 6·488 feet (a length which requires equivalent volume of steam), we find the work to be 2262 lbs. × 6·488 = 14667 lbs. moved over 1 foot as before. Instead of reckoning the whole revolution of the rotary piston, we might take any portion of its revolution, and we should find the power derived from the quantity of steam used, exactly equal to that which would be produced by the same quantity of steam, in any corresponding portion of a cylinder where the piston moves rectilineally. Without reference to any special numerical example, we observe these general laws. Whatever be the form of the rotating piston D E, steam pressing uniformly on its surface produces the same effect to turn it round its centre C, as if the whole pressure were collected into one force acting at the centre of gravity H of the surface of piston; and the work done by the steam during any part of a revolution, is equivalent to the total pressure in the piston, multiplied by the distance traversed by the centre of gravity H, or the portion of the circumference of a circle of which C H is the radius; and, further, the volume of steam required during the given portion of a revolution is (by the well-known law of mensuration of annular solids) measured by the area of the piston, multiplied by the distance passed over by its centre of gravity. In the case of a piston moving rectilineally, the work done by the steam, and the volume of steam used during any portion of a stroke, are measured in precisely the same way, and bear the same relation to each other. There is, therefore, no theoretical objection to the application of steam in such a way as to produce direct rotary motion. That there are considerable practical difficulties in the arrangement of the parts, and their construction, so as to present steam-tight rubbing surfaces, and to avoid undue friction and unequal wear, is doubtless true; but were these difficulties fairly surmounted, we should be in possession of an engine where simplicity, and economy of weight and bulk, might enable us to apply steam-power in many cases where it is not now applicable without inconvenience.

Before leaving the subject of rotary engines, we may mention that steam has been applied successfully to produce rotary motion on the same principle as that of Barker's mill, or the turbine applied to water-power. Steam of considerable pressure, passing through openings on the sides of several tubular arms mounted on an axis, causes them to revolve in the direction opposite to that in which the steam issues, on the same principle as the movement of a rocket, where the issue of the elastic gases, generated by the combustion of the charge at one end, leaves an unbalanced pressure to act on the other end, and thus to force it onward through the air; but we believe this mode of applying steam-pressure, though exceedingly simple, is by no means sufficiently economical to warrant its general adoption.

SUPER-HEATING STEAM.—For several years after the adoption of steam-power for marine propulsion, it was almost exclusively confined to vessels destined to convey passengers over short distances, along coasts or in rivers. The fuel required to maintain the steam-power was to be obtained easily and cheaply, and, as the distance was not great, the space required for the stowage of coals was not so large as to trench inconveniently on the accommodation of the vessel. Under these circumstances, engineers devoted their attention less to economy of fuel than to speed. But since steam-vessels have begun to make long voyages, lasting for several weeks—since the invention of the screw-propeller has rendered them even more servicable as sea-going vessels for carrying cargo than sailing vessels could be, and especially since the application of steam-power to ships of war, the economy of fuel has become a matter of the first importance. Many modifications in the construction of the boilers and of the engines have been introduced for the purpose of saving fuel, and still greater changes will probably be effected in the processes by which the combustion of fuel is applied to the production of motive power. Among these changes, which begin to receive general adoption, may be noted *surface-condensation*, to which we have already alluded (page 873), and *super-heating steam*. The latter process appears to promise great results in economy of fuel, especially when applied in connection to *combined engines* with *surface-condensers*, and we will therefore endeavour to describe how the process is effected, and what are the special advantages which it secures. On looking to the Table of the Temperature and corresponding pressure of steam (page 845), it will be seen that a very small reduction of temperature produces a very considerable diminution of pressure. Thus, steam at a pressure of 4 atmospheres, or exerting on every square inch a pressure of 45 lbs. above that of the atmosphere, has a sensible temperature of 290°. On diminishing the temperature by 15°, the pressure is reduced to three atmospheres, or a loss of pressure is incurred amounting to 15 lbs. on the square inch. At higher temperatures the loss is proportionally greater. Thus, steam at 344°, having a pressure of 8 atmospheres, when cooled down to 320°, has its pressure reduced to 6 atmospheres, losing 2 atmospheres, or 30 lbs. per square inch, by a reduction of its temperature to the extent of 24°.

It may be readily understood, then, that steam, in its passage from the boiler, where it is generated, to the cylinder, where its elasticity is required, exposed, as it is, to the cooling influence of an extended surface of pipe passages and cylinder, all made of rapidly conducting materials, must sustain a loss of effective pressure, which is absolute waste of power or of the fuel used to produce it. Nor is the loss of pressure the only evil resulting from the reduction of temperature. A cubic foot of steam at 290° of temperature and 4 atmospheres of pressure, on having its temperature reduced to 275°, loses, as already stated, 1 atmosphere of pressure; but, as it has still 1 cubic foot of volume, and as, by Mariotte's law, the density is always proportional to the pressure, the loss of pressure is accompanied by a corresponding diminution of density. That is to say, in the case we are examining, *one-fourth* part, or 25 *per cent.* of the steam, becomes actually condensed into water, leaving the remaining three-fourths, or 75 per cent., occupying the volume of 1 cubic foot at the reduced density and pressure. This water accompanies the steam into the cylinder, where it is of no assistance to the steam on the pressure side of the piston; and where, by evolving vapour on the vacuum side it produces a back or retarding pressure. It passes with the steam into the condenser, and there absorbs uselessly a large portion of the cooling power, whether of injection or of cold surface, and therefore, for a given power of engine, necessitates a proportionally greater cooling power, a proportionally larger air-pump, and proportionally increased waste of useful effect in working it. To avoid these evils it has long been usual to clothe the steam-pipes and cylinder with thick felt and wood casing, or non-conducting materials of a similar kind; and, in many engines, the cylinders have been made double, having a jacket or space all round them filled with steam from the boiler, which serves to keep the inner cylinder hot, and to prevent loss of pressure and condensation during the actual expansion of the steam within it. Notwithstanding these precautions, however, a great loss of effect is still incurred, amounting probably to 20 or 25 per cent. under the most favourable conditions, and, under average conditions, to a great deal more. Engineers accordingly begin to adopt the super-heating process, which is found to present an almost complete remedy against these losses. It may simply be described as a mode of surcharging the steam with heat, and raising its temperature considerably above what may be called its natural temperature, or the temperature due to its pressure. In order fully to understand this, it should be remembered that the temperatures given in the Table are those of the steam when it is in contact with water. For instance, when the pressure is equivalent to 4 atmospheres, the steam in contact with water, and the water, have the temperature of 290°; if the temperature were reduced, a portion of the steam would be condensed, and the remainder would present a proportionally diminished pressure. Were the temperature increased, a fresh portion of water would be converted into vapour, which, mingling with the rest, would proportionally increase the pressure. But if the steam were removed into a vessel separate from the water, while it would still be true that a reduction of temperature would cause a condensation and diminution of pressure, it would no longer be true that an accession of temperature would cause an increase of pressure from the generation of fresh steam, because there would be no water from which to generate it. In that case, the steam would probably follow the law of expansion, which is common to all gaseous bodies, increasing in bulk by a certain fraction of its volume, proportioned to its elevation of temperature; or, if its volume were confined, increasing in pressure in the same proportion. But steam, so elevated in temperature, would be in a condition to sustain a certain loss of heat without any part of it becoming condensed. It would, in fact, have a relay of heat stored within it, and might be exposed in pipes or cylinders to cooling surfaces without losing any appreciable per centage of its pressure, or depositing water of condensation. The practical modes by which this super-heating process is effected are various. Their general principle, however, is simply to expose the steam, in its passage from the boiler towards the cylinder, to the heat of the boiler flues; and, in order that this heat may be rendered effective as rapidly and completely as possible, the steam-pipe is subdivided into numerous small pipes or passages, exposing a very extended surface to the hot products of combustion which play upon it. Almost all the super-heating apparatus thus bear a close resemblance to the surface-condensers, though intended for an operation of an opposite character. As in the surface-condenser the steam is subdivided into numerous tubes or channels exposed to cold water for the purpose of cooling and condensing it, so in the super-heater, it is likewise subdivided into channels exposed to hot flame, smoke, and gases, for the purpose of surcharging it with heat.

It is said, that by the use of super-heating apparatus, an economy of fuel has been effected, amounting, in some cases, to 20 and 25 per cent. Probably a portion of this economy may be due to the circumstance that super-heating apparatuses are generally placed in the last part of the boiler flue leading to the chimney, where they utilise a quantity of heat which, under ordinary circumstances, passes up the chimney, and is totally wasted.

APPLICATIONS OF STEAM-POWER.—The chief purposes to which steam-power is applied are the following:—

I. Pumping water for the drainage of mines and docks, or at water-works for the supply of towns.

II. Driving machinery for raising ore from mines, for moving heavy weights, or for agricultural and manufacturing purposes.

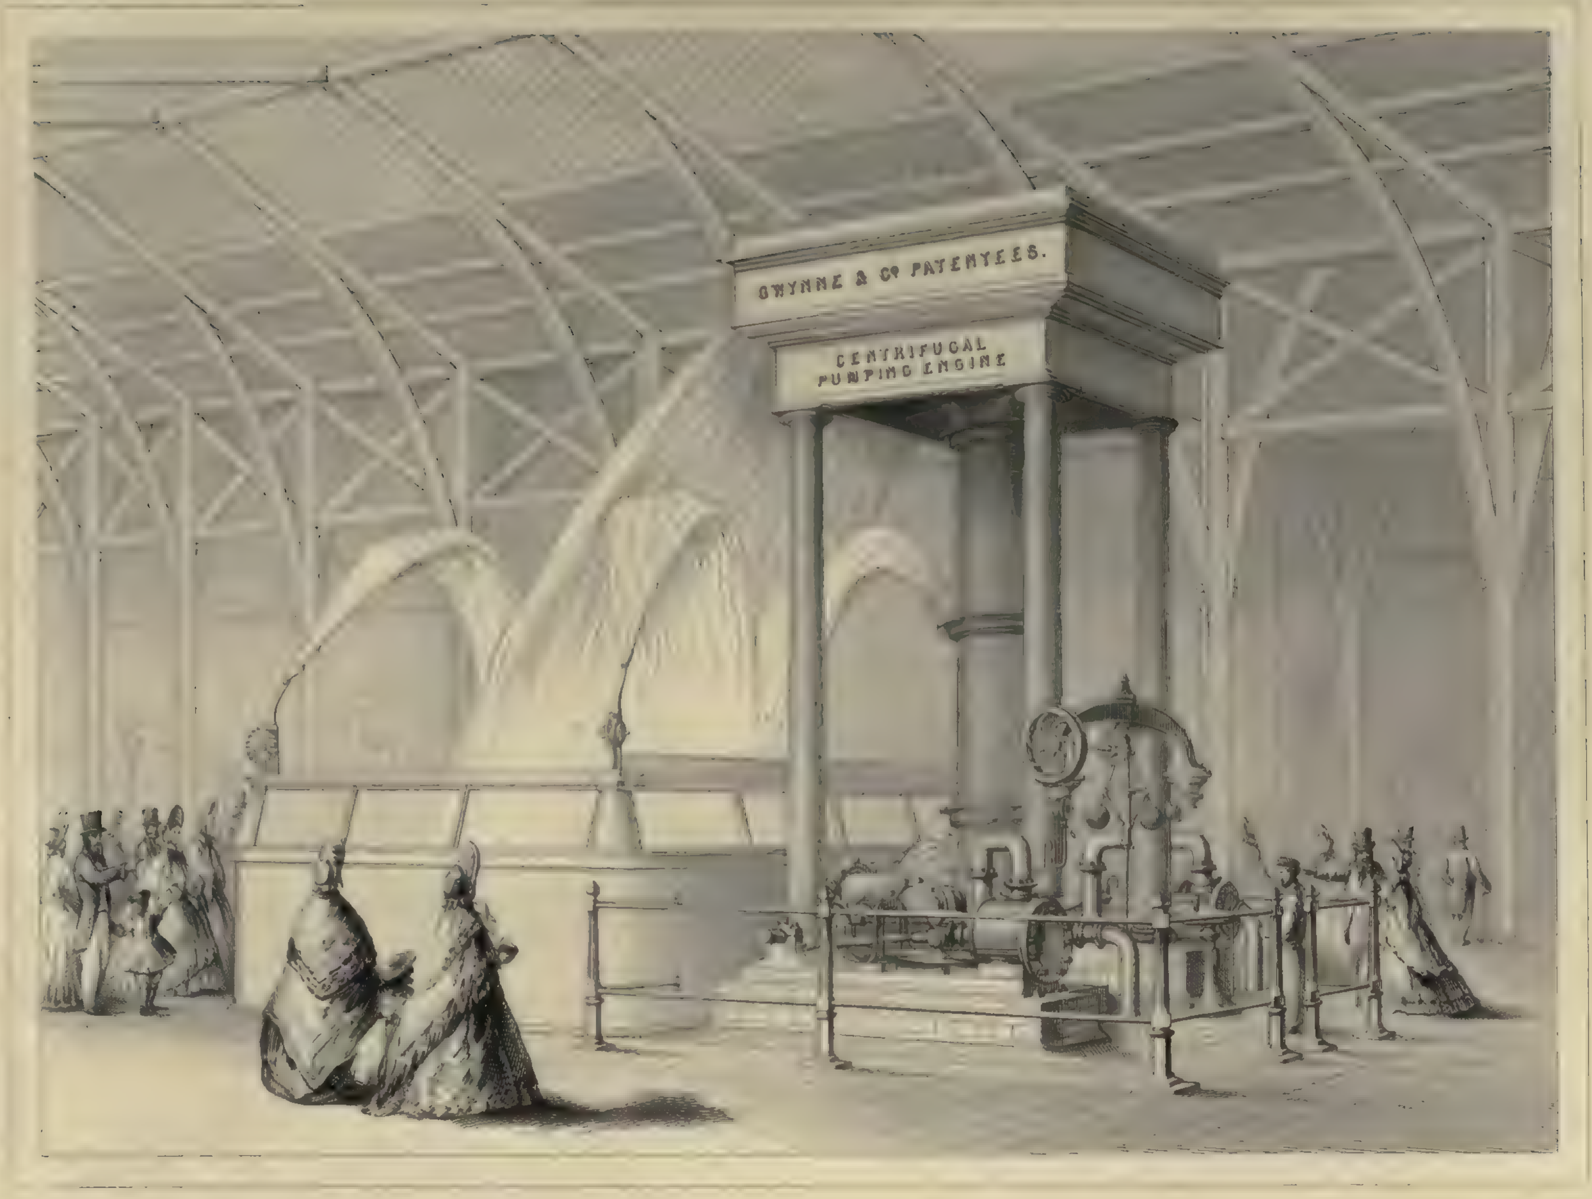
III. For locomotion on railways.

IV. For propelling steam-vessels.

We will briefly discuss the modes in which steam-power is generally made available for these different uses, and the forms of steam-engines most advantageously applied in each case.

I. Pumping.—In pumping water, until of late years, single-acting engines were almost universally applied. We may most readily account for this, not on the ground of any advantage derived from the use of single-acting engines, but from the circumstance that the earliest form of engine that was rendered practically available was that of Newcomen, which was single-acting, and suited only for working pumps; that Watt's improvements were first applied to engines of this kind, and that his engines were introduced at mines to supersede the labour of men and horses formerly applied to pumping; that these engines were of first-rate quality, effective and durable, and naturally impressed the miners with a preference for their form and arrangement; and that engineers in mining districts, applied themselves rather to the perfecting of forms already in use, than to the introduction of new arrangements. So strong, indeed, has been the preference for single-acting engines, especially those of the kind employed in Cornwall, when applied to pumping, that few double-acting engines have ever been employed for this purpose until very recently. We believe, however, that the results have shown decided advantages in favour of the double-acting engines, and that ere long they will supersede the more cumbrous and less advanced form of those that are single-acting.

The pumps employed in mines are of the lifting or forcing kind, having a stroke seldom exceeding 8 or 10 feet. When the mine is deep, the water is raised by stages, each 150 to 200 feet in height. The lowest pumps discharge into a reservoir about that height above the bottom of the mine; the second set of pumps draw from that reservoir, and discharge into the next higher; and so on, until the water is finally delivered at such a level that it may be permitted to flow off by natural drainage. As apparatus is generally required at mines for stamping and crushing the ore, it is not unusual to deliver the water at such a height above the general level of the ground, as may permit its use for driving a water-wheel, from which motion is given to the ore-crushing machinery. But as power is also required for raising the ore, it is generally more advantageous to employ a double-acting engine, besides the main pumping engine, for this purpose, as well as for the preparation of the ore. The power required for raising water depends upon the quantity raised in a given time, and the height to which it is raised. If we suppose that it is necessary to raise 100 cubic feet of water per minute 150 fathoms, or 900 feet, since each cubic foot of water weighs $62\frac{1}{2}$ lbs., the total to be raised is $100 \times 62\frac{1}{2} = 6250$ lbs. per minute. This load, raised through 900 feet, is equivalent to $6250 \times 900 = 5625000$ lbs. raised 1 foot, and would require $\frac{5625000}{33000} = 170$ horse-power, without allowance for friction and excess of power, to give the velocity of movement to the column of water. To estimate this quantity, we should add at least 10 per cent., or $\frac{1}{10}$th, making the power 187-horse, which would be the effective power, after making all allowances for the friction of the engine, and the various losses occasioned by the cooling or leakage of steam, and the working of the air-pump and feed-pump.



GWYNNE & Cº.s CENTRIFUGAL PUMP.

The performance of the Cornish engines has received special attention, from the circumstance that a number of mine proprietors placed their engines under the superintendence of engineers, and had monthly reports published as to the quantity of water lifted, the quantity of coals consumed, and other particulars. Six of the most effective engines reported on, presented the following average results :—

Diameters of cylinder from 60 to 90 inches.
Mean pressure of steam per square inch, 10 lbs.
Length of stroke from 8 to 10 feet.
Average number of strokes per minute, 7.
Diameter of pumps, 9 to 18 inches.
Average length of pump-stroke, 7 feet 6 inches.
Average work, reckoned in lbs. of water lifted 1 foot high by the consumption of 1 bushel of coals, 40,500,000 lbs., or the work of 1,227 horse-power.

In pumping docks, the quantity of water to be lifted in a given time is generally great, but the height inconsiderable, and the pumps may, therefore, be of large diameter. As a practical example, we may take the case of a rectangular dock, 200 feet long, 40 feet broad, and 20 feet deep, the water being lifted 2 feet above the highest level to give a fall for its drainage. The total quantity to be lifted is $200 \times 40 \times 20 = 160{,}000$ cubic feet, or $160{,}000 \times 62\frac{1}{2} = 10{,}000{,}000$ lbs. At the beginning of the work, the water has to be lifted only 2 feet; at the end it has to be lifted 22 feet; and the mean height of lift is, therefore, 11 feet, the work done being equivalent to $\frac{10000000 \text{ lbs.} \times 11}{33000} = 3333$ horse power; or, allowing $\frac{1}{10}$th for friction and velocity, about 3660 horse-power. If the work be done in 1 hour or 60 minutes, the power of the engine must be $\frac{3660}{60} = 61$ horse-power, clear of all losses. As in a case like this, the work at first is very light, and becomes greater as the level of the water is lowered, and the height to be lifted consequently increased, it is advisable to have several pumps, all of which may be kept in action at first, but which may be thrown out of action successively as the load on them becomes increased, the strain of the engine being thereby not greatly varied.

In water-works for supplying towns, not only has the water to be lifted to such a height that it may command the highest level to which it has to rise, but it has also to be conveyed through great lengths of pipe, often extending many miles. It is convenient to arrange, as near as possible to the pump, a high reservoir, of such altitude as may be sufficient to cause the necessary flow in the great length of pipe connected with it. This is effected by pumping the water through an elevated siphon, open at the top to permit the issue of air that may be mingled with the water. The pump, in making its stroke, has thus to put in motion only the column of water contained in the ascending limb of the siphon, instead of the whole mass contained in the pipes. But in order still farther to relieve the pump and engine from the strain required to put in sudden movement even this mass of water, the pump is provided with a capacious air-vessel—a dome-shaped vessel—the upper part of which contains air, and the lower part communicates with the discharge-pipe of the pump. When the pump discharges its contents, the air in the vessel is compressed by the influx of water below it; and while the pump is making its return stroke, the elasticity of the compressed air continues the flow of the water that had been forced into the vessel. The air thus acts as a spring, yielding to the force of the discharge from the pump, and sustaining the pressure on the flow-pipe at intervals when the pump is inactive. When the pump is double-acting, or discharges at both the up-stroke and the down-stroke, the intervals of inaction are only those occupied by the turn of the stroke, and the air-vessel has less to do than when the pump is single-acting. Two single-acting pumps, of which the one discharges while the other is drawing, produces a like effect. Upon the whole, we believe that for simplicity, economy of cost and of working, a good double-acting engine, with double-acting pump, is preferable to two single-acting engines and pumps, each of half the power, or to one single-acting of equivalent power. We know of no advantage possessed by the single-acting engine, which cannot be fully secured in the double-acting engine. It has so happened, that many single-acting engines have been made of large dimensions and long stroke, and that the expansive power of the steam has been employed by cutting it off at an early part of the stroke, to such an extent as to secure great economy of fuel. But in the double-acting engine, particularly when the duplicate cylinder, with high-pressure and low-pressure action, is applied, the same economy of fuel can be secured, and the bulk and weight of the whole are greatly reduced.

An operation, nearly allied to that of pumping water, is the production of the air-blast required for furnaces. At the iron-works, which constitute so important a part of our industry, a very great amount of power is employed for this purpose. The smelting furnaces, in which the metal is separated from the earthy ingredients of the ore, are supplied with the air required for intense combustion forced into them by pumps, which are worked generally by steam-engines. The volume of air supplied is very great, ranging from 1,500 to 2,000 cubic feet per minute; but its pressure is inconsiderable, seldom exceeding 3 lbs. per square inch above atmospheric pressure; and the pumps are therefore made of large capacity. In many places, the air, on its way to the furnace, is heated to a high temperature, so as to maintain a more intense combustion, and thereby extract a greater quantity of metal from the ore at a rapid rate. But it is found that the metal so produced, called *hot-blast* iron, though cheaper than *cold-blast* iron, is of inferior quality for all purposes where strength and tenacity are required. When the blast is not required at so high a pressure as that which is necessary for smelting furnaces—for ordinary foundry furnaces, and for blowing forge fires—the current of air is usually produced by a fan. The annexed plate represents a construction of fan which has obtained considerable, and we believe well-merited, repute for efficiency and durability. The fixed portion of this fan consists of a framing, which is generally bolted securely down to a block of stone or heavy timber, in order to avoid vibration, and a cylindrical casing, with circular openings on either side, and a mouth at one part of the circumference, which is connected to the pipe or channel for conveying the air-blast to the furnace. The framing is formed with long and carefully made bearings, in which a spindle revolves concentric with the cylindrical casing. On this spindle are fixed a number of recurved arms, fronted by plates bent to fit them, and the whole enclosed within two conical sides, which have lips projecting and fitting into the circular openings in the casing. The spindle and the arm-plates and conical sides being put in rotation at a high velocity —1,000, 1,500, or sometimes 2,000 revolutions per minute—air enters by the circular openings of the casing, passes between the two cones, and issues at their circumference into the casing, whence it proceeds with considerable velocity to the furnace. The force which produces the current of air is the centrifugal tendency of every particle to fly from the axis when it is put in rapid rotary motion, and the recurved blades act not only to carry the particles of air round in a circular direction, but also to drive them outwards from their inclined surfaces. The side casings of the blades are made conical, so that the area or channel through which the air passes should be nearly uniform throughout its course.

[On a similar principle, Messrs. Gwynne's centrifugal pump is constructed. The folio plate represents one of these engines, which was at work in the Exhibition at London, in 1862, and which raised a complete torrent of water by the great power it exerted. It is peculiarly suitable for draining purposes, and, generally, for lifting water in great quantities to moderate heights.—Ed.]

II. Driving Machinery.—Where the power required is small, or where fuel is cheap and water scarce, non-condensing engines are generally preferred. But, on the other hand, where there is a plentiful supply of water, and where fuel is expensive, condensing engines are employed; as by a certain expenditure of fuel, there is certainly a greater amount of power generated when the steam is condensed. For large manufactories, cotton, flax, and flour mills, breweries, and like establishments, the beam-engine is generally employed. Its advantages consist in the accessibility of all its parts in case of damage or repair, and the steadiness and regularity of its movement, resulting from its massiveness and solidity. The substantial and imposing look of a large beam-engine is certainly, however, with many persons, an argument for its use, where engines of less weight and bulk might be applied with quite as great advantage. The marine engine, having received great attention to its perfect construction, has often with advantage taken the place of ordinary beam-engines in manufacturing establishments; and we believe the only objection to their general use is, that they are rather more expensive in the first place. Where there is a deficiency of water for condensation, it is necessary to provide large reservoirs, in which the water discharged from the air-pump may have time to cool before it is again used in the condenser. Warm water, when used for injection, must either be admitted in quantities so great as to impede the engine by the additional work thrown on the air-pump—or, if limited in quantity, can only effect partial condensation of the steam, so that the piston is impeded by the imperfection of the vacuum.

The power of an engine required for manufacturing purposes, necessarily depends on the kind of work to be done, and its amount. A manufactory generally contains numerous machines, like and unlike; and unfortunately very few accurate experiments have been made as to the power required for working them. It is stated, that in the cotton manufacture, one horse-power is sufficient for 100 spindles of cotton yarn, and the machinery necessary for the preparation of the cotton; and, again, that one horse-power will work 12 power-looms. But, every day, improvements are being made in the construction of such machinery, and changes are introduced among the methods of preparing the material; and it therefore becomes difficult to assign any determinate method of estimating the power.

In the iron manufacture, steam-power is applied to the processes of rolling, shearing, flatting, punching, turning, planing, and the like. And so with operations on other metals, on wood, and generally all crude materials, the facility of deriving adequate power from the application of heat to water enables us to employ machinery instead of manual labour in a multitude of ways, so as not only to execute works that could not have been attempted without having such a force at command, but to do so with an economy and ease that could not otherwise be attained. In all these manufacturing operations it is essential to the safety as well as to the accurate working of the machinery, that the speed of the prime mover should be uniform.

Where there are numerous machines driven by the same power, it may often happen that several are in operation at once, while at another time none may be at work. To overcome the resistance caused by suddenly bringing a heavy machine into action, as in the case of a set of rollers for preparing iron, and at the same time to prevent the dangerous increase of speed that would result from suddenly throwing it out of work, it is essential that there should be a good governor and a very heavy fly-wheel. The fly-wheel acts as a reservoir of force in the one case, ready to give out a portion of its momentum when the additional resistance comes upon it; and as a reservoir of resistance or inertia, in the other case, ready to absorb a portion of the unnecessary power. The governor, again, permits the supply of additional steam to the cylinder as soon as the velocity of the engine begins to undergo diminution, and checks or throttles the supply whenever the speed rises above the average.

When the power required is small, or under circumstances where there is a difficulty in supplying water for condensation, or where there would be a great disadvantage in having any complicated machinery to be attended to, it is usual to employ non-condensing engines; these being more simple, are less costly in the first place, less liable to derangement and wear, and more easily understood and managed. It is true that for a given amount of power, the expenditure of fuel is somewhat greater than where the steam is condensed; but with a good boiler generating steam at a pressure of 40 to 60 lbs. if the cylinder be made of considerable size, and the steam cut off at an early part of the stroke so as to act expansively, the excess of fuel expenditure is not great. For agricultural purposes, in the colonies, or generally in districts removed from engineering establishments, simplicity is of more importance than even economy of fuel. Many of these non-condensing engines, from 5 to 15 horse-power, are made portable, so that the power may be readily brought to the work instead of the work being brought to the power. The portable engine consists of a cylindrical boiler, perforated with flues or tubes like that of a locomotive, mounted on wheels, with a direct-acting engine laid horizontally upon the boiler, or arranged in some convenient way for lightness and economy of space. For thrashing and winnowing corn, draining or irrigating land, brick and tile making, and field operations generally, these engines are very serviceable, especially in cases where the work of a farm is not enough to keep an engine constantly employed, and where the same engine may do duty throughout a considerable district. We believe, however, that as agriculture approaches more to the condition of a manufacturing art than it has hitherto done, the fixed engine will gradually supersede those that are portable; the farm buildings will become the head-quarters of the various operations; the materials will be brought thither to be operated on; and agricultural processes will be carried on with the regularity and precision of other branches of art. Of late years, many persons of high standing and energetic character have devoted themselves to the furtherance of this object; and their example is being generally followed throughout the country. His late Royal Highness the Prince Consort erected a very complete farming establishment near Windsor. A fixed engine there puts in motion a train of machines for thrashing, dressing, and grinding corn, cutting chaff, bruising beans and oats, steaming the food of cattle, and other processes, all systematically and economically arranged; and similar plans are adopted in many other places at home and abroad.

III. Locomotives.—In no application of steam-power has greater ingenuity been manifested than in locomotive engines. The great essentials of a locomotive are, lightness, compactness of strength of construction, rapidity of action, and facility of management. Some of the earliest attempts at these engines were necessarily rude and imperfect; but the rapid extension of the railway system, and the immense advantages derived from speed in the transmission of passengers and goods, have hurried on improvements so quickly, that in a very few years the locomotive has risen to a high degree of perfection. For some time it seemed difficult to contemplate the possibility of covering the land with a network of iron-ways, extending over many thousand miles in length; and accordingly attention was chiefly devoted to the construction of locomotives for running on ordinary roads. Some of the engines made for this purpose were tolerably successful in their operations, and embodied in their construction a great amount of ingenuity, which has not been without its use in leading to the more perfect locomotive of the present time. Even when railroads began to be formed, the employment of steam on them was a doubtful question, and their most sanguine promoters scarcely dared to hope for a speed exceeding 10 miles an hour, or to expect that passenger-traffic would equal in importance the conveyance of heavy goods. It was feared that the friction of an iron wheel on an iron road would not be sufficient to move onward the locomotive itself, much less a heavy train of carriages; and accordingly it was proposed to apply levers to act as legs and feet propelling the carriage, or to lay down a continuous rack, in which a toothed wheel driven by the engine might work, or an endless chain to be wound round a revolving barrel. It was not until the actual trial was made, that the simple expedient of causing a pair of wheels to revolve on the rails, was adopted without reserve.

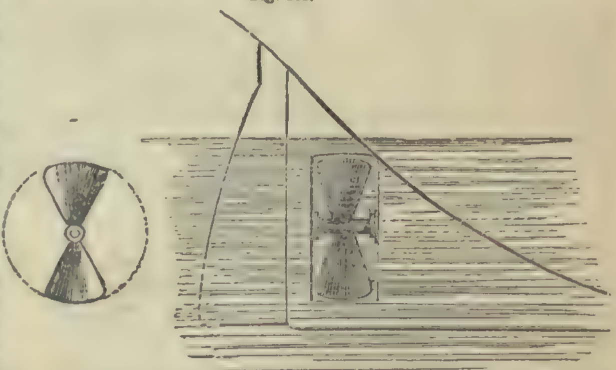
The construction of the boiler and engines of a locomotive has been already referred to (page 866). The whole power is applied to turn the crank-shaft, on which are fixed the driving-wheels. For each revolution of the engine, therefore, there is one revolution of the driving-wheels. Sometimes these are made 6 to 7 feet in diameter, and have therefore a circumference of 20 feet. If we suppose the engines to make 200 revolutions per minute, or 200 × 60 = 12,000 per hour, as the whole circumference of the driving-wheel is brought to bear on the rail during each revolution, if there be no slip, the locomotive must advance 20 feet for each revolution—that is to say, 12,000 × 20 = 240,000 feet, above 45½ miles per hour. When the rails are damp and slippery, the wheels occasionally slip round without taking sufficient hold of them to propel the train. In such cases, a little sand strewn on the rails generally causes sufficient friction to commence the movement of the train; and its momentum once established, the locomotive has only to keep it up against the resistance of the air, and the friction of the running wheels. When the locomotive is applied to the propulsion of heavy goods-trains, especially up inclinations, it is necessary to obtain more friction than could be derived from one pair of driving-wheels. For this purpose the locomotive is fitted with one, and sometimes two additional pairs of driving-wheels, of the same size as those worked by the engine. These wheels are coupled by connecting-rods working on pins projecting from their arms, so that they all revolve simultaneously, and thus present double or treble the amount of rubbing surface on the rails. The locomotive has attached to it a tender, which is an iron tank mounted on wheels, divided into two compartments, one containing fuel and the other water for the supply of the engine. The water-tank is connected by a flexible tube to the feed-pump of the locomotive, by which the pump draws its supply, and forces it into the boiler. In order to save fuel, the water in the tank is heated by steam blown through it from the boiler, while the train is stopping, when the steam is blowing off to waste by the safety-valve. Occasionally the water-tank is fixed on the top of the boiler, and the tender is dispensed with. The engine-driver and stoker stand on a stage at the fire-box end of the boiler, and have under their eye the water and steam-gauges. They have conveniently arranged levers for working the steam-valve, so as to permit more or less steam to enter the cylinder; for moving the link-motion of the slides, so as to reverse the motion of the engines; for adjusting the pressure on the safety-valve, the supply of feed-water, and the break on the wheels when it is necessary to stop or move more slowly. They have convenient means of oiling all the working parts, and of opening pet-cocks in the cylinders to permit the issue of water, and the cock for sounding the steam-whistle as a signal of their approach. Altogether, the locomotive is perhaps the most perfect apparatus that has been designed by engineers; and the materials and workmanship applied in its construction are necessarily of the best kind, to withstand the constantly reiterated shocks of the movement, and to convey power so great through parts so light and apparently so complex.

IV. Propulsion of Vessels.—Although numerous modes of applying steam to the propulsion of vessels have been proposed, only two have met with general adoption—viz., the paddle-wheel and the screw-propeller. The action of paddle-wheel engines is precisely similar to that of locomotives: the paddles in the one case occupying the place of the driving-wheels in the other, and having float-boards successively immersed in the water, and withdrawn from it as the wheels revolve. The paddle of a steam-vessel is, indeed, an undershot water-wheel reversed in its action; that is to say, instead of the wheel being put in motion by the current of water, the wheel put in motion by the steam-engine causes a current of water by its revolution; and the reaction of the water propelled by it backwards, forces the wheel forwards, and with it the vessel to which it is attached. As the float-boards enter and leave the water, they act on it obliquely, tending in some measure to press it down in front and raise it behind. In sea-going vessels, where the wheels often act on the undulating surface of the water, this obliquity of action becomes a very considerable resistance, and tends to retard the engines and give them severe shocks. To obviate this defect, paddles are frequently made in such a manner that while passing through the water the floats hang nearly vertical. Such a wheel is called a *feathering* paddle, because the float-boards *feather*, or enter and leave the water edgeways, like the oar in the hands of a practised rower. The power required for a steam-vessel depends upon its form and tonnage, and the speed at which it is moved.

Steam-vessels are generally made very long in proportion to their breadth, and finely wedge-shaped at each end, so as to cut through the water with as little resistance as possible. In vessels of similar form and proportions, the power required to produce a given speed is nearly as the tonnage. But a very slight increase of speed demands a very considerable augmentation of power, as may be thus estimated:—To double the speed of a vessel it is necessary to push aside double the quantity of water in a given time, and to impel this water with double the velocity, and therefore to encounter four times the resistance; and, as the speed of the engines must be at least doubled, the power expended in a given time must be at least eight times. Generally the power may be taken as the cube of the speed, or rather more. If, for example, a pair of engines working to 100 horse-power, propelled a vessel at the rate of 8 knots (nautical miles) per hour, we should have to work the engines up to 200 horse-power to attain a speed of 10 knots per hour; because while the cube of 8, or 8 × 8 × 8 = 512, the cube of 10 is 1,000, nearly double of 512, and therefore the power in the one case must be double of that in the other. The same law applies in the case of vessels propelled by a screw.

The principle upon which the screw acts as a propeller, may be best understood by considering the action of a windmill reversed. The screw generally consists of two inclined blades (Fig. 211) projecting from an axis mounted in bearings, in what is called the dead-wood of a vessel, or the part of the stern immediately before the rudder. The screw-shaft works through a water-tight tube fixed in the dead-wood, and is put in motion by the steam-engines in the body of the vessel. The whole screw is immersed under water, and the blades are of such size that, looking endways on the shaft, they appear to occupy each about one-sixth of the circle which circumscribes them.

Fig. 211.



The *pitch* of the screw depends on the obliquity of the blades to the plane of the circle, and this obliquity increases from the circumference towards the centre, because the parts nearer the centre travel with less circumferential velocity, and yet the water passes them with equal longitudinal speed. When we say that a screw has twenty-feet pitch, we mean that if the screw-blade were continued through a complete revolution round its axis, any straight line drawn parallel to the axis would cut two portions of the blade at points twenty feet apart. Did the screw, in revolving through the water, put the latter in motion at such a rate as precisely to glide along its blades in straight lines parallel to the axis, every revolution of the screw would move any portion of water exposed to it through a length of 20 feet. But, practically, the water is almost at rest, and the screw worms its way through it, having to put in motion the vessel to which it is connected, and a certain *slip* occurs, or the speed with which the screw and vessel travel through the water is less than that due to the obliquity of the screw by about 25 or 30 per cent. If we suppose that a screw of 20 feet pitch makes 60 revolutions per minute, any point in its surface without slip would move through 20 × 60 = 1200 feet longitudinally per minute, or 1200 × 60 = 72000 feet = 12 knots per hour nearly. But, allowing twenty-five per cent., or one-fourth, for slip, the actual speed would be nine knots per hour.

[THE STEAM HAMMER.—Of late years, the immense demand for heavy forgings has necessitated novel methods for reducing them to the proper shape, especially when required in connection with screw-propellers, one of the largest of which was that used in the *Great Eastern*. The steam hammer has been much employed for this purpose; and in the hands of Nasmyth, Condie, and others, has been brought to a high degree of perfection. The general principle of construction is that of a solid vertical piston, moved in a cylinder by steam; the motion being regulated in a similar manner to that of the ordinary steam-engine, by the action of a slide-valve moved by an attendant. The piston-rod is extended, so as to form the hammer-head; and below, on a suitable block, the iron to be forged is placed. The admission of steam beneath the piston raises it, and the hammer-head can then be driven, so as to impinge directly, at the extremity of the rod, on the article to be forged. By regulating the admission of steam, any amount of power may be exerted—a fact of great value to the practical engineer. The folio plate represents a machine of this kind, which was shown in action in the Exhibition at London, in 1862.—ED.]

CHAPTER VII.

THE COMMUNICATION OF POWER.

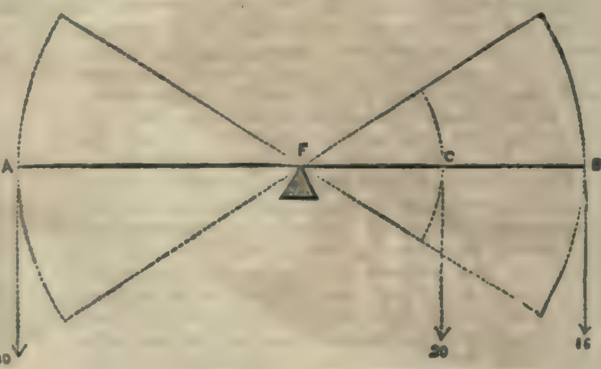
Contents.—WORK AND POWER—ROTARY MOTION—COUPLINGS—CLUTCHES—PLUMMER-BLOCKS—PULLEYS, OR DRUMS—TOOTHED WHEELS—FORMS OF TEETH—INVOLUTE OF A CIRCLE—BEVIL GEAR—RACKS—WORM AND WHEEL—EPICYCLOIDAL TEETH—RECIPROCATING MOTION—DISCONTINUOUS MOTION—RATCHET—CAM—MANGLE-MOTION—REVERSING GEAR—SCREW-CUTTING GEAR—ELLIPTICAL GEAR—SUN AND PLANET—FRICTION BREAKS—DYNAMOMETER—BREAKS—RESISTANCE OF FRICTION—FRICTION OF STRAPS—MOTION OF FLUIDS.

WORK AND POWER.—The communication of power is really the communication of motion, for power implies change, and change of place is motion. A column supporting a weight communicates the pressure of the weight to its foundation; and a string suspending a load from a hook, communicates its tension to the hook; but in neither of these cases is *power* communicated, for no change is effected: time forms no element in the question, the same strain being conveyed to the point of support in an instant, as in a century. But if the column or string be in motion, like the piston-rod of a steam-engine, pushing or pulling against a resisting force, not only is the pressure acting on the piston conveyed through the rod as a simple strain, but it is also conveyed through a certain distance in a certain time, or at a certain velocity, and can, by its motion, effect changes on materials presented to it, proportioned to the amount of power developed, and the time during which it acts. The *power* of any mechanical arrangement, therefore, means its capability of effecting change; while its *work* means the quantity of change effected. The most simple kind of change which we can contemplate is that of position; and we, therefore, take change of position or motion as the measure of one element of work done. The most simple notion as to quantity of change, is that of mass or weight of material moved; and we therefore take weight as the measure of another element of work. Lastly, we estimate the capability of effecting change—that is to say, power—by the time required for the work done. The greater the mass moved, the greater the distance over which it is moved; and the less the time occupied in the motion, the greater the power developed.

An engine of 10 horse-power, means an engine capable of moving 10 times the mass that can be moved by an engine of 1 horse-power over a given distance in a given time, or of moving the same mass over 10 times the distance in the same time, or of moving the same mass over the same distance in $\frac{1}{10}$th of the time. Power, indeed, is simply pressure multiplied by velocity; and if we know the pressures and velocities communicated through any trains of machinery, we compare their powers by comparing the products of these factors.

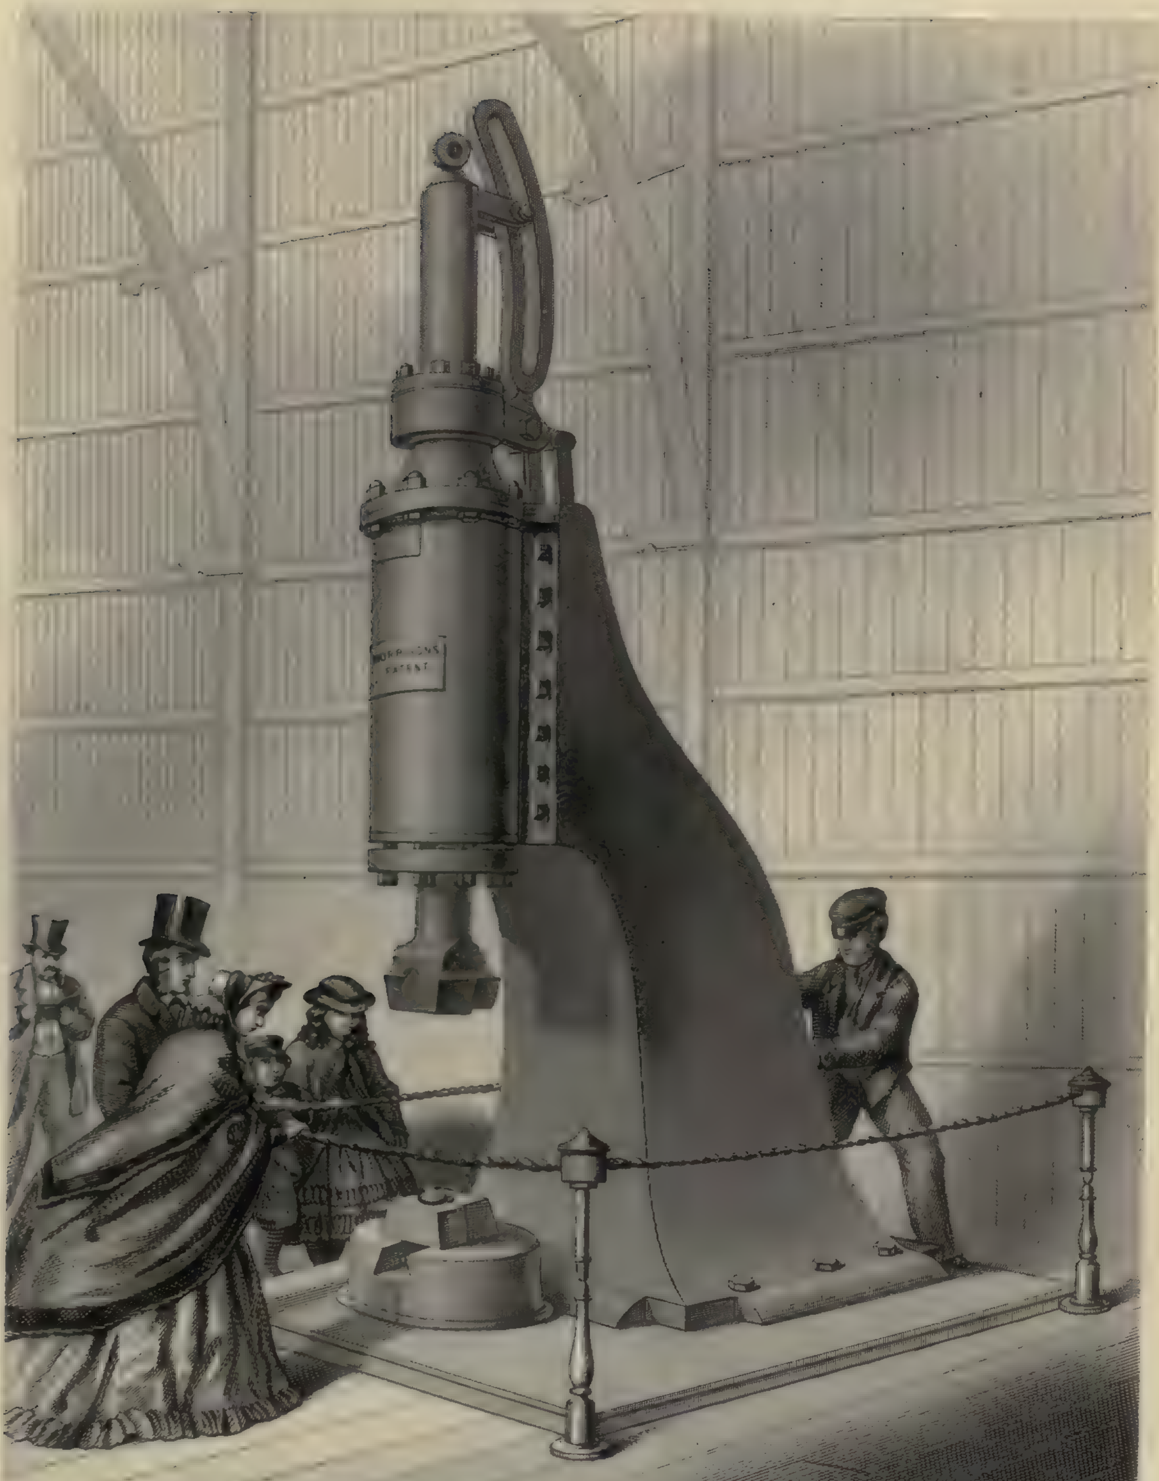
It is a simple law of mechanics, admitting of no exception, that, whatever be the nature or complication of any mechanical arrangement by which power is conveyed, whatever be the power applied to move it, the same power would be given out from every part of it, provided no waste occurred from friction. And the more perfect the construction of the machinery in respect of smoothness of rubbing surfaces, the more nearly is this law practically fulfilled.

Fig. 212.



If we take any of the simple mechanical powers, such as the lever A B (Fig. 212), capable of vibrating on the fulcrum F, we observe that when A F is equal in length to F B, a weight of 10 lbs. hung from A, balances the same weight hung from B; or, when A F is twice F C, a weight of 10 lbs. at A balances 20 lbs. at C.

Such is the law for mere pressure or weight without motion; but when we consider the question in respect of power, we have to imagine that the lever vibrates on its fulcrum, so that every point of it describes a portion of a circle round the centre F. We may suppose one such



MORRISON'S PATENT DOUBLE ACTING STEAM HAMMER.

[illegible]

[illegible]

vibration effected in a second, and that the arc described by A measures 2 feet in length, then will the arc described by C be 1 foot long; and 10 lbs. at A, moving through 2 feet in 1 second, develops the same power as 20 lbs. at C moving through 1 foot in 1 second, because 10 × 2=20 × 1; the products of the pressures by the velocities are equal in both cases. We might trace the same law through all the simple mechanical powers, and through all possible combinations of them; that is to say, through all possible arrangements of machinery.

The practical application of this law in calculating the proper strengths and proportions of parts of machines, is exceedingly simple.

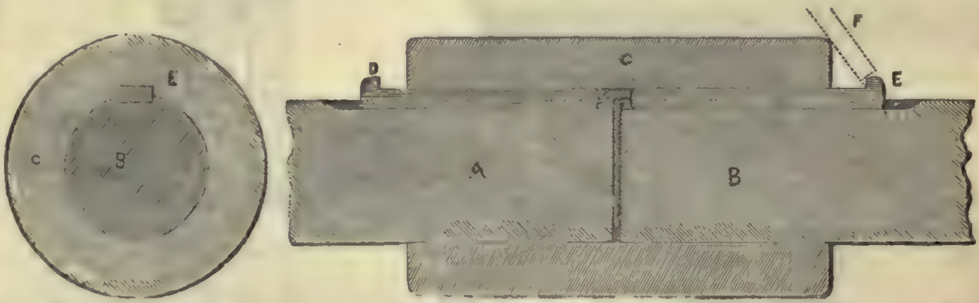
In a machine, for instance, moved by 1 horse-power, whenever we can ascertain the velocity of any part, we can find at once the pressure or strain passing through that part. One-horse power is reckoned as 33,000 lbs. moved 1 foot per minute; if, then, some part of the machine in question were found to move over 10 feet in 1 second, or 600 feet in 1 minute, we should at once know that the strain on that part is equivalent to a pressure of 55 lbs., for 55 lbs. × 600 feet=33000 lbs. × 1 foot. As a practical example, let us suppose that in some part of a machine worked by 5 horse-power, there is a wheel 7 feet in diameter, revolving 30 times in a minute, and that we desire to estimate the pressure on the rim of that wheel, or the resisting force which would have to be applied to balance its rotary force.

The circumference of a wheel 7 feet in diameter is 22 feet, and this moving 30 times round in a minute, has a velocity of 22 × 30=660 feet per minute; the power, 5-horse, is equivalent to 33000 × 5= 165000 lbs. moved through 1 foot per minute, or 250 lbs. moved through 660 feet per minute. The strain on the rim of the wheel is therefore equivalent to 250 lbs. Generally, the rule for estimating the strain (in lbs.) of any part, is to divide the power (expressed in lbs. moved over 1 foot per minute) by the velocity of the part (in feet per minute).

ROTARY MOTION.—The kind of motion most conveniently conveyed through machinery is rotary motion; and the chief subject of our enquiry will be as to how this can be conveyed and converted into motions of another kind, such as vibratory or reciprocating movements.

A shaft or spindle is a rigid bar of metal, or sometimes of wood, caused to rotate round its axis, and capable of conveying the rotary motion given to it along its whole length, and giving it off at any point to machinery connected with it. The lengths of shafts are limited in consequence of the difficulties attending their construction in great lengths. Large shafts, such as are used for the paddles of marine engines, are sometimes 20 or 30 feet long; but smaller shafts seldom exceed 10 or 12 feet in length. When greater lengths are required, the shafts have to be coupled or connected together.

Fig. 213.

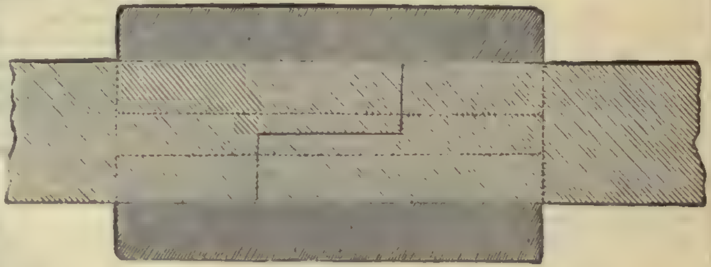


COUPLINGS.—Fig. 213 represents a simple coupling for round wrought-iron shafts. A and B, the ends of the two shafts, being nicely rounded, are inserted into a cylindrical box C bored to fit them, and having a groove or key-way cut along its interior surface, corresponding to grooves cut in the shafts. These grooves are filled by keys, D E, made slightly taper, and driven tightly in from each end. One of the shafts A being caused to rotate, must carry the coupling C round with it, and also the other shaft B, because the keys prevent either shaft from slipping round within the coupling, or the coupling from slipping round either. In making such a coupling of cast-iron, the following proportions will be found practically suitable :—External diameter of coupling double that of shaft; length of coupling three times the diameter shaft; width of key, one-fourth the diameter of shaft; mean depth of key, one-half its width.

The keys should be made with *gib-heads*, as shown in the figure, so that they may be driven out when required, by applying a piece of iron rod to the projecting part and striking it with a hammer, as marked by the dotted lines F, or by driving a wedge between the gib-head and the coupling.*

Some engineers, in coupling the shafts, halve them over each other, as in Fig. 214, and insert a tapered key in a groove formed in the coupling only, its inner surface fitting the shafts. Such a key, called technically a *hollow key*, from the hollowing or concavity of its inner surface, tightens the coupling very firmly on the shafts. The *face-coupling* (Fig. 215) consists of two discs, with projecting bosses keyed on the ends of the shafts facing each other, held together by four or more bolts and nuts passing through corresponding holes in the two discs.

Fig. 214.



Sometimes, when it is desired that by no accident shall the movement of any length of shafting be reversed, a ratchet-coupling is applied. *a* (Fig. 216) is a toothed boss, keyed firmly on the shaft *d*, and *b* a similar toothed boss capable of sliding longitudinally on the shaft *c* along a *feather* or parallel key, which prevents it from turning round independently of *c*. So long as the shaft *d* revolves in one direction, it carries the other shaft *c* round with it; but should the rotation of *d* be reversed, the pressure on the inclined faces of the teeth causes the boss *b* to slip out of gear with *a*, and thus to uncouple the two shafts.

CLUTCH.—When it is desired to couple or uncouple two lengths of shafting at pleasure, a *clutch*, like that represented in Fig. 217, is generally employed.

A, the driving shaft, on which is keyed firmly a half

* A "key," used for fixing a coupling or any other piece of machinery on a round shaft, is a piece of iron or steel of parallel breadth, but slightly tapered in thickness, so that on driving it into the "key-way" or recess provided for it, it acts as a wedge, pressing the opposite surface of the shaft against that of the hole. A "feather" is a key of equal breadth and thickness throughout, fitted into a recess in the shaft, and projecting from it into a slot formed in the hole of the coupling or other boss, which can thus slide along the shaft longitudinally, but must turn with it.

clutch C, having two projections from its face; B the driven shaft, the end of which rests in the hole of C, and on which is fitted, by a *feather* or parallel key, the other half clutch D, having also projections on its face similar to those on C. A groove is formed in D, and fitted with a ring E, put together in halves, and having pins projecting from its opposite sides, which may be taken hold of by hand or by a lever. The half clutch D being capable of sliding on the shaft B, can, by means of the ring, be pushed in or out of gear with C; and as the feather prevents it from turning on its shaft, when the projections on it are inserted between those in the other half clutch, the shaft B is caused to revolve by the rotation of A. Sometimes, when it is desired that the strain passing through any shaft shall be limited, recourse is had to *friction-clutches*. A very common mode of forming a friction-coupling is to key on one length of shaft, a boss with a conical hole bored in its face, and on the other to fit by a feather, a conical boss fitting nicely into the conical hole. When the one is pressed into the other, the friction of the conical surfaces causes them to revolve together; but should an excessive resistance be opposed to the rotation of the driven shaft, the friction of the surfaces proves insufficient to overcome it, and the cone on the driving shaft slips round that on the other without driving it.

Fig. 215.

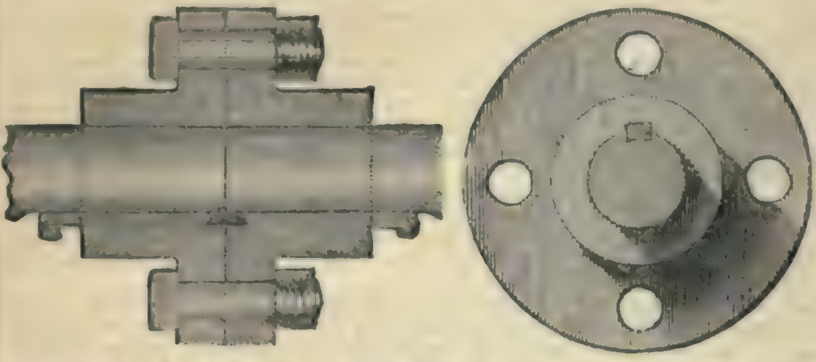


Fig. 216.

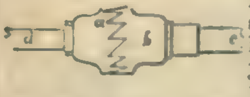

Fig. 217.

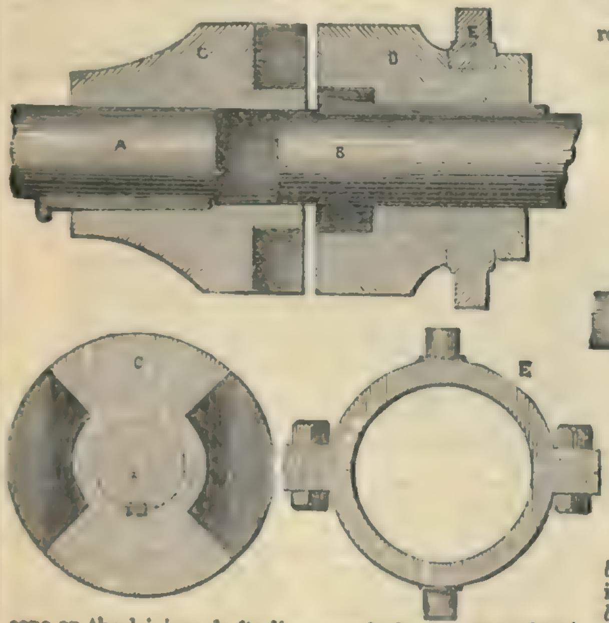
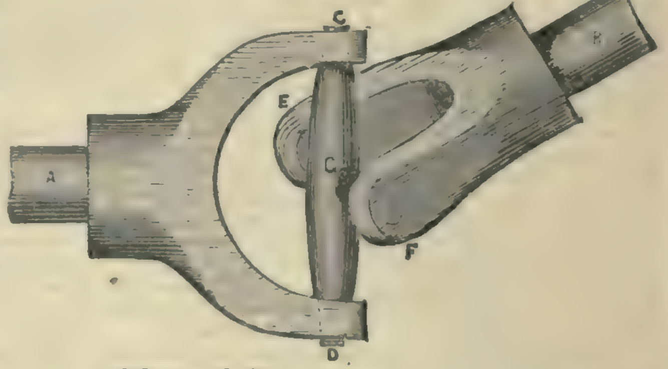


UNIVERSAL JOINT.—When two shafts, not lying in the same straight line, are to be coupled, recourse is had to a universal joint. On each of the two shafts A and B (Fig. 218) is keyed a fork, in the ends of which, at C, D, E and F, are pivoted the ends of a cross G, so as to permit its partial rotation on either of its two axes C D or F E. On A being caused to revolve, the cross is carried with it round its centre G, and its ends E F also rotate round the same centre, giving rotary motion to the other fork and shaft B, the pivoting of the cross permitting it to accommodate its position to the varying obliquity of the forks during their rotation.

When two shafts are not quite in the same straight line, but nearly so, they may be coupled by cranks. The shaft A (Fig. 219) has a crank C and pin keyed on to it, and the shaft B has also a crank D, with a slot cut in it to receive the crank-pin of C. The pin must be sufficiently long to allow for the departure of the two cranks from each other by obliquity of position (as indicated by the dotted lines representing them at the opposite point of their revolution); and the length of the slot must be such as to allow for the difference of level of the two shafts.

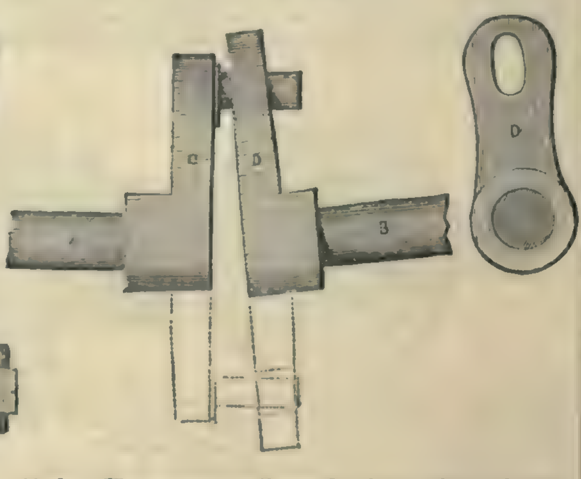
Fig. 218.



PLUMMER-BLOCKS.—The bearings in which shafts revolve, are technically called *pillow-blocks* or *plummer-blocks*. They are generally made of two pieces of cast-iron, the *base* A, and the *cap* B, lined with gun-metal *bushes* C, each half a cylinder (Fig. 220).

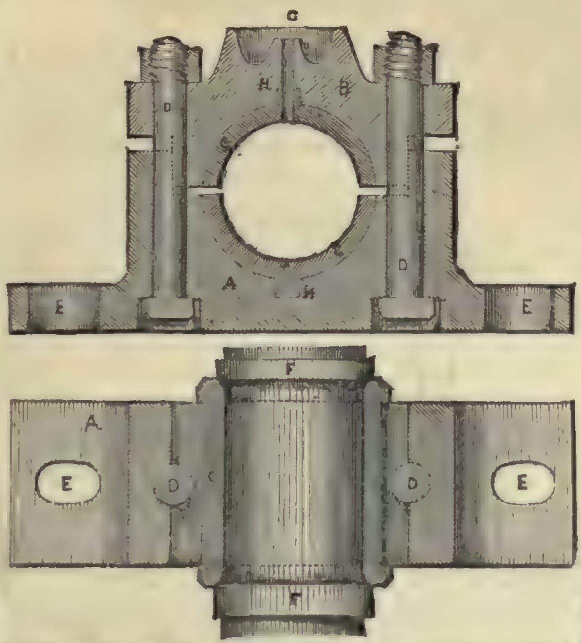
The base is recessed to receive projecting parts of the cap; and two bolts D, with nuts at their upper ends, pass through holes in both, so as to secure the cap firmly

Fig. 219.



on the base when the shaft has been laid in its place. The base has projecting flanges, with holes E, through which bolts pass for securing the *plummer-block* to the beam or frame on which it may be fixed. These holes are lengthened to permit a little transverse adjustment of the plummer-block. The cap has generally an oil-cup in its upper part, with a projecting nipple perforated, through which a cotton wick conveys a supply of oil to the surface of the shaft, acting like a siphon by capillary attraction. The *brasses* C are sometimes made square or octagonal in their outer surfaces, to prevent them from turning round within the plummer-block ; or, when they are quite cylindrical, small studs or steady-pins H, projecting from them into holes in the cap and base, answer the same purpose. The shaft has collars F, or parts of larger diameter outside the brasses, and the brasses have lips or flanges, to prevent the shaft from moving longitudinally. As the shaft or brasses wear from the constant friction, the cap and upper brass can be more tightly screwed down by the nuts of the bolts D, which are often made double, so that the one nut tightens the other in its place, and prevents it from becoming loosened by the shaking of the machinery.

Fig. 220.



Of late years, many bearings, instead of being fitted with gun-metal bushes, have been lined with a soft metal, in which tin is the principal ingredient.

Fig. 221 represents a transverse section of a bearing lined with soft metal ; A the cast-iron cap, and B the base, cast with a hole larger than the shaft. D D soft metal linings, filling the space between the surface of the shaft and that of the cast-iron. The shaft, or a piece of iron of equal size, being supported in the hole of the bearing, the soft metal, melted, is poured into the space ; and if the iron have been previously heated to nearly the melting temperature of the soft metal, the latter, on cooling, presents a smooth internal surface, in which the shaft revolves with little friction or wear. When it is inconvenient to form collars on the shaft to prevent longitudinal motion, rings E, bored to fit the shaft, are put on, and kept in their places by tightening-screws pressing against the shaft.

Fig. 221.

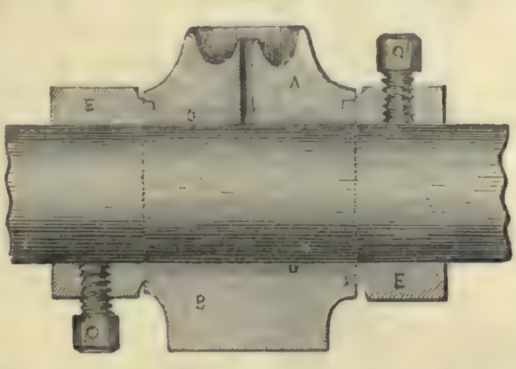


Fig. 222.

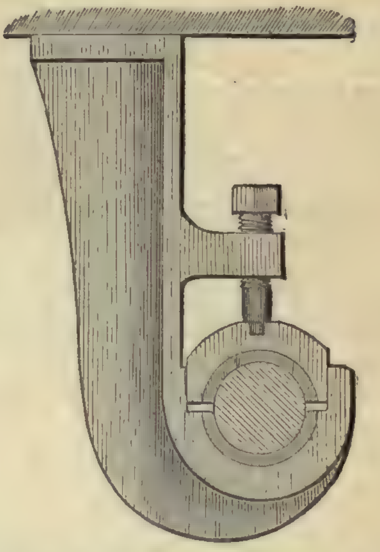

When it is not convenient to rest a shaft in plummer-blocks supported on walls or beams, they may be made to revolve in hanging bearings screwed up to a beam above. These bearings may be lined as plummer-blocks, with gun-metal or soft metal, and the cap tightened down by a setting-screw, as indicated in Fig. 222.

PULLEYS OR DRUMS.—When it is desired to convey motion from one shaft to another lying parallel to it, each shaft has a *pulley* or *drum* attached to it, and round their circumferences a flexible strap or band is tightly strained. Thus *e* and *f* (Fig. 223) being parallel shafts at some distance apart, a pulley *a* is keyed on the one, and a pulley *b* on the other, the flexible strap passing round both. On rotary motion being given to the shaft *a* and its pulley, the friction between the strap and its circumference puts the former in motion, and it conveys the rotation to *b* and its shaft in the same direction.

Fig. 223.

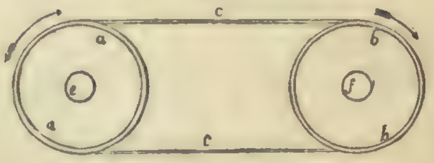

Fig. 224.

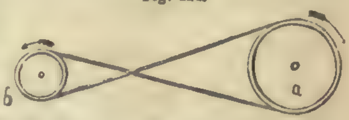


When it is desired to reverse the direction of rotation, the strap is crossed (Fig. 224). Also when a different angular velocity of rotation is desired, the pulleys are made of different sizes. If we suppose that the driving pulley *b* has a circumference of 6 feet, and the driven pulley *a* circumference of 3 feet, half the former ; since the strap travels at the same rate with the circumference of the driving pulley, and causes the circumference of the driven pulley to move round with equal velocity, it is clear that the latter must make two revolutions round its axis while the former makes one ; or that the angular velocity of the smaller pulley is just double that of the larger, because its circumference is half the length. If we take the circumferences in any other ratio, we should find the angular velocities in the inverse ratio. As the circumferences of circles are exactly proportional to their diameters, the angular velocities of pulleys connected by straps are inversely as their diameters, or the diameter of each pulley, multiplied by its speed, gives a like product. In calculating the speeds due to given dimensions of pulleys, or the dimensions suited for given speeds, we have therefore the following simple rules :—

Given the angular velocity of one of two pulleys (*i. e.*, the number of revolutions per minute), and the diameters of both, to find the speed of the other.

Rule.—Multiply the speed of the first by its diameter, and divide by the diameter of the other.

Example.—A pulley 36 inches in diameter, making 80 revolutions per minute, drives a pulley 24 inches in diameter : required the speed of the latter.

$$\frac{80 \times 36}{24} = 120 \text{ revolutions per minute.}$$

Given the angular velocities of two pulleys and the diameter of one, to find that of the other.

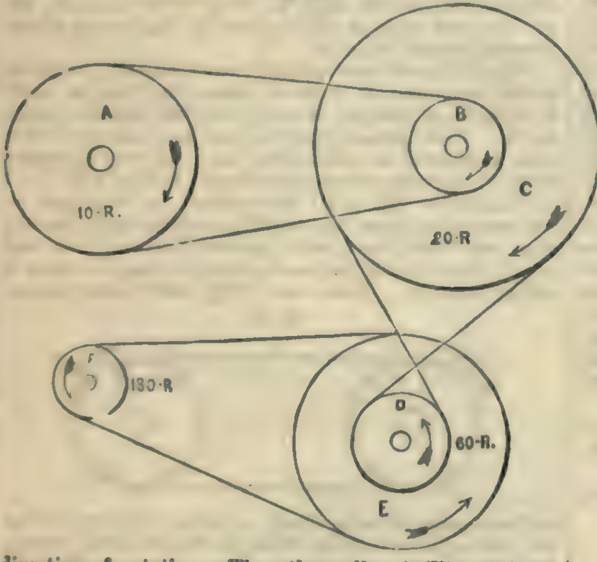
Rule.—Multiply the speed of the first by its diameter, and divide by the speed of the other.

Example.—A pulley 24 inches diameter, making 120 revolutions per minute, drives another at 80 revolutions per minute : required the diameter of the latter.

$$\frac{120 \times 24}{80} = 36 \text{ inches.}$$

Pulleys are often combined with direct or crossed straps, as may be required, in order to vary the velocity and direction of rotation. Thus the pulley A (Fig. 225), 24 inches diameter, revolving at the rate of 10 revolutions per minute, drives B, 12 inches diameter, at 20 revolutions, because $\frac{24 \times 10}{12} = 20$. On the shaft of B is fixed a pulley C, 36 inches diameter, revolving at the same speed with B, and driving D, 12 inches diameter, by a crossed strap at 60 revolutions, because $\frac{20 \times 36}{12} = 60$. Again, on the shaft of D is another pulley E, 27 inches diameter, revolving with a speed of 60, and driving F, 9 inches diameter, at a speed of 180, because $\frac{60 \times 27}{9} = 180$.

Fig. 225.



In estimating the final speed produced by such a train of pulleys, it is not necessary thus to calculate the velocity of each, as we find the same result by multiplying the initial speed of the driver A, by the product of the diameters of all the drivers A, C, and E, and dividing by the product of the diameters of those driven, B, D, and F ; or

$$\frac{10 \text{ revols.} \times 24 \times 36 \times 27}{12 \times 12 \times 9} = 180 \text{ revolutions, the speed of F.}$$

Sometimes, when it is desirable to have the power of varying the speed of machinery driven by a strap, the pulleys are elongated and made conical, and the strap is shifted longitudinally to such a position as shall give the speed required. Thus, if *a a* be the driving-shaft, revolving 24 times per minute, and it be desirable that *b b* shall be driven at any speed from 8 to 72 revolutions per minute, each pulley being made conical with the larger end 3 times the diameter of the smaller, the strap *c* may be shifted from one end to the other to give the desired variation of speed. Nor is the tightness of the strap materially altered ; for as it is made to pass round a larger circumference of the one, it passes round a smaller circumference of the other, and so gains nearly as much as it loses. Most of the machines that are driven by straps do not require so nice an adjustment of velocity, but act very well at various speeds within certain limits. In such cases the conical pulleys are made with regular steps, or consist each of a set of pulleys placed side by side, having diameters increasing as much in the one as they decrease in the other (Fig. 227). Thus, if the driving-shaft make 48 revolutions per minute, the driven shaft may be made to revolve at the following different speeds :—

Fig. 226.

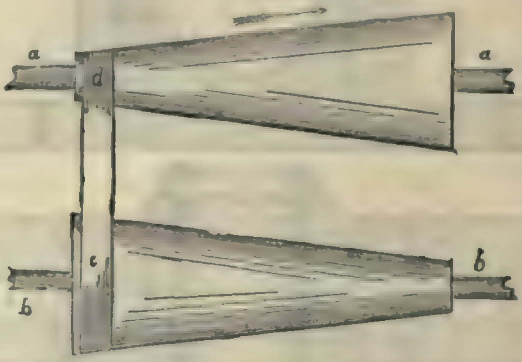


Fig. 227.

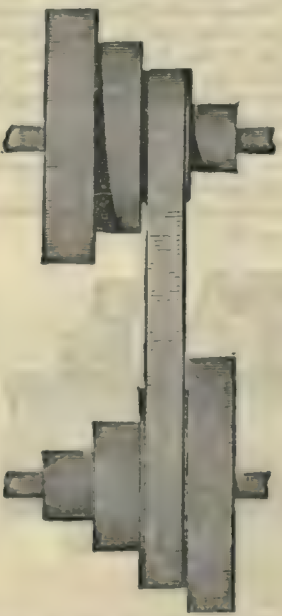

Fig. 228.

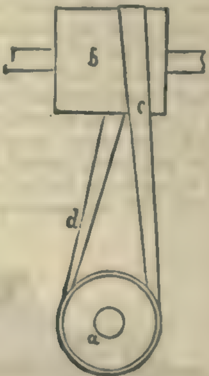

$$\frac{48 \times 16}{4} = 192,\ 48 \times \frac{12}{8} = 72,$$

$$48 \times \frac{8}{12} = 32, \text{ and } \frac{48 \times 4}{16} = 12$$

revolutions per minute; the diameters being 16, 12, 8, and 4 inches in each.

Occasionally, a strap may be employed when it is desired that the motion shall be changed transversely, as indicated in Fig. 228. In such a case it is necessary to have very wide pulleys, *a* and *b*, because the two parts of the strap *c* and *d* must pass obliquely over their surfaces. This mode of employing a strap is, however, very disadvantageous, for the strap must be continually slipping longitudinally along the face of each pulley, and thereby be subjected to friction and wear.

In a manufactory where numerous machines are employed, it is essential to have a ready means of throwing any of them into action or out of action at pleasure. When the machine is driven by a strap, this operation is conveniently effected by what are called the *fast* and *loose*, or the *live* and *dead* pulleys; that is to say, two pulleys of equal size placed side by side on the shaft, one being firmly fixed to the shaft by a key so as to revolve with it, while the other revolves freely on the shaft. When it is desired to put the machine in action, the band is put on the *fast* pulley, and thus gives motion to the shaft or receives motion from it. For throwing the machine out of action, the band is shifted to the circumference of the *loose* pulley, which revolves idly on the shaft. The shifting of the strap from the one pulley to the other is effected by means of the *striking gear*, a forked lever *f e d* (Fig. 230) moving on a pivot *e*, and holding the strap *c* within its forked part *d*. By pulling round the handle *f* of the lever, the band, being pressed edgeways by one side of the fork, is pushed gradually on to the fast pulley *a* or the loose pulley *b* at pleasure. It would be difficult thus to shift a tight strap when at rest; but while it is in motion, with the pressure of the fork directed on it, it is gradually edged off from its former position. For this reason, the *fast* and *loose* pulleys should always be placed on the *driven* shaft, because, were they placed on the *driving* shaft, the band when on the *loose* pulley, being at rest, could not easily be shifted.

Fig. 229.

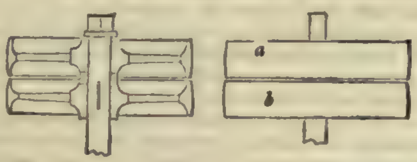

Fig. 230.

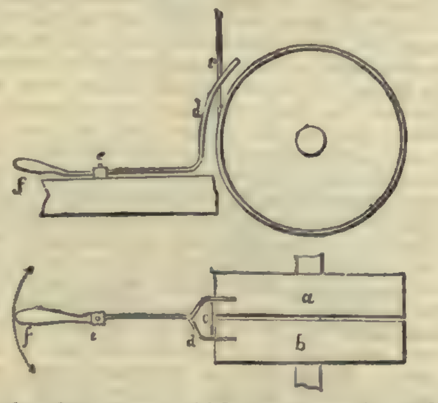
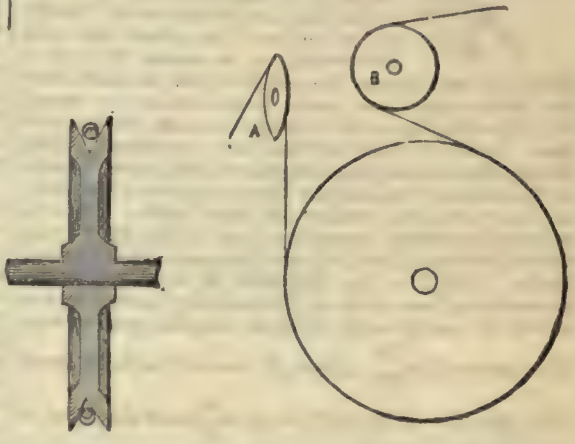


In order that straps, which are generally made of leather, india-rubber, or *gutta-percha*, may act well without slipping ineffectively along the surfaces of the pulleys, they should be tightly strained into their place. The pulleys should be turned true and smooth on their circumferences; for the smoother the pulley, the more driving friction appears to take place between its surface and that of the strap. When the strap is not sufficiently tight, or does not take sufficient hold of the pulley to drive the machinery with which it is connected, it must be made of greater breadth, and strained more tightly. Sometimes, when a strap slips, powdered resin is strewn upon its inner surface with good effect. The greater the arc of the circumference which a strap embraces, the firmer is its hold, or the less tendency has it to slip; and the greater the width of the strap, the firmer also is its hold. The diameter of the pulley does not affect the slip of the strap, except when the diameter is very small; while the strap is rigid, and not easily bent closely round the circumference.

Were straps perfectly flexible, it would be found that, with a given breadth and tightness, the driving power would be the same for all diameters of pulleys.

It is often convenient to use cylindrical bands or cords, made of catgut, or gutta-percha, instead of flat straps (Fig. 231). In such cases, the pulley is grooved in the circumference, and the band wedges itself into the groove, and thus exerts sufficient friction on the circumference for the communication of power from one pulley to another. The principal advantage of bands of this kind is, that by means of guide pulleys, A and B, grooved in the circumference, the band may be led in almost any direction on the plane of the pulley, or oblique to it.

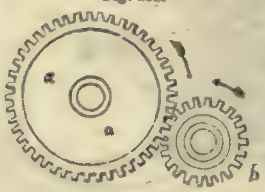
Fig. 231.



Straps are best suited for machinery driven at high speeds, with small pressures; they are cheap, convenient, and smooth and noiseless in their action; and when any undue strain comes upon the machinery, they slip, and thus act as a safeguard against damage. But for all machinery intended to communicate heavy strains through their parts, as in cranes, and whenever certainty of connection between one moving part and another is required, as in clockwork, recourse must be had to *gearing*, or toothed wheels.

TOOTHED WHEELS.—Were we to mount two wheels on parallel axes, so that their circumferences touch each other, by causing the one to revolve we should also cause the other to revolve, provided the friction between their surfaces at the point of contact were sufficient to overcome such resistance as might be presented to the rotation of the driven wheel. Practically, this friction is not sufficient in ordinary cases, and it becomes necessary to fit the circumferences with teeth or cogs, or projections and recesses at corresponding intervals, so that each tooth of the one fits successively in each recess of the other. By this arrangement, the direction of rotation is reversed, as indicated by the arrows in Fig. 232. When it is desired that the direction of rotation be retained the same, it is twice reversed by the intro-

Fig. 232.



duction of an intermediate wheel *b* (Fig. 233). Sometimes wheels are geared internally (Fig. 234), where *a* is a portion of the one, and *b b* part of the circumference of the other. In this case, the direction of rotation is not reversed.

Fig. 233.

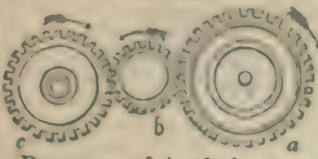


Fig. 234.

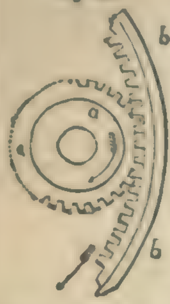
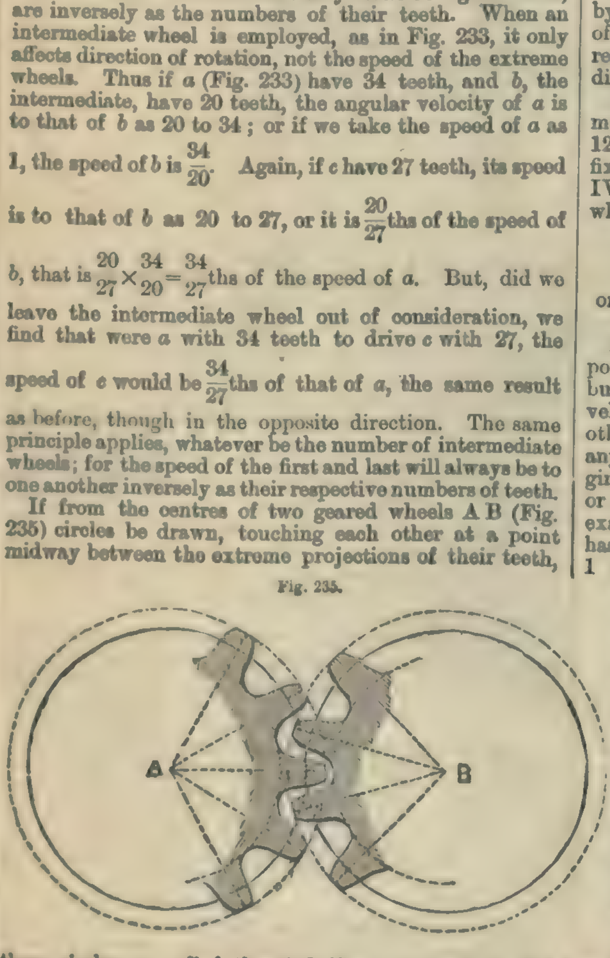


By means of toothed gearing, the angular speed of rotation may be altered at pleasure, as will be evident from the following considerations. The larger wheel (Fig. 232) has 45 teeth, and therefore, during each revolution, presents 45 successive recesses for the teeth of the smaller pinion, which number 22. For every revolution of the wheel, therefore, the pinion must make 2 revolutions and advance the space of 1 tooth, because $2 \times 22 + 1 = 45$; during 2 revolutions of the wheel, the pinion makes 4 revolutions and 2 teeth; and so on, until the wheel has made 22 revolutions, or caused $22 \times 45 = 990$ of its teeth to pass the point of gear, in which time the pinion must have made 45 revolutions, or caused $45 \times 22 = 990$, the same number, to pass the point of gear. And so it would be found with any other number of cogs, that the angular velocities of the geared wheels, or the number of revolutions they make in a given time, are inversely as the numbers of their teeth. When an intermediate wheel is employed, as in Fig. 233, it only affects direction of rotation, not the speed of the extreme wheels. Thus if *a* (Fig. 233) have 34 teeth, and *b*, the intermediate, have 20 teeth, the angular velocity of *a* is to that of *b* as 20 to 34; or if we take the speed of *a* as 1, the speed of *b* is $\frac{34}{20}$. Again, if *c* have 27 teeth, its speed is to that of *b* as 20 to 27, or it is $\frac{20}{27}$ths of the speed of *b*, that is $\frac{20}{27} \times \frac{34}{20} = \frac{34}{27}$ths of the speed of *a*. But, did we leave the intermediate wheel out of consideration, we find that were *a* with 34 teeth to drive *c* with 27, the speed of *c* would be $\frac{34}{27}$ths of that of *a*, the same result as before, though in the opposite direction. The same principle applies, whatever be the number of intermediate wheels; for the speed of the first and last will always be to one another inversely as their respective numbers of teeth.

If from the centres of two geared wheels A B (Fig. 235) circles be drawn, touching each other at a point midway between the extreme projections of their teeth,

Fig. 235.



these circles are called the *pitch* lines or circles of the teeth, and their circumferences being equally divided, give the intervals from tooth to tooth in each, or what is technically called the *pitch* of the teeth. When we speak of a wheel of 1 inch *pitch*, or 2 inches *pitch*, we mean that the distance measured from the centre of one tooth to that of the next (these centre points being taken on the pitch circle) is 1 inch or 2 inches, as the case may be. In Fig. 235, the distance between any two adjoining points, where the dotted radii from A and B cut the pitch circles, is the *pitch* of either wheel, and these *pitches* are necessarily equal in length, in order that the wheels may gear. But as this distance is the interval between the central points measured in a straight line, or along the chord of the small arc intercepted between them, it does not accurately correspond to the length of the arc. The larger the circle of which the arc is a portion, and the smaller the pitch or portions into which the circumference is divided, the more nearly do the circular arc and its chord approach to equality. Accordingly, in cases of nearly equal wheels, or whenever the pitch is small in proportion to the dimensions of either wheel, the more nearly do the numbers of teeth express the proportions of the circumferences. But the circumferences of circles being exactly proportional to their diameters, the numbers of teeth are very nearly in the same proportion; and the angular velocities of geared wheels are therefore inversely as the diameters of their pitch circles.

When there is a train of geared wheels, so arranged that the first shall drive the second—that the third, fixed on the shaft of the second, shall drive the fourth—the fifth, fixed on the shaft of the fourth, shall drive the sixth, and so on—we readily find the angular velocity of any wheel in the train thus.

Rule.—Multiply the angular velocity of the first driver by its number of teeth or diameter, and by the numbers of teeth or diameters of all the drivers, and divide the result by the product of the numbers of teeth or the diameters of all the driven wheels.

Example.—Wheel I., 36 inches diameter with 72 teeth, making 120 revolutions per minute, drives wheel II., 12 ins. diam. with 24 teeth; on the shaft of wheel II. is fixed wheel III., 10 ins. dia. with 30 teeth, driving wheel IV., 6 ins. diam. with 18 teeth: required the speed of wheel IV.

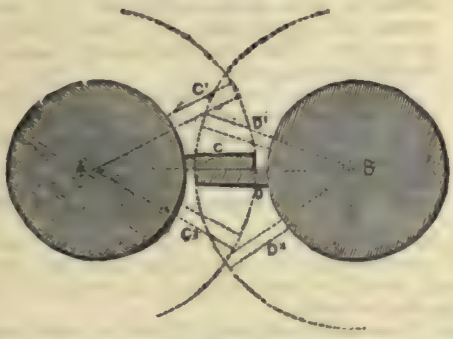
$$\frac{120 \text{ rev.} \times 36 \text{ ins.} \times 10 \text{ ins.}}{12 \text{ ins.} \times 6 \text{ ins.}}$$

$$\text{or } \frac{120 \text{ rev.} \times 72 \text{ teeth} \times 30 \text{ teeth}}{24 \text{ teeth} \times 18 \text{ teeth}} = 600 \text{ rev. per min.}$$

From the general principle of mechanics, that no power can be gained or lost in any train of mechanism, but that only the two elements of power, pressure and velocity, can be interchanged, irrespective of friction or other useless resistances, it follows that, at the end of any train of wheels, the power is the same as at the beginning; but the velocity being different, the pressure or strain on the teeth must be different also. In the example we have given, if we suppose that 1 horse-power has given motion to wheel I., we should expect to get 1 horse-power from wheel IV.; but as the speed of wheel IV. is five times that of wheel I., so the pressure exerted by it at any point is $\frac{1}{5}$th of that exerted by wheel I. at a point equally distant from its axis. To show that this is true, not only in general terms, but in the particular case, we shall suppose 1 horse-power passing through the teeth of wheel I., 18 ins. from its axis. The teeth of wheel II. being in contact with those of wheel I., receive its full power at 6 ins. from its axis, and convey it through its shaft to the teeth of wheel III., distant 5 ins. from its axis, and, therefore, sustaining a pressure of $\frac{6}{5}$ths of the original pressure. Again, this strain being given to the teeth of wheel IV. at 3 ins. from its axis, is equivalent to $\frac{3}{18}$ths of $\frac{6}{5} = \frac{1}{5}$th of the original pressure estimated at 18 ins. from the axis of the last wheel. In any train of wheelwork, then, we may safely diminish the sizes and strengths of the teeth as their velocity increases; and, conversely, we should increase their strengths as the velocity diminishes.

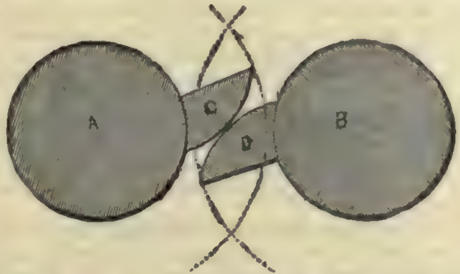
FORMS OF TEETH.—One of the most important matters connected with toothed wheels refers to the forms or outlines of the teeth. It is to be desired that engineers generally should determine on some standard form, so that all wheels of equal pitch should work or gear properly together. Unfortunately this is not the case: the wheel made by one machinist is unsuited to that made by another. It often becomes necessary to make costly patterns of wheels to suit some that may have been already made; these patterns, again, are not suited for other cases; and thus a great amount of time, labour, and material is misapplied in a matter where a little harmony among the views of machinists might do much to avoid these evils. That such a mutual understanding is not impossible, may be proved by the fact, that in a similar case, that of screw-threads, among which there once existed quite as great a variety, almost all engineers now adhere to certain forms and proportions; so that the screw which fits one nut, readily fits any other nut of equal diameter, wherever the screw or the nut may have been manufactured. Perhaps the principal cause of difference in the forms of teeth, has been the want of knowledge among practical men as to what the true forms should be. Much has been written on this subject, but a great deal is of too abstruse a character to be generally understood or appreciated; and the practical mechanic, desiring information, is discouraged by the difficulties with which the subject appears to be invested. We will endeavour to point out, as simply as possible, the laws which should govern the forms of teeth, and to lay down a few easy rules for delineating and executing them.

Fig. 236.



If we suppose A and B (Fig. 236) to be the bosses or central parts of two wheels having straight teeth or flat blades C and D projecting from them respectively, on tracing several positions of these, such as C C_2 and D_1 D_2, we observe that there must be considerable inequalities in their relative movements; or if C_1 C_2 make equal angles with the line of centres A B, D_1 and D_2 do not make equal angles with the same line. Again we observe that the points of each tooth must rub along the flat surface of the other in the course of the motion; and were this form of tooth practically carried out, the cutting and wear would be considerable. But if, as in Fig. 237, the wheel B have a tooth D of some curved outline, we may perhaps find some particular curve for the face of tooth C, such that an equable movement of the one wheel shall produce an equable movement of the other, and that the surfaces of the two teeth shall rather roll along each other than rub with a pushing or sliding movement. Now, although it may be generally possible to find a proper form for C, whatever be the form of D, yet it is desirable for many reasons that both these curves should be traced according to some fixed type, which shall be constant, whatever the dimensions of the wheels or their numbers of teeth. If we examine somewhat closely the relative motions of two toothed wheels, we may perhaps discover an appropriate form for their teeth.

Fig. 237.



INVOLUTE TEETH.—If A B (Fig. 238) represent a strap passing round the circumferences of two equal pulleys, and therefore touching both, and if through C, the middle point between their centres, two circular arcs be described, these may represent the pitch circles of two equal toothed wheels, whose relative rotation should be precisely the same from the gearing as it is from the motion of the strap, unwinding from the one pulley and winding on to the other. But farther, if we continue the lines A B and D E, and from some other point F in D E describe a circle touching A B in G, and another circle (dotted) through the point C;—since F C bears the same ratio to C E as F G to E B, it appears that the rotation of the large wheel, if geared with the other at C, should be precisely the same as if it were caused by the strap winding on to its pulley, of which F G is the radius. If we assume the angular velocity of the pulley D to be uniform, the rectilineal velocity of the strap A B G must also be uniform, and likewise the angular velocities of the wheels E and F. Whatever, then, be the relative sizes of the geared wheels, the rectilineal motion of the strap, with relation to the rotary motion of any one of them, is always constant; and if from this relation we can trace out a form of tooth, that form will apply in all cases, whatever be the diameters of the wheels that are geared together.

Fig. 238.

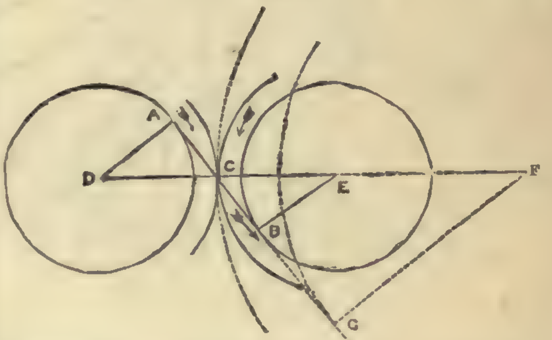


Fig. 239.

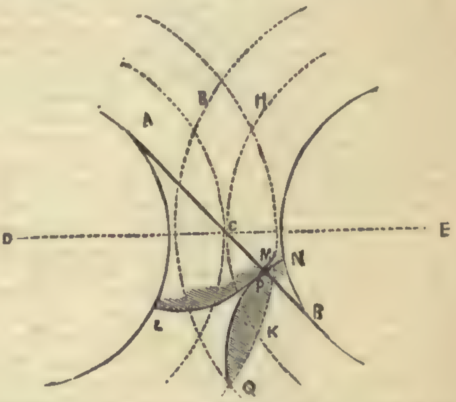
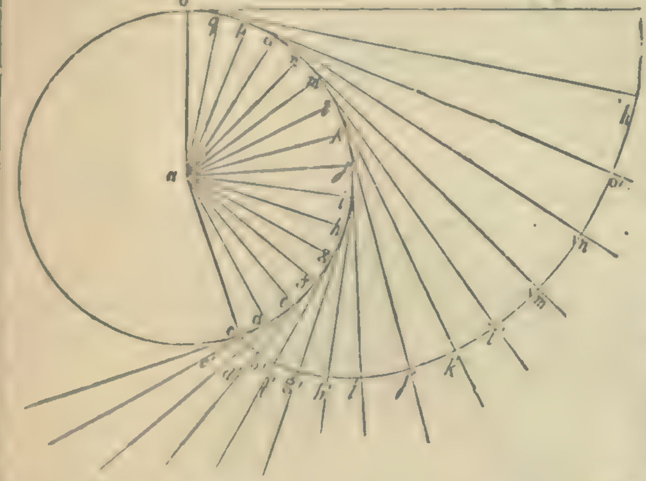


In order to avoid complexity, let us first take one wheel, supposing it a circular disc of paper, of which H M K (Fig. 239) is a portion, and let us suppose that the strap A B has a pencil projecting from it at some point P, so that as the disc rotates while the strap travels, the pencil shall trace on the disc a line L P M, compounded of these two motions. If, now, we take the other wheel (marked by the dotted lines), and suppose its disc extended to R Q overlapping the former, the same pencil would trace a corresponding line N P Q on it. Now, as the curves thus produced are traced by the same point in the band, and under precisely similar conditions of uniform rotation, we might cut the paper discs to their outlines, and making them rotate in contact, we should obtain that uniform relative motion which is required. The mathematical name of each of the curves so described is the *involute of the circle*, because it is produced by the point of a thread wound on to (or a circle, or wound off from a circle. The nature of the curve may be best understood by a reference to Fig. 240.

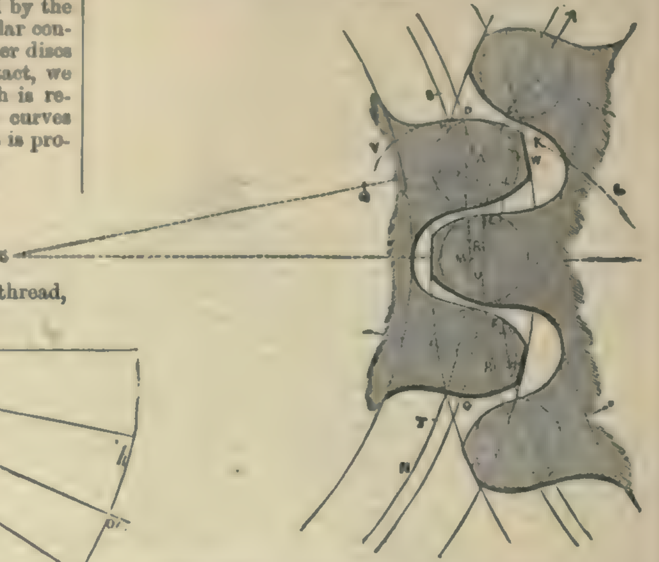
If *a* be the centre of a circle or plan of a roller, on which is wound a thread having its end at *c*, a pencil or tracing point being fixed at the end of the thread,

Fig. 240.



will trace the involute *c* to *q′*, as the thread is unwound; or *b q′* being the unwound thread, its point will trace the involute back to *c* as it is wound round the circle. If we divide the circumference into any number of equal parts at *d*, *e*, *f*, *g*, &c., and from these points draw tangents or lines touching the circle, at right angles to the radii *ad*, *ae*, *af*, &c., respectively, making the lengths of the tangents equal to the lengths of circumference measured round from *c*, the curve joining the extremities of the tangents is the involute—the proper outline for the teeth of wheels that we have just described. In applying this theory to the practical formation of teeth, we do not find it necessary to describe the actual involute form, because the portion of the curve that belongs to any tooth is so small, that we can draw a circular curve so near to the involute as to cause no material error in working. Thus, if C (Fig. 241) be the centre of the wheel, and A, B the centres of two adjoining teeth on the pitch circle, small circles being described round those centres to fix the breadth of each tooth D E and F G, and H M N being part of the generating circle of the involutes, the portion H K of any involute H K L very nearly corresponds with a circular arc of which M is the centre, and the radius D M is a tangent to the generating circle H M N at M. In practice, therefore, it is only necessary to determine the circle H M N, and the length of the radius D M, for describing the curved sides of the teeth. From what has preceded, it is clear that we may take any convenient generating circle H M N, but that whatever be the one we may select for any one wheel, that for any other wheel gearing with the former must be proportional to it. It is found practically convenient to make the radius D M, with which the side of the tooth is described, $\frac{1}{4}$th of the pitch radius C A, and the generating circle or locus of centres H M N should be described within the pitch circle, the interval between them A P being $\frac{1}{8}$th of D M or $\frac{1}{32}$nd of C A. If this rule be adhered to, all wheels of equal pitch will gear with one another, whatever be their diameters. In drawing or setting out teeth, then, the following process will be found convenient.

Fig. 241.



1st. From the centre C, with radius C A, describe the pitch circle, and divide it by the compasses into equal parts, A B, each equal to the given pitch. The pitch radius may be determined by the following rule:—

Multiply the number of teeth by 7 times their distance apart, or pitch, and divide by 44.

Example.—Required the pitch radius of a wheel having 28 teeth of $\frac{3}{4}$ inch pitch.

$$\frac{28 \times \frac{3}{4} \times 7}{44} = 3{\cdot}341 \text{ inches the pitch radius.}$$

NOTE.—When the number of teeth is small, and their pitch considerable, the pitch radius must be a little increased, as will be found necessary on trying the division of the circumference.

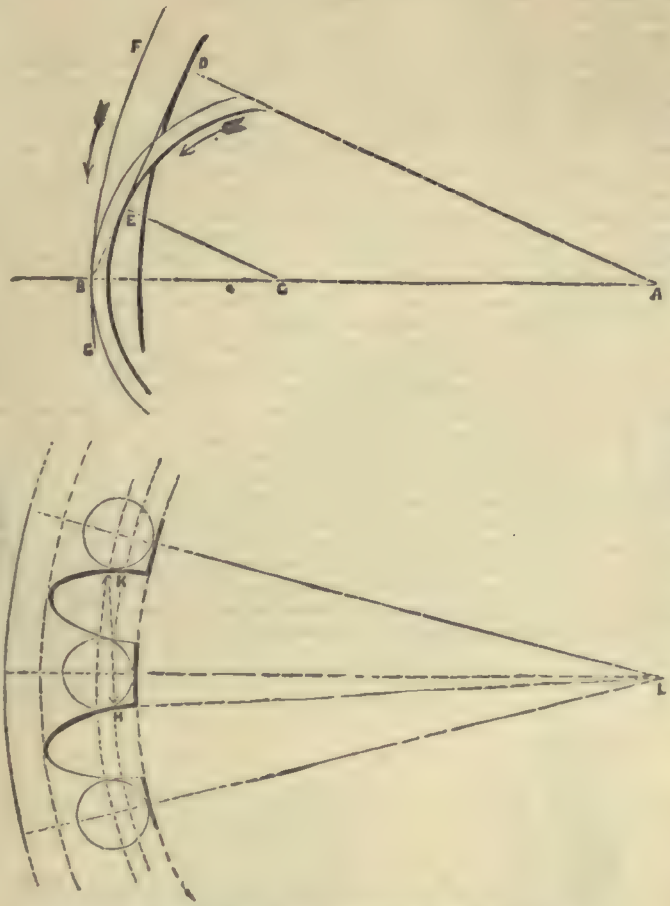
2nd. Round the centres A, B describe circles, each of diameter somewhat less than half the pitch: to determine the breadth of the teeth. The reason for making the breadth of teeth less than half the pitch, is to give a little room or clearance in the spaces between them, so that in the event of slight irregularities occurring in the workmanship, the teeth of two wheels may not become bound or locked into each other. When the teeth are cut by machinery to their exact form, this clearance is not necessary; but when they are merely cast and not shaped afterwards, there should be an allowance of about $\frac{1}{32}$nd of an inch for each inch of pitch—that is to say, if A B be 1 inch, D E should be $\frac{1}{2}$ an inch, wanting $\frac{1}{32}$nd of an inch, or $\frac{15}{32}$nds of an inch, while E F is $\frac{1}{2}$ of an inch and $\frac{1}{32}$nd of an inch, or $\frac{17}{32}$nds of an inch. Were A B 2 inches, then D E would be $\frac{15}{16}$ths of an inch, and E F $\frac{17}{16}$ths of an inch, and so on in like proportion.

3rd. Take A Q = $\frac{1}{4}$ of A C, and A P = $\frac{1}{8}$th of A Q, and from the centre C describe through P a circle of centres H M N.

4th. From the points D, E, F, G, with radius A Q in the compass, mark off the points R, S, T, U on the circle H M N, and from these points as centres, with the same radius A Q, describe the curved sides of the teeth as V H D K.

5th. It now only remains to determine the tops of the teeth and the bottoms of the spaces between them. The spaces should have somewhat greater depth below the pitch circle than the height of the teeth beyond it, to allow the teeth to clear; and it is convenient both for giving strength of form to the teeth and for providing this clearance of the teeth, especially in case of dirt getting between the gearing, to make the bottom of the spaces semicircular. It will be found convenient to make A W, the height of the point of the tooth above the pitch circle, half the space E F between two teeth, and A K the depth of the space below, greater than A W by $\frac{1}{8}$th of an inch for every inch of pitch; and circles described through W and X will determine the tops of teeth and bottoms of spaces.

Fig. 242.



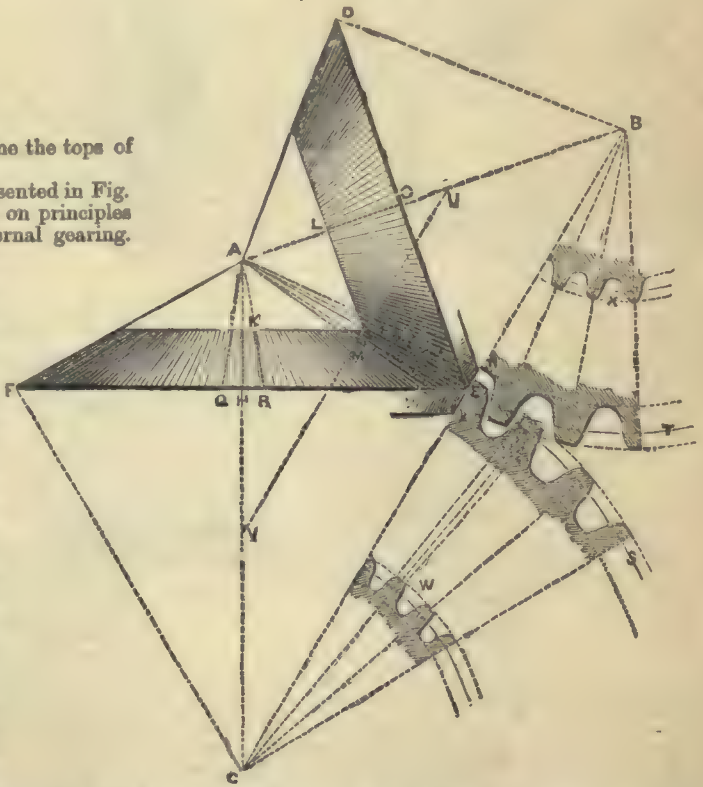
In the case of internal gearing (as represented in Fig. 242), the form of teeth may be developed on principles similar to those we have adopted for external gearing. If A B (Fig. 242) be the pitch radius of the wheel, F B G being a portion of the pitch circle, and C B the pitch radius of the pinion working within it, and if on the axes of the wheel and pinion we suppose pulleys to be fixed, having radii A D and C E, respectively proportional to the pitch radii, a band E D winding off the one and on to the other pulley would give them the same relative angular velocities as would be produced by the friction of their circumferences at B. And D E, the common tangent of the two pulleys, which, when prolonged, must always pass through B, may be supposed to have a pencil fixed to its prolonged part, tracing on the planes of the revolving wheel and pinion, the outlines of their respective teeth, which would manifestly be involutes of the generating circles D and E.

The inclination of D B being the same as that adapted for external gearing, the teeth of the pinion would evidently be the same, but the teeth of the wheel would be similar in form, not to the teeth of an externally geared wheel, but to the spaces between them. L being the centre of the wheel, L H = $\frac{3}{3}\frac{1}{2}$nds of the pitch radius, and H K = $\frac{1}{4}$th of the pitch radius, the side of a tooth at K is part of a circle described with radius K H. The tops of the teeth in this case project *within* the pitch circle, as far as in external gearing they project *beyond* it, and the bottoms of the spaces may be made semicircular, and of depth similar to that determined for external gearing.

The gearing we have hitherto described applies only in the case of wheels revolving in one plane or on parallel axes.

BEVIL GEAR.—When the axes are not parallel, it is necessary to employ *bevil gear.* Let A B and A C (Fig. 243) be the two axes meeting in A, and D E and E F the proper diameters of the wheels to give the required speed; if we suppose the cones D A E, F A E to roll upon one another touching along the line A E, then the velocities of their touching surfaces will be equal at any point, such as M, along the cone, because L M and K M, the radii of rotation at that point, bear the same proportion to each other as G E and H E the radii at any other point E, and therefore the circumferences at these points are in like proportion. Taking a portion of each cone (that shaded), if we conceive their meeting surfaces at M E to have sufficient friction, by causing one to rotate round its axis, we should also cause the other to rotate. But as practically the friction is not sufficient, it is necessary to cut the surfaces of the cones into teeth and spaces, as in plain gearing. It is evident that these teeth must taper towards A, both in width and in height. If a line C E B be perpendicular to A E, and N and P the tops of the teeth at E, the converging lines A N and A P will define the tops of the teeth along their whole extent. And again, if Q R be the breadth of a tooth at H, the converging lines A Q and A R will define the tapering breadth. The line P N is part of the boundary of coni-

Fig. 243.



cal surfaces, of which C is the apex for the one wheel, and B the apex for the other; and if from the centres C and B the circles E S and E T be described, they will represent the outlines of the developed surfaces of the cones F C E, D B E respectively, and become the pitch circles on which the outlines of the teeth at E may be described. Were we to cut these teeth in paper, and then wrap them round the cones F C E and D B E, we should have them interlacing and gearing into each other at E. Proceeding in the same manner at the point M, by drawing U V through M perpendicular to A E, and describing from centres C and B the pitch circles W and X, with radii respectively equal to V M and U M, we get the development of the teeth at M, which are precisely similar to those at E, but on a smaller scale, their outlines being defined by the radii converging from those in S and T towards C and B, the centres of development.

Bevil gearing applies when the motion is to be conveyed at any rate of speed from one axis to another, as in Fig 244, where *a a* is the large *bevil wheel*, and *b b* the smaller one, or the *bevil pinion;* or the motion may be communicated at any other angle, and in various directions by combinations of bevil wheels and pinions, as in Fig. 245, where the pinion *a* drives the wheel *b b* mounted obliquely to it; and the pinion *c*, fixed on the shaft of *b b*, drives the wheel *d d* at some other angle with it.

Fig. 244.

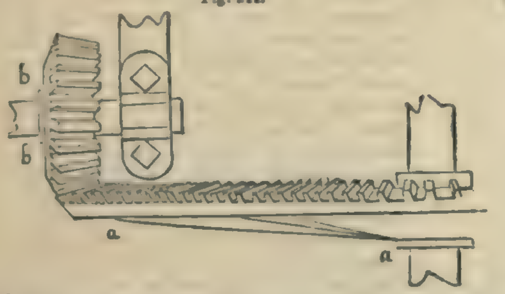


Fig. 245.

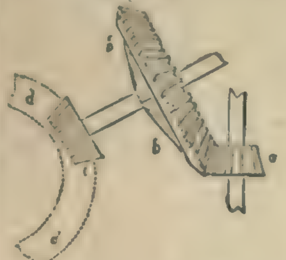

Fig. 246.

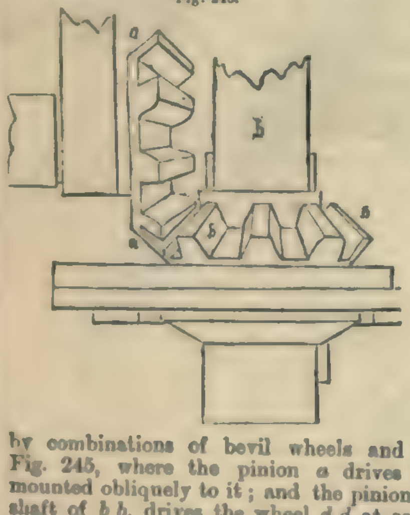

When the wheels are equal, and their axes at right angles to one another, as in Fig. 246, the wheels are technically called *mitre wheels.*

The general law as to velocities of rotation and pressure conveyed through bevil gearing, is precisely the same as in the case of plain gearing.

RACKS.—Gearing is sometimes used to convert a rotary into a rectilineal motion, by the use of a rack and pinion.

The pinion *a* (Fig. 247) has teeth which fit between the teeth of two racks *b* and *c*; and by giving *a* a reciprocating rotary motion round its centre, these two racks are put in reciprocating rectilineal motion.

The proper form for the teeth of a rack, so as to gear with those of pinions formed as we have described, may be ascertained thus (Fig. 248):—In describing the teeth of a wheel, the radius C F of the generating circle bears a certain proportion to C B the pitch radius; or, as we have taken it, C F is $\frac{3}{3}\frac{1}{2}$nds of C B. Again, F B, the radius of the side of the tooth, is $\frac{1}{4}$th of C B, or bears also a constant ratio to C B. Hence, for every wheel, B F makes a constant angle F B C with A C. Apply this to a rack N G, the radius of the tooth must be at the same angle to D E as that of F B to B C, or the angle N G E must be equal to the angle F B C; but as the pitch line of the rack is a straight line, or may be supposed a circle of infinitely great radius, so the radius N G of the tooth, being $\frac{1}{4}$th of the pitch radius, must also be infinitely great, and the portion of the circular side of the tooth described with this infinite radius must be a straight line H G perpendicular to N G. To find the amount of obliquity or inclination of H G to D E, we observe that it is the same with the inclination of B F to B M (which is perpendicular to A C). Now M F is very nearly bisected in L; and as F L is $\frac{1}{8}$th of F B, F M is very nearly $\frac{2}{8}$ths or $\frac{1}{4}$th of F B. So, in the rack, H K must be $\frac{1}{4}$th of K G; and hence we have a simple mode of setting out H G, the side of the rack tooth, by taking G K any length, such as 1 inch, along the line G D, and measuring up an offset K H = $\frac{1}{4}$th of K G. The line H G is the side of the tooth, of which the top and bottom may be determined as in wheel gearing.

Fig. 247.

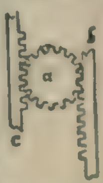

Fig. 248.

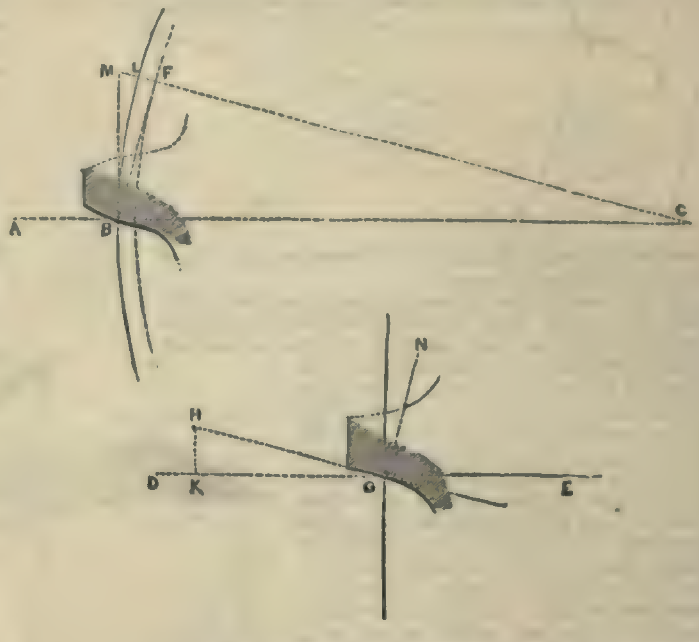
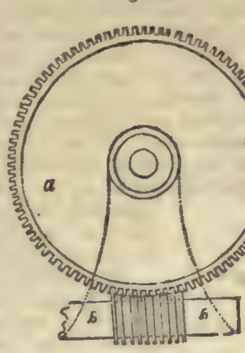


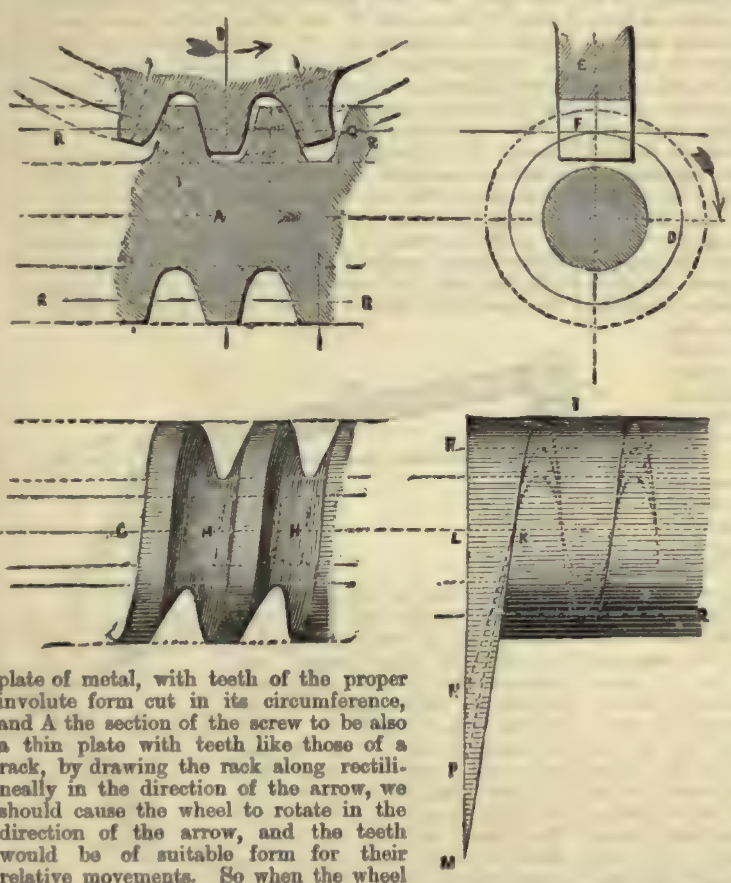
WORM AND WHEEL.—There still remains a kind of gearing most applicable in cases where it is desired to reduce very greatly the angular velocity, or to increase the moving pressure. We allude to the *perpetual screw*, or *worm and wheel*, as it is usually called (Fig. 249): *b b* the driving shaft has a screw or worm cut on its cylindrical surface, the coils of which fit between teeth on the driven wheel *a a*. These teeth have sides inclined to the plane of their wheel, in such a manner as to suit the obliquity of the screw-thread. When the worm is caused to revolve, one portion of the worm pressing against a tooth of the wheel, causes it to advance over a distance equal to the pitch of the thread or of the teeth (which are necessarily alike); and by the time one tooth is disengaged from the worm by the revolution of the wheel, another tooth has come into action, and is caused to advance in like manner. Every revolution of the screw round its axis thus causes the wheel to rotate through a portion of a revolution, equivalent to the distance of the centre of one tooth from that of the next; and if the wheel have, for example, 100 teeth, it thus requires 100 revolutions of the worm to cause one revolution of the wheel. It is evident that, whatever be the size of the worm, the same relation of angular velocities subsists, while the number of teeth in the wheel remains constant; but when we alter the *pitch* of the screw, that is to say, the distance from one of its coils to the next, we must alter, to a corresponding extent, the *pitch* of the toothed wheel; and, if its diameter be fixed, the number of its teeth must be altered accordingly.

Fig. 249.



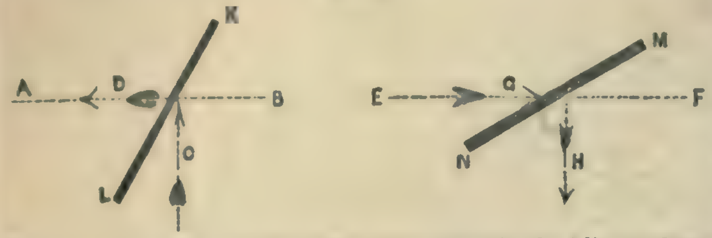
In deciding on the form of teeth for screw-gearing, we must be guided by considerations similar to those which we have dealt with in respect of ordinary gearing. If we suppose the screw-wheel B (Fig. 250) to be a thin plate of metal, with teeth of the proper involute form cut in its circumference, and A the section of the screw to be also a thin plate with teeth like those of a rack, by drawing the rack along rectilineally in the direction of the arrow, we should cause the wheel to rotate in the direction of the arrow, and the teeth would be of suitable form for their relative movements. So when the wheel is of some thickness, as shown in section at E, with teeth F projecting within the outer circumference of the screw, and clearing the solid central portion, we have only to make the teeth F inclined so as to suit the obliquity of the screw-thread, as indicated by the dotted lines H H on the plan of the screw G; and, instead of moving the screw longitudinally like a rack, we may cause it to rotate round its axis; and while we prevent its longitudinal motion, the teeth of the wheel will be caused to move onwards by the inclined action of the screw-thread. As no part of the screw-thread is a straight line, the teeth of the wheel, indicated by the dotted lines H H, ought theoretically to be curved; but when the diameter of the screw is large in proportion to its pitch, the portions of the thread, with which the teeth are in contact, approach very nearly to straight lines, and the oblique sides of the teeth may therefore, without much practical error, be made straight. Their proper obliquity may be found thus:—Let I be a cylinder of the same diameter with the screw, on which is wound a triangular piece of paper, so that its edge shall form the outline of the screw. If at any one of its convolutions K, instead of continuing to wind the paper on the cylinder, we stretch it out straight as K M L, if K L be half the pitch of the screw, or L half-way between K and the point where the next convolution after that at K would cross the axis, then L M must be equal to half the circumference of the cylinder (about 3$\frac{1}{7}$ times its radius), in order that the point M may be brought round to L when the paper is wound on to the cylinder. By taking K L half the pitch of the screw, and L M half its circumference, and joining K M, we get a line at the proper obliquity to the axis to suit the thread of the screw. By taking a cylinder equal to the inner part of the screw, or of diameter equal to that of the screw at the bottom of its thread, and proceeding in a similar way (as indicated by the dotted lines), we get the line K N of the proper obliquity to suit the bottom of the thread. Now, as the tops or points of the teeth of the wheel gear with the bottoms or hollows of the screw-threads, and the bottoms of the teeth gear with the tops of the screw-threads, we should make the tops of the teeth less inclined to the plane of the wheel than their bottoms, and we should gradually increase the obliquity from the tops of the teeth downwards. It would be very difficult to effect this in practice; and, indeed, even if it could be done with ease, it would be positively disadvantageous, because some of the teeth are always coming into such a position with respect to the thread as that marked Q, where the outer portion of the tooth is in contact with the upper part of the thread. Practically, then, it is best to make the obliquity of the teeth like K P a mean between those due to the upper and the lower parts of the screw-thread. In other words, tracing a pitch-line R R for the screw touching the pitch circle of the wheel, and then developing the obliquity K P due to the diameter of the screw measured to that pitch-line, we get an average inclination for the teeth, somewhat in error at points above and below the pitch-line, but correct where the principal contact and communication of power takes place. The greater the diameter of the screw, and the smaller its pitch, the greater is the inclination of the thread to its axis, and the less is the error of obliquity in the contact of the teeth and screw-thread above and below the pitch-line. Therefore, when the screw by rotating drives the wheel, the screw should be made as large in diameter as is consistent with

Fig. 250.



the necessary strength. But when it is intended that the rotation of the wheel shall cause the screw to rotate, the diameter of the screw should be made as small and its pitch as great as possible, so that the thread and the teeth may have small obliquity to the axis of the screw. In either case the screw-thread may be considered as a continuous inclined plane presented to the teeth of the wheel, and the effect of greater or less obliquity becomes very evident. In the first case, where the screw drives the wheel, A B (Fig. 251) being the axis of the screw, K L, part of its inclined surface, travelling in the direction of the arrow C, has to move the tooth of the wheel in the direction of the arrow D; the greater the inclination of K L to the axis, or the more nearly it approaches to a perpendicular to it, the better its effect to move the tooth, or the less is the lateral strain it produces on the tooth. In the second case, where a tooth moving in the direction of the arrow G, and pressing against the inclined side of the screw-thread M N, causes it to travel in the direction of the arrow H, the less the inclination of M N to the axis E F, or the more nearly it approaches to coincidence with it, the better is the action of the tooth to give it lateral motion, or the less is the longitudinal strain in the direction of the axis.

Fig. 251.

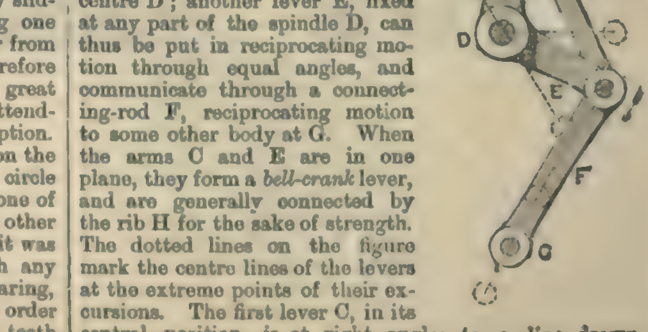


Before leaving the subject of toothed gearing, it is proper to remark, that the form of tooth which we have described—the involute of the circle—presents one disadvantage in use. The surfaces of the teeth do not roll over one another when in motion, but rub or slide along each other, and consequently absorb a portion of the power in mere useless friction, and in time wear each other out. There is a form for teeth which secures rolling contact of their surfaces, called the epicycloidal tooth, from the name of the mathematical curve, the epicycloid, adopted in its formation. If one circle be caused to roll round the circumference of another circle at rest, every point in the circumference of the rolling circle describes a curve, called the epicycloid, which is the resultant of its two motions, the rotation round its own centre and the revolution round the centre of the other circle. If now the circle which was fixed be caused to roll round the other, every point in its circumference would similarly describe the epicycloidal curve proper to its motion. And if both circles were caused to roll on each other at their due relative speeds, the *relative* motion of every point in their circumferences would be traced along their respective epicycloidal curves. If these curves were cut out in the circumferences of the two wheels, like teeth, projecting between and interlacing with each other, their surfaces would bear against each other without any sliding or rubbing motion, but simply rolling along one another like wheels upon rails. The loss of power from friction, and the amount of wear would be therefore very small. So far epicycloidal teeth are of great advantage. But there is one great difficulty attending them which practically forbids their general adoption. As the form of the epicycloidal depends not only on the size of the rolling circle, but also on that of the circle round which it rolls, a wheel made to gear with one of a given size cannot properly gear with one of any other size. With the involute tooth, on the contrary, it was shown that the same form applies to gearing with any size whatever. In a great many applications of gearing, it is necessary to change the wheels and pinions in order to change the rates of motion; and if epicycloidal teeth were employed, the number of wheels and pinions necessary to give the required changes would be enormous; whereas with involute teeth, a large number of changes can be effected by different combinations of a few wheels and pinions. Moreover, for large work, wheels and pinions are generally cast from patterns which are costly, and it therefore becomes important to make the teeth such as will suit all cases, instead of being limited to one particular case. When teeth are cut out of the solid metal, the form of the cutter can as readily be made to suit the epicycloid as the involute; and in such cases, especially for clock-work, and all work of an exact and light character, the epicycloid is certainly preferable to the involute.

RECIPROCATING MOTION.—Although continuous rotary movements are the most convenient for communicating power from one point to another, yet there are many operations to which machinery is adapted demanding motions of another character. These are chiefly of a reciprocating kind; and, whether the reciprocating movements take place in a straight line or about a centre or axis, it becomes important to inquire into the modes by which continuous rotary motion may be converted into them, or the converse. Sometimes it is desirable that these reciprocating movements should be continuous; at others that there should be intervals of rest between them; occasionally that they should be equal in velocity; and, again, that the time occupied by them should vary, according to the special character of the work to be done, and the intensity of the force transmitted. To describe all the known modes of effecting these objects would be to compile a list of almost all the mechanical inventions ever made, and, were it possible, would demand space far beyond the limits of a treatise like this. We will, therefore, merely draw attention to some of the modes of converting motion most generally applied in machinery. The arrangement best adapted to any particular case, or the special modification of action that may be most suitable, are matters that must be left to the ingenuity of the designer.

The most simple arrangement for converting continuous rotary motion into reciprocating motion, is the crank or eccentric, which we have already described in connection with the steam-engine. It is generally convenient to obtain the reciprocating movement in the arc of a circle instead of in a straight line. For instance, the revolving crank A (Fig. 252), connected by a rod B with the arm C of a lever mounted on an axis or spindle D, causes it to vibrate in the arc of a circle round the centre D; another lever E, fixed at any part of the spindle D, can thus be put in reciprocating motion through equal angles, and communicate through a connecting-rod F, reciprocating motion to some other body at G. When the arms C and E are in one plane, they form a *bell-crank* lever, and are generally connected by the rib H for the sake of strength. The dotted lines on the figure mark the centre lines of the levers at the extreme points of their excursions. The first lever C, in its central position, is at right angles to a line drawn

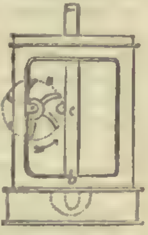
Fig. 252.



through the centre of the crank bisecting the vibration of the lever, or cutting the arc in which the pin of the lever vibrates in such a manner, that its deviations from the straight line at its middle and extreme points are equal. So also the line in which the point G is required to reciprocate, when prolonged, bisects the vibration of the arm E. By this arrangement the deviation of the pins moving in circular arcs from rectilineal motion is rendered as small as possible, and lateral strain from obliquity of connecting-rods is proportionally reduced. By varying the length of the arms C and E, the amount of vibration may be varied at pleasure; for while the angles in which they vibrate, remain equal, the lengths of the circular arcs in which their pins vibrate, are proportional to the lengths of their radii.

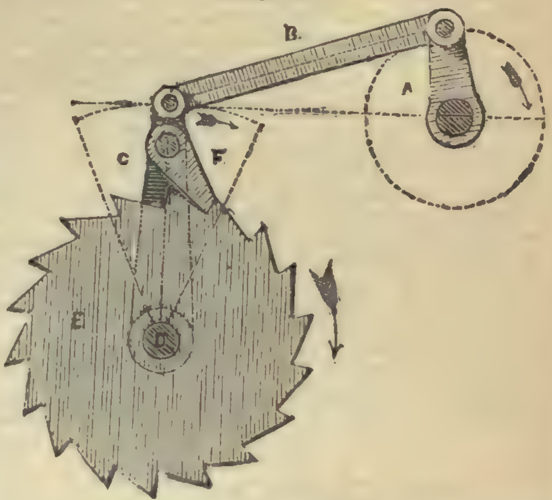
By proper arrangements of cranks, levers, and connecting-rods, in respect of lengths and relative positions, it is generally possible to convert a given rotary or reciprocating movement into one of greater or less extent, in a different plane or direction. When the reciprocating movement of a lever is applied to produce the rotary motion of a crank, it is necessary either to fit the spindle of the latter with a heavy fly-wheel to bring the crank over its *dead-centres*, or to adopt some other combination of cranks, as in the duplicate marine or locomotive engines, so that while one is on the *dead-centre*, the other is receiving motion from its connecting-rod. The crank or eccentric can give reciprocating movement to a lever, only in such a manner, that for each revolution of the crank the lever makes one complete double stroke, or an excursion from one extreme of its vibration to the other and back. Sometimes it is desirable that each revolution of the rotating shaft shall cause a number of reciprocating movements of a lever or rod connected with it. There are several methods of effecting this object. For moving a stamper *b* (Fig. 253) so as to crush or pulverise materials subjected to it, a wheel *a* is fitted with several curved arms or *wipers*, which, as the wheel revolves, come successively in contact with a pin or projection *c* on the stamper, lift it, and let it drop. If the wheel have six arms, the stamper makes six strokes during each revolution. Such an apparatus is frequently applied in cases where repeated strokes of falling heavy bodies are required for special operations, as for tilt-hammers used in iron manufacture, seed-crushers, fulling-mills, and washing-machines. For lighter work, such as the movement of pendulums or balance-wheels of timekeepers, there are numerous ingenious arrangements of escapement-wheels having their circumferences cut into teeth of suitable form, and capable of acting on the pallets presented to them, with the regularity and precision required.

Fig. 253.



INTERMITTENT MOTION.—Sometimes it is desirable to convert continuous rotary movement into one that shall proceed by fits and starts. A crank or eccentric A (Fig. 254) on the continuously rotating shaft connected by a rod B with a lever C, causes it to vibrate once during each revolution of the crank round a spindle D, on which is mounted a *ratchet*-wheel E, having teeth like those of a saw. The lever C is fitted with a *pall* F hanging freely from a pin, and formed so as to drop into the space between the ratchet teeth. One half-revolution of the crank A causes the *pall* to move over one or more teeth without putting them in motion, as it can slide freely along their inclined sides; but the other half-revolution bringing back the lever and *pall* which bears against the abrupt face of a tooth, causes the ratchet-wheel to rotate through the same arc with the point of the pall. In many cases where this arrangement of ratchet and pall is applied, it is necessary to vary the amount of movement of the ratchet-wheel at each stroke. This is effected either by varying the throw of the crank A, or the position of the connecting-rod pin on the lever C, so as to make the back stroke of the pall pass over two or more teeth, as may be required. In machines for boring, turning, planing, and shaping metals, in machinery for sawing timber and such like operations, this arrangement is applied for moving the material operated on, so as to present a new portion to the action of the tool or saw at each stroke.

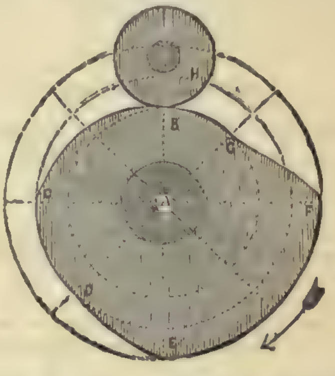
Fig. 254.



CAMS.—In describing the methods of regulating the flow of steam in engines, we alluded to the *cam* as an apparatus by which the continuous rotation of a shaft is made to lift a valve, sustain it for a certain period, and then let it drop. *Cams* are also applicable to many other mechanical movements of a similar character; and as their forms may be varied indefinitely, so almost any recurring movement can be effected by their use. As an example of what may be effected by a cam, let us suppose that, having a rotating shaft, we desire it, during $\frac{1}{4}$th of a revolution, to raise a weight 1 inch; during $\frac{1}{8}$th to retain it at that height; during the next $\frac{1}{8}$th to raise it 1 inch more; to retain it there during $\frac{1}{4}$th; during the next $\frac{1}{8}$th to drop it the two inches through which it had been raised; and during the remaining $\frac{1}{8}$th to retain it at its lowest position until it is again raised.

Let A (Fig. 255) be the shaft revolving in the direction of the arrow, and let three circles be described round its centre, the inner circle being of any convenient radius, and the others having radii respectively 1 inch and 2 inches greater. Let the circles be divided into eight equal segments, and let H be a roller connected with the weight to be lifted, bearing on the inner circle at B.

Fig. 255.

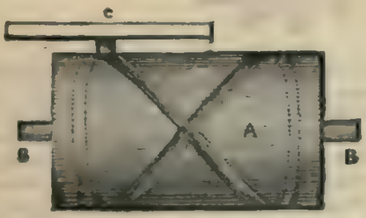


From B to C, $\frac{1}{4}$th of a revolution, let the circumference be part of a spiral curve touching the inner circle B and the middle circle at C; from C to D, $\frac{1}{8}$th of a revolution, let it follow the middle circle; from D to E, $\frac{1}{8}$th of a revolution, let it be another spiral curve touching the middle circle at D and the outer at E; from E to F, $\frac{1}{4}$th of a revolution, let it follow the outer circle; from F to G, $\frac{1}{8}$th of a revolution, let it again be a spiral touching the outer and inner circles; and from G to B, the remaining ¼th of a revolution, let it follow the inner circle. It is obvious that, as the shaft rotates and brings the different portions of the cam's circumference successively under the roller, the centre of which we suppose to be capable of vertical movement only, it successively lifts it one inch, retains it, lifts it again one inch, retains it, and permits it to drop, and remain down according to the conditions of the problem. The principal point to be attended to in the construction of a cam is, that the spiral portions leading from the one part of the circumference to the next be not too abrupt, and that they be carefully graduated from the one curvature to the other, so that the roller be not subjected to sudden jerks, but be made to rise from or fall towards the centre as gently and easily as possible. When the rotation of the cam is rapid, this is of the greatest importance: the amount of eccentric movement given to the roller should be as small as possible; or it should be spread over as large a part of the circumference as possible, so that the inclination of the revolving slope may be gentle.

In some kinds of printing machinery a peculiar form of screw-cam is applied, for the conversion of a continuous rotation into a reciprocating rectilineal motion.

A cylinder A (Fig. 256), rotating in bearings B B, has a double groove of a screw form cut in its surface, in which a pin C, projecting downwards from the table of the printing machine, is free to slide. The table being guided to slide backwards and forwards in a straight line, is caused to move by the revolution of the cylinder presenting always the inclined face of its screw-groove to the pin. The screw is double, of opposite direction, with a portion at each end not oblique to the axis of the cylinder. One half-revolution of the cylinder causes the pin to travel throughout the length of its screw; another half-revolution retains it at the end of its stroke; the next half-revolution carries it back to the opposite end; the next retains it; and so on successively to suit the alternate rest and motion of the printing-table to the successive impressions and intervals between them.

Fig. 256.



MANGLE MOTION.—Racks and partly-geared pinions are sometimes used for a similar purpose, thus:—A double rack *a a* (Fig. 257), guided at the ends *b* and *c* to move only longitudinally, is acted on by a partly-geared pinion *e* continuously rotating. When the teeth of the pinion gear with those of the upper limb of the rack, it is caused to move from *b* towards *c*, until the pinion, having left that limb, enters into gear with the other, giving it the contrary movement, and so on, successively.

Fig. 257.

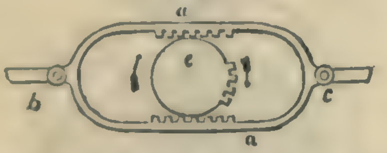


Fig. 258 represents an arrangement of a similar character, applied to produce alternating rotary motion. A pinion *c* continuously rotates on an axis fitted with a universal-joint, such as may permit the pinion to gear either with the exterior or interior cogs of the double circular rack *b*, fixed on the face of a drum or pulley *a*, and thus to give it rotary motion round its centre *e*, in directions alternately opposite. This apparatus having been applied to driving mangles, has received the name of the *Mangle Motion*.

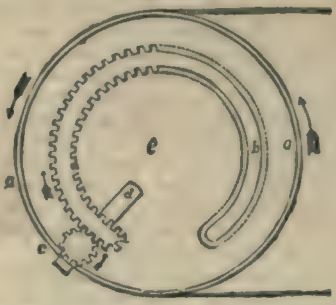
Fig. 258.



REVERSING GEAR.—On referring to our remarks respecting the communication of motion by pulleys and straps, it will be seen, that while a pulley, driven from another by a direct strap, revolves in the same direction, one driven by a crossed strap revolves in the opposite direction. This principle is frequently applied in machinery where it is desired to reverse the direction of motion. Two pairs of fast and loose pulleys are arranged on a shaft, so that one pair may be connected by a direct, and the other pair by a crossed, strap, with pulleys on the prime mover; when the direct strap is on its fast pulley, while the crossed strap is on its loose pulley, the machine is driven in the direction of the prime mover; but when the direct strap is thrown on its loose pulley, while the crossed strap is brought on its fast pulley, the contrary motion is produced. In apparatus where an arrangement of this kind is applied, as in machines for planing iron, the movement of the table of the machine to each extreme of its stroke is made to shift the straps by very simple mechanism, which is capable of being adjusted so as to vary the amount of stroke at pleasure.

Fig. 259 represents another method of reversing rotary motion, frequently employed: *a* and *b* are two bevil pinions revolving loosely on a shaft *d e*, and gearing with a bevil wheel *c*. Between the pinions is fitted a clutch, sliding on, but revolving with, the shaft *d e*. The pinions being geared into opposite sides of the wheel, rotate in opposite directions; and as the clutch is thrown into gear with the one or the other, the shaft *d e* is caused to rotate in the one direction or the other accordingly. Instead of a toothed clutch, a conical friction clutch is occasionally employed with good effect, because, in the first place, a very slight movement of the lever pressing the cone into its seat on either side, is sufficient to couple the shaft with either wheel; and, in the next place, the shaft being driven solely by the friction of the conical surfaces, cannot be subjected to any strain exceeding the friction in amount, the cones slipping when subjected to extreme strain. In powerful rolling machinery, this plan prevents a sudden shock, always inseparable from the use of the clutch, and which may cause the breaking down of some part of the machinery.

Fig. 259.

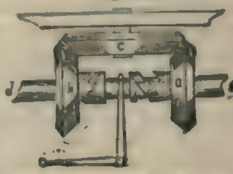


Fig. 260 indicates a mode of reversing the direction of rotation by means of toothed gearing. A being a toothed wheel on the driving-shaft, and B one on the shaft to which it is required to convey motion in either direction, C, D, and E are intermediate pinions mounted on a frame capable of vibrating on A as an axis. When C is geared with A and B, as in I., both revolve in the same direction; but when C is thrown out of gear with B, and E brought into gear with it, as in II., the direction of its rotation is reversed, as indicated by the arrows. By some such arrangements, or modifications of them, suited to the circumstances of any particular case, the direction of rotation may be readily varied.

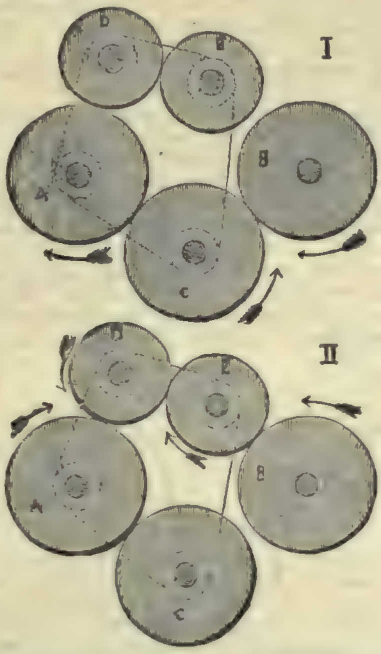
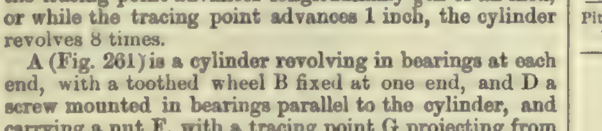
Fig. 260.



SCREW-CUTTING GEAR.—It is often required to change a rectilineal motion, having a certain velocity, to one having another velocity, particularly in machinery for cutting screws. A screw, as we have already described, is a line traced on the surface of a cylinder by the motion of a point moving longitudinally along the cylinder, parallel to its axis, while the cylinder revolves. The pitch of the screw is the distance through which the tracing point moves longitudinally while the cylinder makes one revolution; and in practice, it is necessary to form screws of numerous different pitches, according to their dimensions, and the circumstances under which they are to be used. The pitch of a screw is generally named according to the number of turns or convolutions which the screw makes in a certain length of the cylinder. Thus, when a screw has 8 turns to the inch, we say that it has a pitch of $\frac{1}{8}$th of an inch—that is, during one revolution of the cylinder on which the screw is formed, the tracing point advances longitudinally $\frac{1}{8}$th of an inch, or while the tracing point advances 1 inch, the cylinder revolves 8 times.

Fig. 261.



A (Fig. 261) is a cylinder revolving in bearings at each end, with a toothed wheel B fixed at one end, and D a screw mounted in bearings parallel to the cylinder, and carrying a nut F, with a tracing point G projecting from it, to meet the surface of the cylinder, the screw having a toothed wheel E, gearing into an intermediate wheel C, which also gears into B. On causing the cylinder A to revolve, the screw D is also caused to revolve; the nut F and tracer G are made to move longitudinally parallel to the axis of A, and the screw-curve traced on A is that due to the velocity with which A revolves, as compared to the speed with which G advances. By altering the proportions or numbers of teeth in the wheels B and E, the relative velocities of the cylinder and screw may be changed at pleasure, and the pitch of the screw traced on A from a screw D of constant pitch may be proportionally varied. In lathes, or machines for cutting screws, the cylinder A is the piece of metal on which the screw is to be cut; its axis is what is technically called the *mandril* of the lathe; and the tracing point G is a steel tool cutting into the metal, so as to leave the screw-thread projecting. The screw D has generally a pitch which is some simple fraction of an inch, such as $\frac{1}{2}$ or $\frac{1}{3}$rd of an inch, and the lathe is furnished with numerous toothed wheels, which may be put in the place of B and E to vary the pitch of the cut-screw, as may be required. If we take the case of a lathe having a screw D of $\frac{1}{2}$ an inch pitch, or making 2 turns per inch, when the wheels B and E have equal numbers of teeth, whatever be the size of the intermediate wheel C, the screw D revolves with the same angular velocity, and in the same direction with the work A. The tool G, therefore, advances $\frac{1}{2}$ an inch along the surface of A during each revolution of A, and cuts a screw of precisely the same pitch, and lying in the same direction with that on the screw D. But if in place of two equal wheels B and E, we put wheels, B having 20 teeth, and E having 40, then the screw D will be caused to revolve at $\frac{20}{40}$ths, or $\frac{1}{2}$ the speed of A, and the tool will advance $\frac{1}{2}$ of $\frac{1}{2}$ an inch, or $\frac{1}{4}$th of an inch, during each revolution of A, and thus to cut a thread of $\frac{1}{4}$th of an inch pitch upon it. Screw-cutting lathes are generally furnished with a table of screw pitches, and the appropriate wheels for producing them, such, that the workman, by inspecting the table, can at once select the proper wheels for giving the desired pitch. The wheels belonging to the lathe have their numbers of teeth stamped upon them, to save the trouble of counting them. Sometimes, when the difference of the speed of the screw and of the work is required to be considerable, instead of the simple intermediate wheel C, it is necessary to introduce a wheel and pinion C and *c* fixed together. Thus, if it were required that the screw should revolve at $\frac{1}{25}$th of the velocity of the mandril, were the smallest possible wheel B to have 20 teeth, it would be necessary that E should have 500 teeth, because $\frac{20}{500} = \frac{1}{25}$th, if the simple intermediate wheel C were employed. This size of wheel for E might be extremely inconvenient, and it would be better to employ the compound intermediate wheel and pinion C and *c*. In this arrangement, B having 20 teeth, C 100, *c* 20, and E 100, the speed of E is $\frac{20 \times 20}{100 \times 100} = \frac{1}{25}$th of that of B. In the lathe table, the first column gives the pitch of the screw to be cut; the second gives the number of teeth on the mandril wheel B; the third and fourth give the numbers of teeth in the intermediate wheels C and *c* respectively; and the fifth gives the number on the screw-wheel E. When the compound intermediate wheels are not required, the columns of intermediates are left blank, as any simple intermediate may be employed without altering the relative velocities of the mandril and screw-wheels. The following is part of a table for a lathe having a screw of $\frac{1}{2}$ inch pitch:—

TABLE OF SCREW GEARING FOR LATHE.

Pitch: Turns per inch.	Teeth in Mandril Wheel.	Teeth in Intermediate and Pinion Wheel.		Teeth in Screw-wheel.
20	30	120	40	100
18	30	90	30	90
16	30	120	40	80
15	40	100	30	90
15	or 20	...	...	150
14	20	80	40	70
12	20	...	...	120
11	20	...	...	110
10	20	...	...	100
9	20	...	...	90
8	30	...	...	120
7	20	...	...	70
6	40	...	...	120
5	40	...	...	100
4	40	...	...	80

If we examine any part of the table, as, for instance, the numbers given for 14 turns to the inch, we find the following rule obtains :—The pitch in the first column is equal to twice the product of the numbers in the third and fifth, divided by the product of those in the second and fourth. Thus $14 = 2 \times \frac{80 \times 70}{20 \times 40}$. Again, where no compound intermediate is employed, the pitch is twice the number in the fifth column divided by that in the second. Thus $6 \text{ pitch} = 2 \times \frac{120 \text{ teeth.}}{40 \text{ teeth.}}$

MICROMETER.—For machinery by which straight lines or the circumferences of circles are divided into a number of equal parts, as for the marking out of scales for measuring or astronomical instruments, or for cutting teeth in racks and wheels, the screw and the worm and wheel are often employed in order to give the means of delicate subdivision. When a screw is used for such a purpose, it is generally called a micrometer (small measurer) screw, and the principle on which it acts may be thus described :—If we suppose an accurately cut screw, having $\frac{1}{10}$th of an inch pitch, to be fitted with a nut, the motion of a screw through one revolution would advance the nut through $\frac{1}{10}$th of an inch. If on one end of the screw there were fitted a wheel having its circumference divided into 100 equal parts, the screw might be turned round any number of revolutions or hundredths of a revolution, as marked by a fixed index pointing to the divisions on the wheel. But for every hundredth part of a revolution of the screw, the nut would be advanced $\frac{1}{100}$th of $\frac{1}{10}$th, that is, $\frac{1}{1000}$th part of an inch ; and by using a screw of still finer pitch, and having a wheel mounted upon it divided into still smaller and more numerous parts, the longitudinal advance of the nut through still smaller fractions of an inch could be effected and estimated. It is by such an arrangement that the fine divisions of mathematical instruments are traced, and the fine lines traced upon medallion drawings are engraved. For circular division, the screw, instead of moving a nut longitudinally, acts as a worm on the teeth of a wheel, and causes it to revolve through any required part of its circumference. Thus, if we had a worm-wheel with 360 teeth, and a worm with a wheel fitted on its axis, having 360 divisions, we could move the worm-wheel through $\frac{1}{360}$th of $\frac{1}{360}$th, that is, $\frac{1}{129600}$th of a revolution, or any number of such fractions of a revolution. And farther, if the wheel upon the screw were a toothed wheel, and we had numerous other toothed wheels, with various numbers of teeth like those we have described for a screw-cutting lathe, we might, by the proper selection of wheels gearing with that on the screw, effect the division of the circle into any number of required equal parts. Such apparatus are employed for dividing the circumferences of astronomical instruments, and also for cutting the teeth of wheels. When the number of teeth to be cut is a multiple of some simple numbers, such as the number 60, which is a multiple of some of the numbers 2, 3, 4, 5, 6, 10, 12, 15, 20, 30, it is generally easy to select wheels which, in connection with the screw, shall give the required number of equal divisions ; but when the number of teeth is what is called a prime number, such as 59 or 61, which is not capable of subdivision, we must either provide wheels having such a number of teeth already cut in them, or resort to methods of approximation for their subdivision. Thus, if with the 360 teeth on the worm, and 360 divisions on the screw-wheel, we desired to divide a circle into 61 equal parts, we should for each part turn the screw through $\frac{129,600}{61} = 2124\frac{1}{2}$ divisions, or $\frac{2124\frac{1}{2}}{360} = 5$ revol. $324\frac{1}{2}$ div. nearly. The error at the end of the process would be found thus :

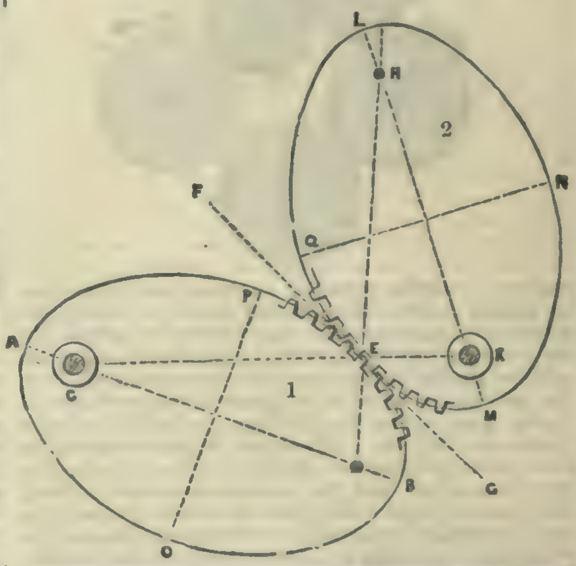
Since the total number of divisions due to a complete revolution are 129,600,

and since $2124\frac{1}{2} \times 61 = 129,594\frac{1}{2}$,

the revolution of the wheel would want $5\frac{1}{2}$ divisions of being complete, that is, $\frac{5\frac{1}{2}}{129,600}$, or about $\frac{1}{23564}$th part of its circumference : a quantity quite inappreciable.

ELLIPTICAL GEAR.—In several machines it is necessary to provide a rotary motion more rapid at one portion of a revolution than at another, as, for instance, in machines for slotting and planing iron. The iron to be planed, or the tool which planes it, makes a rectilinear stroke slowly in the one direction while the metal is being cut, but may be drawn back rapidly in the opposite direction when no work is done. For producing motion of this kind, elliptical geared wheels are sometimes employed (Fig. 262). The ellipse is a curve, of which the line A B is called the greater axis, and each of the two points C and D in that line is called a focus. If to any point E in the circumference of the ellipse, lines C E and D E be drawn from the foci, the sum of their lengths is equal to that of the axis A B. Farther, if the lines C E and D E be prolonged beyond the curve, and a line F G drawn so as to divide equally either of the angles formed by their intersection, the line F G is a tangent to the curve at E ; that is, it touches it, but does not cut it ; or every part of it, except merely the point E, lies entirely outside of the curve. If, in the prolonged portions of the lines C E and D E, lengths E K and E H be measured off equal to D E and C E respectively, H and K may be taken as the foci of another ellipse, precisely equal in every respect to the original ellipse, and having the axis L M, and the tangent F G touching it at E ; and as F G touches both ellipses, they touch each other at the same point E ; and the length of the line C K, which is made up of C E and E K, or its equal E D, is equal to A B or L M.

Fig. 262.

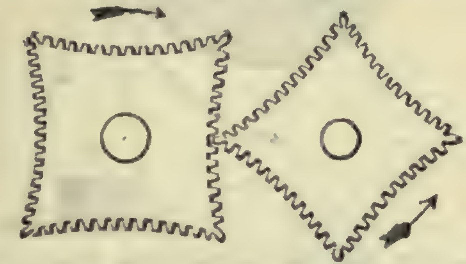


These peculiar properties of the ellipse enable us to employ elliptical wheels, each revolving round a focus as a centre, C for the one and K for the other, the two foci maintaining a constant distance apart, whatever be the relative position in which the wheels lie with respect to each other. The circumferences are cut into teeth and spaces like ordinary circular gearing, the elliptical curves being their pitch lines, on which the equal divisions are set out.

It will be observed that, during a revolution of these wheels, the point M gears with B, and the point L gears with A ; but as the radii of these points are C B and K M, and K L and C A respectively, the angular velocities of the wheels at these points vary inversely as the lengths of these radii. If, for instance, C A be $\frac{1}{4}$th of A B, and therefore C B = $\frac{3}{4}$ths of C A, K M being equal to C A, and K L to C B, when the points B and M are engaged, the wheel 2 is revolving with 3 times the angular velocity of 1, because the radius C B is three times the length of K M; but when the points A and L are engaged, the wheel 2 is revolving with $\frac{1}{3}$rd of the angular velocity of 1, because A C is $\frac{1}{3}$rd of K L. So at all points intermediate to these, except at N, O, P, and Q, where the radii are equal, the relative angular velocities of the wheels vary between the limits we have named.

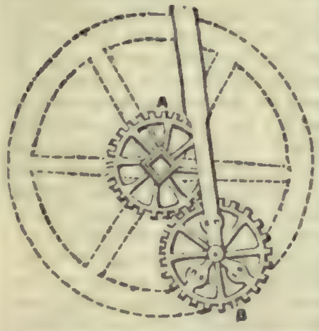
For some purposes in the manufacture of textile fabrics, gearing like that in Fig. 263 is employed. These vary the angular velocities 4 times in every revolution; and the principal condition of their construction is, that the distance between their centres must be a constant quantity.

Fig. 263.



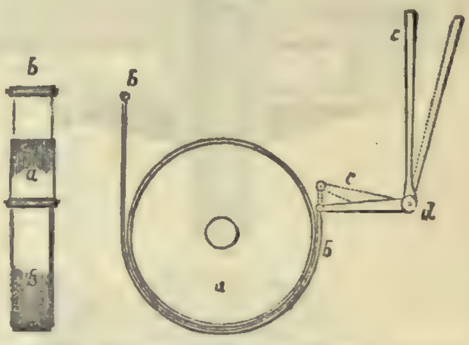
SUN AND PLANET.—The *sun and planet-wheel* is a contrivance for converting a reciprocating into a rotary motion. It was employed by Watt instead of the crank in a steam-engine, not because he preferred it to the latter, but because, through the bad faith of a workman who patented the crank as his own invention, he was precluded from employing it. The sun or central wheel A (Fig. 264) gears with the planet-wheel B, which is caused to revolve round A without rotating round its own centre, being fixed to the end of the connecting-rod, and retained in gear with A by means of a link which connects their centres, and revolves freely with B. When the sun and planet-wheels have equal numbers of teeth, every revolution of the latter causes 2 revolutions of the former, as may be understood by watching the relative positions of a tooth in each at different parts of a revolution. When the planet is vertically above the sun-wheel, the tooth B of the one is engaged with the space A of the other; and when the planet has made half a revolution, so as to be vertically below the sun, the sun has made a complete revolution, so as to bring the space A quite round to the point where it was at the commencement. One half-revolution of A is owing to the half-revolution of B propelling it round, while the other half-revolution of A is effected by the roll of the toothed half circumference of B presenting fresh teeth and spaces to A at the successive points of its revolution. When the numbers of teeth in the two wheels are different, the velocity of the sun-wheel varies accordingly, as may be best understood by an example. Let us suppose that the sun-wheel has 40 teeth, and that the planet has 50; then, during one revolution of the planet, it has presented the whole of its 50 teeth to the sun-wheel, and therefore turned it through 50 teeth, as well as its own complete revolution of 40 teeth. The sun-wheel, therefore, during 1 revolution of the planet-wheel, turns round a distance equivalent to 90 of its teeth, or $\frac{90}{40}$ths = $2\frac{1}{4}$ revolutions.

Fig. 264.



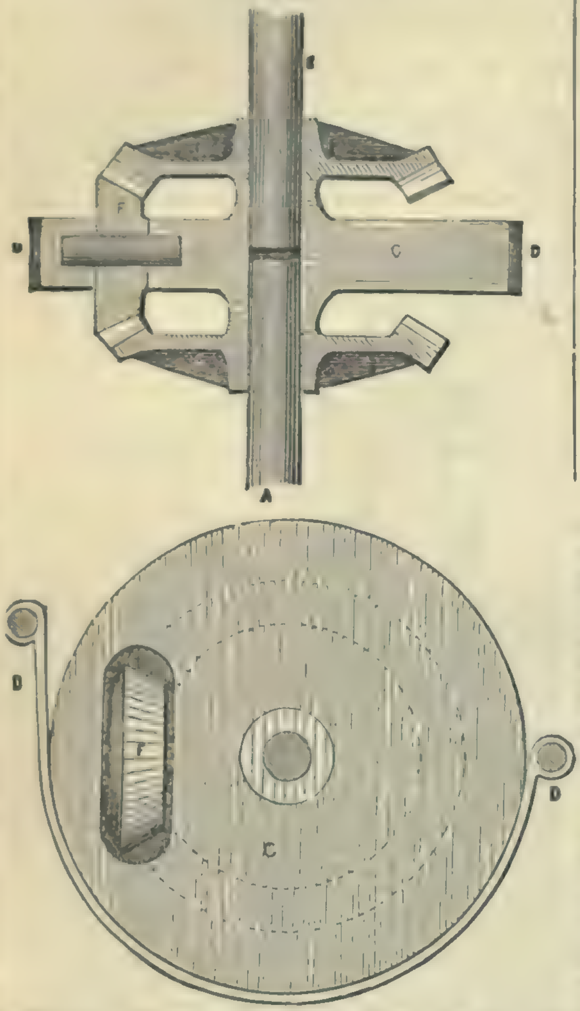
FRICTION-BREAKS.—It is often necessary to provide the means of stopping the motion of machinery when the mere cessation of power in the prime mover is not sufficient for the purpose. In a crane, when lowering a heavy weight, it may be desirable to lower it to a certain point and no farther, and therefore to stop the machinery of the crane when the weight has descended sufficiently far. Or, again, in any apparatus provided with a fly-wheel, or parts moving with considerable momentum, such as might continue the movement after the power has been withdrawn, it may be essential to provide the means of stopping the movement more suddenly. The most simple arrangement for this purpose is the *break* or friction-strap (Fig. 265). *a* is a wheel revolving with the rest of the machinery, and *b b* a flexible strap of iron passing round part of its circumference. One end of this strap, being fixed by a pin to some motionless part of the machine, and the other attached to a lever *c* pivoted on a fulcrum *d*, on applying force to the long arm of the lever, the strap is drawn tightly round the circumference of the wheel, and the friction caused by the close contact soon brings the wheel to rest. The great advantage of employing friction as a means of arresting motion, consists in the circumstance that it acts, not suddenly, but gradually. Were some solid obstacle presented to the motion of any part of a train of heavy or rapidly moving machinery, the momentum of all the moving parts would have to be suddenly destroyed; and as no time would be afforded for this operation, the strain would be incalculably great, and inevitable damage would ensue. But when the friction-break is employed, the wheel to which it is applied makes perhaps two or three revolutions before it comes finally to rest, and the time so occupied allows the momentum of all the parts connected with it to expend itself, in overcoming the great additional resistance caused by the friction.

Fig. 265.



In putting an extensive train of machinery in motion, the inertia of all the parts at rest has to be overcome in like manner; and were this done suddenly, the strain would be as great as in the opposite case of suddenly arresting their motion. This contingency is generally met by the use of pulleys and straps in communicating the power. A strap, communicating motion from one pulley to another, acts only by its friction on their circumferences; and when the strain which it has to overcome exceeds the force due to its friction, the strap slips at first to a considerable extent, but gradually less and less, until the proper velocity is attained, and the strap and circumference of the pulley move in unison. In cases where straps cannot be conveniently applied for driving a train, a friction coupling is employed. Fig. 266 is a diagram of one very generally used. A is the driving shaft, and B the driven shaft, the ends of which are free to revolve in the boss of a wheel C, true and smooth on its circumference, to which is applied a friction-strap D, worked by a suitable lever. Within the wheel C a bevel-pinion F is mounted in bearings, its axis being at right angles to that of the wheel and shafts; and bevel-wheels G and H, one on each shaft, are fitted to gear with the pinion F. If the friction-strap D be loose, so as to leave the wheel C free to revolve, the rotation of the shaft A, and its wheel G, gives motion to the pinion F, and causes its teeth to travel in those of the stationary wheel H, and thus to make the wheel C rotate at half the angular velocity of A, without putting B in motion. But if C be arrested by the friction of the strap D, the axis of F becomes fixed, and the rotation of A and G is communicated through F to B and H at the same speed, but in the opposite direction. The use of the friction-strap in this apparatus, presents the advantages in gradually generating momentum in the driven machinery, similar to those derived from its use in destroying the momentum of machinery in motion. Although, for the sake of simplicity, we have represented only one bevel-pinion F mounted in the friction-wheel, it is customary to provide at least two on opposite sides of the centre in order to balance it; and sometimes four are fitted for the sake of equilibrium and strength.

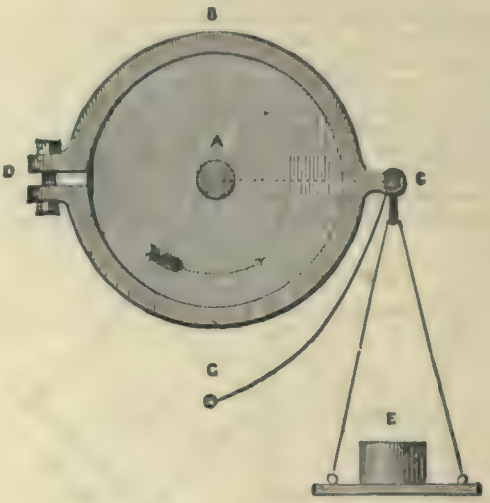
Fig. 266.



DYNAMOMETER.—It often becomes important to inquire what amount of power is communicated through a certain train of machinery. When a steam-engine is employed as the prime mover of any machine, the power communicated can be readily ascertained by the indicator. The engine is first worked alone, or with merely the train of wheel-work, in order that the power necessary to overcome friction may be estimated. It is then worked in connection with the machine, and the driving-power required for the machine is ascertained by subtracting the force necessary to overcome friction from the total power, including friction and the resistance of the machine. When machinery is driven by some other power, or when the indicator cannot be conveniently applied, the *dynamometer* (power-measurer) is employed.

The most simple kind of dynamometer consists of a pulley A (Fig. 267), fixed on the driving-shaft of the machinery whose power is required to be known. This pulley is surrounded by a flexible friction-strap C B D, the ends of which may be drawn close together by a screw at D, so as to tighten the strap as much as may be necessary on the circumference of the pulley. From a hook C, attached to the strap, is suspended a scale E, in which sufficient weights may be placed to prevent the strap from being carried round by the pulley in its revolution. A loose cord or chain C G, fixed at G, is also provided to keep the strap in its place, in case of the load E being insufficient to counterbalance the friction of the strap. Without this loose cord, a sudden increase of speed or friction might lift the scale and weights, and, whirling them round the pulley, do serious damage to the machinery. In using this machine, the speed of the shaft is carefully ascertained by counting the number of its revolutions per minute, and the screw D is gradually tightened until the scale and its load are just kept up by the friction, the imaginary line A C being horizontal. If the tightening of the screw cause the scale to be lifted, without reducing the speed of the pulley, more weight has to be added to the scale; but if the scale with its load cannot be lifted without retarding the pulley, the weight must be reduced. Having found the weight that is just supported when the velocity is correct, the power may be ascertained as follows:—The length of A C being the leverage at which the weight E acts to retard the rotation of the pulley, the power passing through the pulley must be such as would lift the given weight at the distance A C from its centre, or that would, during each revolution, move the weight E through a space equivalent to the circumference of a circle having A C for its radius. Since twice A C is the diameter of this imaginary circle, and the circumference is $3\frac{1}{7}$ times the diameter, $2 \times 3\frac{1}{7}$, or $6\frac{2}{7}$ times A C, is the space through which the weight is driven during each revolution; and this quantity multiplied by the number of revolutions per minute, is the total space through which the resistance is moved during each minute. The power is the weight multiplied by its velocity, or the distance through which it is moved per minute; and as 33,000 lbs. moved through 1 foot per minute is the standard horse-power, we have the following rule for estimating the horse-power as indicated by the dynamometer.

Fig. 267.



Rule.—Multiply the weight E (in lbs.) by the length of A C, the lever at which the weight acts (in feet), by $6\frac{2}{7}$ and by the number of revolutions of the pulley per minute, and divide by 33,000 for the horse-power.

Example.—The length of A C being 2 feet 4 inches, or $2\frac{1}{3}$ feet, the load E (including the weight of the scale) being 78 lbs., and the velocity of the pulley 120 revolutions per minute, required the power.

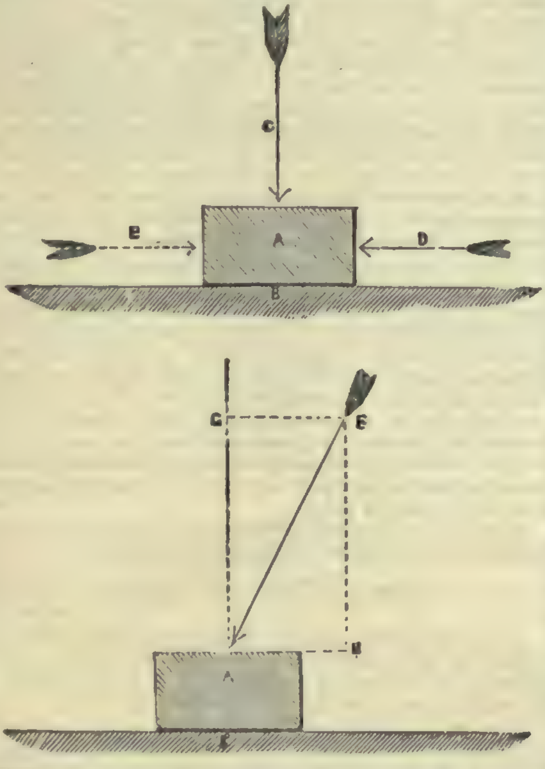
$$\frac{78 \text{ lbs.} \times 2\frac{1}{3} \times 6\frac{2}{7} \times 120}{33000} = 4{\cdot}16 \text{ horse-power.}$$

In dynamometers of this kind the friction-strap is plentifully supplied with oil, and it is found better to face the interior of the friction-strap with blocks of wood bearing on the surface of the pulley; because the friction of wood on iron is of a more constant character than that of iron on iron. When iron rubs on iron without the presence of oil or grease, great heat is produced, and the metal surfaces cut into each other and become roughened. But when wood bears on iron, if the surfaces are not oiled, the heat produced by the friction will only char the wood without damaging the iron, and will not effect any great variation in the amount of friction.

BREAKS.—Friction is also employed as a means of arresting motion in the case of carriages on declivities and railway trains. By the use of wheels to carriages, the friction is transferred from the surface of the road or rail to that of the axle. As the radius of the wheel is the length of lever at which any obstacle opposed to its progress acts, while the very much smaller radius of the axle is the lever at which its friction acts to oppose the rotation of the wheel, the larger the wheel and the smaller the axle, the less is the resistance from friction. If we were to suppose the axle extended to almost the whole dimensions of the wheel—that, in fact, the wheel were only the thin iron tyre revolving round a solid central part, the resistance to the motion of the carriage would be almost as great as if it were dragged along like a sledge. So if the wheel be prevented from revolving, it has to be dragged along the road, and the opposition which the friction thereby created presents, acts as a great retarding force. In ordinary carriages the wheel is generally prevented from revolving by placing under it a skid or plate of iron attached to the carriage by a chain, which has to be dragged along like a sledge. In railway carriages, the rotation of the wheels is arrested by means of blocks of wood pressed against their circumferences. These blocks are connected by levers and rods with screws conveniently situated, so that the engine-driver and guards can force them against the wheels, or remove the pressure at pleasure.

RESISTANCE OF FRICTION.—Except in these few instances, and that of pulleys and straps, in which friction is employed as a means of communicating power or arresting motion, it acts as a resistance in all mechanical arrangements. Although this resistance cannot be totally overcome, yet by carefully designing the arrangements of machinery with regard to the simplicity and proper formation of its parts, by good execution of the work, by the selection of suitable materials, and due provision of lubricating materials wherever surfaces move in contact with each other, it may be diminished to a very great extent.

Fig. 268.



In order that we may form a clear estimate of friction as a retarding force, we may suppose A (Fig. 268) to be a piece of material, such as iron, wood, brass, or the like, having a smooth lower surface in contact with a smooth table B of the same or any other material. If A be pressed down by a perpendicular force C, it will be found, that in order to move it laterally along the table, some force D will have to be impressed upon it, and this force will be greater the greater the perpendicular pressure C. There is, therefore, under these circumstances, a force acting in the direction of the arrow E, not tending to put A in motion, but resisting its motion in obedience to the force D. The resisting force E is the friction of the surfaces A and B. In order to measure the amount of this resistance, let us suppose a force F A acting obliquely at such an angle as just to cause A to slide along the table; then, on completing the parallelogram F G A H, while F H or G A measures the amount of force acting perpendicularly to the table, F G or H A measures the force acting parallel to the table, and causing A to slide along it.

Now it is found, practically, that whatever be the absolute force F A, and whatever be the extent of A's surface in contact with B, the obliquity of F A, or the angle F A G, which it makes with the perpendicular, when it just causes A to slide, is very nearly constant for any given material.

The ratio which A H bears to A G, or the fraction expressing the division of A H by A G, is called the *coefficient of friction*, and the angle F A G is called the *limiting angle of resistance*. Some very careful experiments have been made to determine the values of these for different materials; their results are embodied in the accompanying table. The coefficient of friction is the tangent of the limiting angle of resistance; and if we know the one, we can easily find the other from a trigonometrical table. We have, however, given an approximate value of both, to save the trouble of reference. As an example of the practical application of these numbers, we may take the case of brass and iron, for which the coefficient of friction is ·142, and the limiting angle 8°. If, then, a piece of smooth iron weighing 1 cwt. rested on a brass plate, it would require a lateral force of 16 lbs. to cause it to slide, for 112 lbs. (the vertical pressure) × ·143 = 16 lbs. Or, if the brass plate were inclined 8° to the horizon, the iron would slide along it from its own weight. Or, again, if we suppose a smooth round shaft of iron, weighing 1 ton, revolving in a brass bearing, the force necessary to be applied at the circumference of the shaft to overcome its friction, would be $2240 \times \cdot 143 = 320$ lbs. Assuming the shaft to be 6 inches diameter, or to have a radius of 3 inches at the bearing, the length of the radius, 3 inches, is the leverage at which the friction acts to resist its rotation, and the resistance, 320 lbs., at this leverage is equivalent to $320 \times \frac{12 \text{ in.}}{3 \text{ in.}} = 80$ lbs. at a radius of 1 foot. By a similar method of calculation, the resistance due to the sliding friction either of plane or of cylindrical surfaces of these or other materials may be readily estimated.

The numbers in the following table apply in the case of smooth surfaces, such as are employed in well-constructed machinery. When the surfaces are rough, the resistance may be increased indefinitely, and there can be no means of calculating its amount. When the surfaces are oiled, the friction is considerably reduced; but as, in all machinery, the rubbing surfaces are liable to become dry, or roughened by wear or the presence of grit, we think that in estimating the loss by friction, the numbers in the table should be employed without any allowance for lubrication.

TABLE OF FRICTION.

Materials of which the Rubbing Surfaces Consist.	Coefficient of Friction, Pressure being 1.	Limiting Angle of Resistance.
Steel and Ice	0·014	¾°
Ice and Ice	0·130	7½°
Hard Wood and Hard Wood .	0·135	7¾°
Brass and Steel or Iron . . .	0·142	8°
Soft Steel and Soft Steel . .	0·147	8¼°
Cast Iron and Steel	0·150	8½°
Wrought Iron and Wrought Iron	0·160	9°
Cast Iron and Cast Iron . .	0·163	9¼°
Hard Brass and Cast Iron . .	0·167	9½°
Cast Iron and Wrought Iron .	0·170	9¾°
Brass and Brass	0·175	10
Tin and Iron	0·180	10¼°
Soft Steel and Wrought Iron .	0·190	10¾°
Leather and Iron	0·250	14°
Tin and Tin	0·265	14¾°
Granite and Granite	0·300	16¾°
Yellow Deal and Yellow Deal	0·347	19¼°
Sandstone and Sandstone . .	0·364	20°
Woollen Cloth and Woollen Cloth	0·435	23½°

The best experiments made to fix these numbers are those by Rennie, who tested the materials under a pressure of 36 lbs. per square inch of rubbing surface. For greater pressures the friction is rather less in proportion, but the numbers given are sufficiently near for practical use. In general, it appears that when both surfaces are of the same material, the friction is greater than when they are of different materials. This is believed to be owing to the presence of a certain amount of that cohesive force which holds the molecules of any material together; and it is found to be greater the smoother the surfaces, and therefore the more intimate their contact. Independently of this circumstance, however, it is generally found inexpedient to make the rubbing surfaces in machinery of the same material, especially when there is any risk of their becoming heated by great pressure or rapidity of motion. In such cases, the particles of the one appear to blend with those of the other; the surfaces become cut into ridges and hollows, and sometimes cohesion takes place with such force that the materials themselves give way rather than separate from each other at their surfaces. This result is particularly observed in cases where iron and iron rub upon each other, especially when the iron is soft. When it is desired that the rubbing surfaces should be both of iron, it is better to case-harden the rubbing surfaces, as is usually done in the case of carriage axles. The process of case-hardening is effected by exposing the smooth surface to a red heat for several hours in a furnace, in contact with substances capable of furnishing it with carbon and nitrogen, such as prussiate of potash, leather shavings, and the like. The outer skin of the iron is penetrated by the carbon and nitrogen, and becomes a species of steel, which is rendered very hard by plunging it while still red-hot into cold water. After hardening, the surfaces have to be carefully ground smooth and true with oil and emery, or such-like polishing substances; and, before use, the emery must be carefully cleaned off, as its presence would otherwise cause the surfaces to cut, to become hot, and to cohere. In the case of shafts revolving in bearings, the shafts being generally of iron, are made to rest in bushes made of brass, gun-metal, tin, or some soft alloy. The rubbing surfaces are made to fit each other accurately, being turned, bored, filed or scraped where necessary, until the contact is made nearly perfect. When the contact is very imperfect, or only takes place at a few points of the surface, these become rapidly worn and cut, and the heat produced by their wear expands unequally other portions of the surfaces, which become abraded in their turn. In cases where great pressure is sustained on a bearing, the surfaces of contact are extended as much as possible, so that the intensity of pressure on any portion of the surface may be as small as possible. For shafts lying in cylindrical bearings, the extension of surface is best effected by lengthening the bearing, not by increasing its diameter. By increasing the length, the surface is proportionally increased; the pressure per square inch is proportionally diminished; the amount of friction is not altered, but the tendency to cutting or wear is reduced. But were the diameter increased, although the surface would be also increased, and the wear reduced, yet the friction would act at an increased leverage, and have greater effect as a resisting force. When the pressure is directed longitudinally along the shaft, the bearing surface is increased by forming on the shaft numerous collars or projecting rings, which are made to press against fixed ring-bearings fitted between them. The total pressure of the shaft is thus subdivided over the combined surface of all the collars, and the ring-bearings being made capable of adjustment by regulating screws, no one of them is unduly pressed upon. Such a form of bearing is particularly useful in steam-vessels fitted with screw-propellers. The propeller, in revolving, tends to throw the water backwards from the vessel, and the reaction of the water is the force which propels the vessel. But this force, sometimes amounting to several tons, is communicated through the shaft of the propeller to some fixed point in the vessel; and at this point is situated the bearing such as we have described, technically called the *pushing or thrust bearing*.

FRICTION OF STRAPS.—The friction of straps upon pulleys depends upon the extent to which they are tightened, the extent of circumference with which they are in contact, and their breadth. It is commonly believed, that the greater the diameter of pulley, the more surely does the strap cause it to revolve without slipping. Theoretically, however, and we believe practically, it will be found that, with equal degrees of tightness, equal breadths of strap, and equal circumstances as to perfection of contact, the friction of a strap on the circumference of a pulley is the same, whatever be its diameter. The only circumstance that can affect the constancy of the result is, that straps not being perfectly flexible, lie more closely to surfaces curved to a large radius than to those of smaller radius. When a certain amount of power has to be communicated through a strap, the speed at which the strap moves has to be taken into account, because power being pressure multiplied by velocity, the greater the velocity with which the power is transmitted, the less the pressure that has to be communicated at that speed. In this sense, then, it appears that the larger the pulley the less is the slip of the strap, because the greater the circumference of the pulley revolving at a given angular velocity, the greater is its absolute velocity through space, and therefore the less the pressure required to communicate a given power. It is found, practically, that a leather strap 8 inches wide, embracing half the circumference of a smoothly-turned iron pulley, and travelling at the rate of 100 feet per minute, can communicate 1 horse-power. For communicating any given power at any given velocity, the breadth of the strap may be found thus:—

Rule.—Multiply the power (horse) by 800, and divide by the speed (in feet per minute); the quotient is the breadth of strap in inches.

Example 1.—Required the breadth of strap, travelling 600 feet per minute, to communicate 12 horse-power.

$$\text{Width, } \frac{12\times800}{600}=16 \text{ inches.}$$

Note.—When the diameter of pulley (in feet) and the number of revolutions per minute are given, the speed of the strap is found by multiplying the given number of revolutions by the diameter (in feet), and by 3⅐.

Example 2.—Required the breadth of strap for communicating 10 horse-power to a pulley 3 ft. 6 ins. diameter, revolving 150 times per minute.

Speed of strap, $150 \times 3\frac{1}{2}$ ft. $\times 3\frac{1}{7} = 1650$ feet per minute.

$$\text{Breadth, } \frac{10 \times 800}{1650} = 5 \text{ inches nearly.}$$

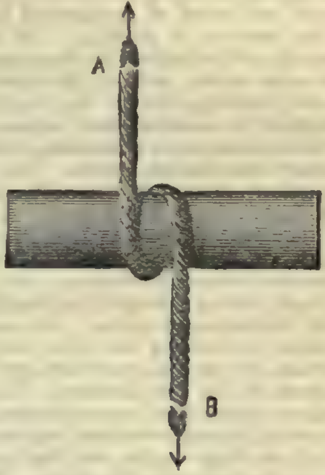
When less than half the circumference of the pulley is embraced, the strap must be proportionally wider; and when more than half the circumference is embraced, its width may be less.

The law according to which the friction of a strap increases with an increased arc of contact, is of a peculiar character, but may be readily understood by comparing the friction on arcs of different lengths. If a pulley (of any diameter whatever) were prevented from revolving, and a strap passing over part of its circumference were stretched by a certain weight at each end, additions might be made to the weight at one end until the strap began to slip over the pulley. The ratio which the weight so increased might bear to the weight at the other end, would measure the amount of friction. For example, in experiments made to test a theoretical investigation on this subject, a strap passing over a pulley in contact with 60°, or $\frac{1}{6}$th of its circumference, was stretched by a weight of 10 lbs. at each end. One of the weights was increased until it amounted to 16 lbs., when the strap began to slip. The ratio of 16 to 10, or $\frac{16}{10} = 1{\cdot}6$ was then the measure of the friction. When 20 lbs. at each end were used to stretch the strap, the one weight was increased to 32 lbs., giving the ratio of $\frac{32}{20} = \frac{16}{10} = 1{\cdot}6$, the same as before. And likewise when 5 lbs. were used for stretching, the weight at one end was increased to 8 lbs., giving still the same ratio $\frac{8}{5} = 1{\cdot}6$. So far, then, the friction was precisely proportional to the stretching weight, as might have been expected from the ordinarily received doctrine on the subject of friction. On extending the arc of contact to 120° = $\frac{2}{6}$ths or $\frac{1}{3}$rd of the circumference, the ratio was found to be 2·56, or 1·6 multiplied by 1·6, or the square of 1·6. And again, on embracing 180° = $\frac{3}{6}$ths or $\frac{1}{2}$ of the circumference, the ratio was found to be 4·1, very nearly the cube of 1·6. The theoretical investigation (given shortly in the note below*) brought out this result independently, and the following law may therefore be taken as established:—

If, for any given arc of contact, the one weight bears to the other, at the point of slipping, a certain ratio—for double the arc, the ratio will be squared; for triple the arc it will be cubed; for 4 times the arc it will be raised to the 4th power; and so on.

In all cases, however, much depends on the tightness of the strap, the limits to the force with which it is strained being, first, the tensive strength of the strap itself, and, secondly, the amount of pressure that it may be convenient to throw upon the shaft and its bearings. New straps become extended by use, and it is therefore frequently necessary to take them up or shorten them. Before use, they should be strained for some time by weights suspended from them, so as to leave less room for extension while in use. Wherever straps are employed, they should be of the greatest breadth, and travel at the greatest speed consistent with convenience, as it is most important to have the requisite strength in the form best suited for flexure, and the least possible strain on the shafts and bearings.

Fig. 269.



When ropes or chains are employed, as in cranes, capstans, windlasses, or the like, for raising heavy weights or resisting great strains, the requisite amount of friction is obtained by coiling them more than once round the barrel of the apparatus. It is found that one complete coil of a rope, as in Fig. 269, produces a friction equivalent to 9 times the tension on the rope, the barrel being fixed; that is to say, 1 lb. or 1 cwt. of tension on the end of a rope at A, can support 9 lbs. or 9 cwt. of tension at B. Were the end B of the rope coiled again round a barrel, it would support 9 times its tension; that is, 9 × 9, or 81 times the tension of A, and so on, coil after coil increasing the friction in a very high ratio, as may be calculated according to the law given above, thus:—

Multiply 9 by itself as many times as there are coils, and the product will be the number of times the tension at one end that will be supported at the other. For example, 1 cwt. at one end of a rope coiled three times round a barrel, would support $9 \times 9 \times 9 = 729$ cwt., or $36\frac{1}{2}$ tons at the other end of the rope. The diameter of the barrel does not affect the result. Having regard to these facts, we may readily understand the force with which a knot on a cord or rope resists the slip of the coils of which it consists, for the several parts of the cord act as small barrels, round which the other parts are coiled; and the yielding nature of the material of which the barrels are composed, permits the coils to become impressed into their substance on the application of force, and prevents them from slipping more effectually than if they were coiled on a hard and resisting barrel.

MOTION OF FLUIDS.—Before concluding this part of the subject, we may briefly allude to suggestions that have from time to time been made for communicating power by means of the movement of fluids. Some of these have been practically carried out with very good effect, and we believe that much may yet be done in this direction.

Manufactories, containing numerous machines, are generally arranged in such a manner that the power of a

---

* If w be a weight straining one end of a strap, and W a greater weight applied at the other end, just sufficient to cause the slipping of the strap when it is in contact over an arc of the circumference θ; then, while θ remains constant, the ratio $\frac{W}{w}$, which may be called f, is constant, whatever the absolute weights W and w may be, or the friction is proportional to the pressure; for $W - w$ is the measure of the friction; and while W and w maintain the same proportion, $W - w$ also maintains the same proportion to either of them. But if the strap supporting W be bent farther round the circumference, so as to embrace an arc increased by $\triangle\theta$, W will have to be increased by a quantity $\triangle W$ to produce slip, which must be proportional to W, the friction on any arc being proportional to the pressure. Hence ultimately

$\frac{dW}{d\theta} = aW$, when a is some constant depending on the nature of the rubbing surfaces. Integrating, we have $\log. W = a\theta + C$. When $\theta = o$, $W = w$, because the friction is $= o$. Hence $\log. \frac{W}{w} = a\theta$, or $\frac{W}{w} = f = \varepsilon^{a\theta}$. If when the arc is Θ, the friction be $F = \varepsilon^{a\Theta}$ and hence $f = \varepsilon^{a\theta} = \left(\varepsilon^{a\Theta}\right)^{\frac{\theta}{\Theta}} = F^{\frac{\theta}{\Theta}}$, or the ratio expressing the friction over any arc is, as the friction over any other arc raised, to the power expressed by the ratio of the one arc to the other great prime-mover, such as a steam-engine or water-wheel, is communicated by shafts, pulleys, straps, and wheel-work, to the different machines. However excellent may be the arrangements or workmanship of the connecting machinery, still there must be considerable waste of power in overcoming the mere friction attending its motion; and this waste is very much increased when the accuracy of arrangement is affected by wear, or by the unequal settlement of any part of the building supporting the bearings of shafting. Of late years, engineers have devoted attention to the communication of power, to some extent, without the intervention of wheel-work and shafting, but by the supply of steam from a central boiler to numerous small engines, arranged throughout the building, in the immediate neighbourhood of the machinery to be put in motion. The pipes that convey the steam are cheaper in first cost than shafting of equivalent length; their efficacy is not dependent on accuracy of levels, nor is it impaired by wear; and the friction attending the passage of steam through them is much less than the friction of shafting. It is true that the force of steam passing through great lengths of pipes is considerably diminished by cooling; but much of this loss may be saved by covering the pipes with non-conducting materials, such as felt or sawdust, and by superheating the steam in the first instance. The objection generally made to this mode of communicating power is, that the first cost of the numerous small engines generally exceeds that of one large engine, and that each of the small engines requires separate attendance. We believe, however, that, in an extensive work, the cost of steam-pipes and numerous small engines will not be found to exceed that of a large engine, with all the shafting and connecting machinery; and that, with proper arrangements, the attendance given by workmen to the separate machines will be sufficient for the engines that put them in motion. A number of machines are now made to act directly by steam-power, without the intervention of machinery. Among them we may cite, as examples, the steam-hammer and steam riveting machine. In both these cases, the direct pressure of steam upon a piston takes the place of the former complicated arrangements of wheel-work, eccentrics, cams, and levers, which were necessary for converting the rotary motion of shafting into the reciprocating movements required for hammering and riveting. To many other manufacturing operations we think the same principle of movement might be applied with good effect; and we believe that the simplicity, directness of action, and facility of control attending such arrangements, would soon cause them to take the place of the more complicated methods of deriving power from rotary motions.[*]

The atmospheric railway is an example of an arrangement for communicating power on a large scale by means of the fluid motion. A pipe, several miles in length, with a longitudinal slit or opening along its upper side, is laid down between the rails. The pipe is fitted with a piston, and the slit is covered by a flexible valve, which can be lifted so as to permit an upright rod attached to the piston to pass through the upper part of the pipe to a carriage mounted on the rails. When the carriage and piston are at one end of the pipe, the valve being closed tightly over the slit, and luted by grease melted over it, the air is extracted from the pipe by pumps worked by a steam-engine; and the pressure of air on one side of the piston being thus in a great measured removed, the atmospheric pressure, acting on the other side, forces it along the pipe with great velocity, and thus gives motion to the carriage which is connected with the piston and the train of carriages attached to it. The piston and connecting-rod are fitted with suitable rollers for lifting the valve in front of the upright rod, and for closing it and sealing it up behind it; so that after the passage of the train in one direction, the pipe may be ready for exhaustion to draw a train in the opposite direction. In the trials made with this system of propelling trains, it was found possible to secure great velocities, and to move very heavy trains over severe inclinations when the pipe and its valve were in good order. But the great practical difficulties attending the construction and tight-closing of the valve proved an almost insuperable objection to the use of the atmospheric railway, as even a small leakage of air into the vacuum-pipe necessitated the expenditure of great power in the pumping engine to sustain the required vacuum.

It was at one time proposed, that in the case of a city like London, with numerous small steam-engines and boilers scattered through it, power should be communicated to different establishments from some central source, by means of compressed air forced through pipes laid down like the gas and water-pipes in the streets. One large engine, continually sustaining a supply of air condensed to a pressure of several atmospheres, would thus take the place of the numerous separate boilers now supplying steam, and the air thus supplied would work the present engines as effectually as the steam. There is little doubt that, were such an arrangement carried out, the first cost of the air-pipes being met, there would be considerable advantages attending it, in respect of economy and the diminution of danger from boiler explosions, as well as the removal of numerous sources of offence from the chimneys of manufacturing establishments.

Arrangements of a similar character might at present be carried out in cities like London without any great outlay, where the supply of water is adequate. The pumping engines of the water companies might be made the means of supplying power to numerous establishments of machinery at a very cheap rate. It is found, practically, that in pumping water, 1 ton of fuel is capable of raising 25,000 gallons of water 100 feet high; and as water from a cistern 100 feet high would press with a force of 46 lbs. on every square inch of a piston exposed to its action, this power might be readily made available for raising weights, giving pressure, or even driving machinery by the intervention of properly constructed water-pressure engines.[†]

CHAPTER VIII.

RULES AND TABLES.

Contents.—SYMBOLS OF ARITHMETICAL OPERATIONS—WEIGHTS AND MEASURES—TEMPERATURE—ARCS AND ANGLES—CIRCUMFERENCES—SUPERFICIES—SOLIDS—SOLIDS OF REVOLUTION—DUODECIMALS—WEIGHTS OF MATERIALS.

THE practical mechanic has frequent occasion to calculate the lengths of lines, areas of figures, capacities of solids, and weights of masses of material. We think, therefore, that we cannot better conclude the general view we have endeavoured to give of mechanics practically applied, than by furnishing a few of those simple rules and methods of calculation, which most commonly occur in practice.

[Many of these rules have been dealt with already in a scientific form in the section on Mathematics, but this statement, in a simple and concise form, may render them more easily understood by persons not familiar with abstract science].

---

[*] In Manchester and Glasgow it is usual to fix a separate steam engine to each calico-printing machine, partly for the reasons assigned above, and also that each machine may be independent of a main moving power, whose speed could not be readily varied to suit the exigencies of the work in hand.—ED.

[†] Since the completion of the Loch Katrine water-works, by means of which Glasgow is supplied with water at a high pressure, many small water engines have been erected for working cranes, &c., which are charged at a fixed annual rental.—ED.

We must presume that the mechanic is tolerably intimate with the ordinary operations of arithmetic—Addition, Subtraction, Multiplication, and Division; and that he will bear in mind the following symbols, as a kind of arithmetical short-hand, often useful in expressing rules and modes of operation.

+ placed before a quantity, means that it is to be added to the quantity preceding it.

— placed before a quantity, means that it is to be subtracted from the quantity preceding it.

× placed between two quantities, means that the first is to be multiplied by the other.

÷ placed between two quantities, means that the first is to be divided by the last.

When instead of two dots in this symbol of division, one quantity is written above the line and the other below it, the upper is to be divided by the lower. Thus $12 \div 4$ may be written $\frac{12}{4}$, which means that 12 is to be divided by 4.

= placed between two quantities, means that the one is equal to the other.

Example 1.—*Power = weight × velocity,* means that the power of any machine is equal to the weight raised by it, multiplied by the velocity with which it is raised. Thus, if an engine raise 330 lbs. at the rate or velocity of 100 feet per minute, we should say its power is equivalent to 330 lbs. × 100 feet = 33,000 lbs. at the rate of 1 foot per minute.

2. *Horse-power* $= \frac{\textit{weight (lbs)} \times \textit{velocity (ft. per min.)}}{33000}$

means that the power of a machine reduced to the standard of horse-power, is equivalent to the weight in lbs. multiplied by the velocity in feet per minute, and divided by 33000. Thus, if an engine raise 330 lbs. 100 feet high per minute, its horse-power is $\frac{330 \times 100}{33000} = 1$; that is to say, one-horse power.

WEIGHTS AND MEASURES.—The table of weights and measures most necessary in computations connected with Practical Mechanics, are those of Avoirdupois Weight, Lineal, Superficial, and Solid Measure, Time, Temperature, and the Division of the Circle. Unfortunately for ease of recollection and computation, the English Tables of measures have no regular system, and, therefore, require to be remembered separately, or to be constantly referred to. The French have adopted a regular and simple system, both in the names and in the relations of their different denominations. As their measures are frequently referred to in scientific works, we subjoin tables of them along with the English tables; and short rules for the reduction of quantities given in the one, to their corresponding values in the other.

TROY WEIGHT.

Used for the precious metals and for chemical analysis.

		Contracted.
24 Grains	= 1 Pennyweight	24 gr. = 1 dwt.
20 Pennyweights	= 1 Ounce	20 dwt. = 1 oz.
12 Ounces	= 1 Pound	12 oz. = 1 lb.

1 pound troy therefore contains 5760 grains.
1 pound avoirdupois contains 7000 troy grains.

AVOIRDUPOIS WEIGHT.

Used for weighing all materials except those to which troy weight is confined.

		Contracted.
16 Drachms	= 1 Ounce	16 dr. = 1 oz.
16 Ounces	= 1 Pound	16 oz. = 1 lb.
28 Pounds	= 1 Quarter	28 lbs. = 1 qr.
4 Quarters	= 1 Hundredweight	4 qrs. = 1 cwt.
20 Hundredweights	= 1 Ton	20 cwt. = 1 ton.

FRENCH DECIMAL SYSTEM OF WEIGHT.

10 Milligrammes = 1 Centigramme
10 Centigrammes = 1 Decigramme.
10 Decigrammes = 1 Gramme = 15·434 troy grains.
10 Grammes = 1 Decagramme.
10 Decagrammes = 1 Hectogramme.
10 Hectogrammes = 1 Kilogramme = 2·20486 lbs. avoirdupois.
10 Kilogrammes = 1 Myriagramme.
10 Myriagrammes = 1 Quintal = 1 cwt. 3 qrs. 25 lbs., nearly.
100 Quintals = 1 Millier or Bar = 9 tons. 16 cwt. 3 qrs. 12 lbs.

The general principle adopted in the French system, is that of the decimal scale. They settle on some unit of weight or measure—as the gramme for weight, and the mètre for measure. For the names of all fractions of that unit, proceeding by tenths, hundredths, and thousandths, downwards, they prefix the Latin numerals *deci* for tenth, *centi* for hundredth, *milli* for thousandth, to the name of the unit. Thus, a centigramme is the hundredth part of a gramme, and would be written in figures 0·01 gramme; a millimètre is a thousandth part of a mètre, and would be written 0·001 mètre. Again, for the names of all multiples of the unit, proceeding by tens, hundreds, thousands, and ten thousands upwards, they use the Greek numerals—*deca*, ten; *hecto*, hundred; *kilo*, thousand; *myria*, ten thousand, prefixed to the unit. Thus, for a thousand mètres, they say a kilomètre, written 1000 mètres; for ten thousand grammes, they say myriagramme, written 10,000 grammes. There are a few exceptions for the larger denominations in the scale of weights, which we have given in full. According to this system, each denomination finds its place in the ordinary decimal scale of notation, and arithmetical operations are reduced to the simple rules, without the necessities of complicated reduction.

For example, if we wished to ascertain the cost of 7 myriagrammes, 3 kilogrammes, 4 hectogrammes, 6 decagrammes, 5 grammes, 3 centigrammes, of a material at 2 francs 20 cents per kilogramme,

we should write the quantity . 73465·03 grammes
which is equivalent to . . . 73·46503 kilogrammes, pointing off 3 figures.
Multiply by the price per kilo. . 2·2

14693006
14693006

161·623066 francs.

Or, 161 francs, 62 cents.

In the English system, on the other hand, a similar question—as, for instance, the cost of 17 tons 4 cwt. 3 qrs. and 18 lbs., at 12*s.* 9*d.* per cwt.—would involve the necessity of reducing the several denominations, or of artifices for employing fractional parts as in the ordinary arithmetical rule of Practice.

To reduce kilogrammes to lbs. avoirdupois.

Rule.—Multiply by 2·20486.

Example 1.—To reduce 17 kilogrammes to lbs.

Multiply by 2·20486

37·48262 lbs.

For general practical computations, the decimal fraction, after its first figure, may be neglected, and the multiplier may be taken as 2·2 simply.

Example 2.—To reduce 23 kilogrammes to lbs.

$$23 \times 2{\cdot}2 = 50{\cdot}6 \text{ lbs.}$$

For closer approximation, after multiplying the number of kilogrammes by 2·2, add to the result the 200th part of the number, or the half with two decimal places pointed off.

Thus, $23 \times 2{\cdot}2 = 50{\cdot}6$
add $\frac{1}{200}$th of 23 ·115

50·715 lbs.
The accurate number 50·71178

To reduce lbs. avoirdupois to kilogrammes.

Rule.—Divide by 2·20486, or multiply by its reciprocal ·45355.

Example 1.—To reduce 37·48262 lbs. to kilogrammes.

Dividing by 2·20086) ———

17 kilogrammes.

The reduction may be effected with sufficient accuracy by the following artifice :—

Add together one-third of the given number of lbs , one-third of that third, and one-twelfth of the last third.[*]

Example 2.—To reduce 37·48262 lbs. to kilogrammes.

one-third	12·49421
one-third of one-third	4·16473
one-twelfth of the last	·34706
	17·00600

Example 3.—To reduce 5 cwts. 2 qrs. 12 lbs. to French weight.

4

22 qrs.
28

3)628 lbs.

3)209·33
12) 69·77
5·81

284·91 kilogrammes.

LINEAL MEASURES.

12 Inches	=1 Foot	6 Feet	=1 Fathom
3 Feet	=1 Yard		
$5\frac{1}{2}$ Yards	=1 Pole or Rod	7·92 Inches	=1 Link
40 Poles	=1 Furlong	100 Links	=1 Chain
8 Furlgs.	=1 Mile	80 Chains	=1 Mile

The measures employed for the smaller dimensions of mechanical work, are the foot, its twelfth part the inch, and the fractional divisions of the inch, dividing successively by 2 ; viz.—the half, the quarter, the eighth, the sixteenth, the thirty-second, &c. For larger works, as cuttings, embankments, shafts of mines, and the like, the yard of 3 feet, or the fathom of 6 feet, are the ordinary units. For surveying purposes, the chain of 11 fathoms, or 22 yards, or 66 feet, or 100 links is the unit. And for greater dimensions, the mile, or 1760 yards, or 5280 feet, and its fractional divisions by 2, the half-mile, the quarter mile, the eighth of a mile or furlong, are employed.

The nautical mile or knot measures 6080 feet.

The unit of French measure is the mètre, which is equal in length to 39·371 English inches, or about 3·281 English feet, or 3 feet $3\frac{3}{8}$ inches very nearly.

To reduce French measure to English.

Rule.—Multiply the number of French mètres by 3, and take the product as so many English feet, so many inches, and so many eighths of inches ; or add together the product, its twelfth part, and the eighth part of the twelfth, for the value in English feet.

Example 1.—To reduce 53 mètres to English measure.

	ft.	in.
53 × 3=	159	
159 inches=	13	3
159 eighths of inches= .	1	$7\frac{7}{8}$
	173	$10\frac{7}{8}$ nearly.

Example 2.—To reduce 42 kilomètres to English miles. The kilomètre is 1000 mètres, and 42 kilomètres are therefore equivalent to 42000 mètres.

	42000
Multiply by	3
	126000
One-twelfth . .	10500
One-eighth . .	1312·5

One mile contains 5280)137812·5 feet.

26·1 miles nearly.

1 kilomètre is exactly 1093·6389 yards.
1 mile is exactly 1760 yards.

Therefore, to reduce kilomètres to miles, multiply by $\frac{1093 \cdot 6389}{1760}$, or ·621386.

For rough calculations, take $\frac{5}{8}$ths decimally, ·625.

To reduce miles to kilomètres, multiply by $\frac{1760}{1093 \cdot 6389}$, or 1·60931 nearly.

For rough calculations take $1\frac{3}{5}$th decimally, 1·6.

The French pied or foot, is equal to 1·09 English foot.

The French pouce, or inch, is equal to 1·09 English inch.

SUPERFICIAL MEASURE.

144 square inches = 1 square foot.
9 square feet = 1 square yard.
$30\frac{1}{4}$ square yards = 1 square pole.
40 square poles = 1 rood.
4 roods = 1 acre.

The acre, therefore, contains 4840 square yards, or 10 square chains, each of 484 square yards.

The French superficial measure is, for small areas, reckoned by the squares of the mètre and its parts, the mètre carré, or square mètre, being 10·765 square feet, or 1·196 square yard. For larger areas, the French unit is the Are, which is a square decamètre, or 100 square mètres, equivalent to 119·605 square yards.

SOLID MEASURE.

1728 cubic inches = 1 cubic foot.
27 cubic feet = 1 cubic yard.
42 cubic feet = 1 ton of shipping.
40 ,, = 1 load of rough timber.
50 ,, = 1 load of squared timber.

The French solid measure is reckoned by the cube of the mètre and its parts.

1 cubic foot = ·0283 cubic mètre.
1 cubic yard = ·7645 ,,
1 cubic mètre = 35·32 cubic feet.

LIQUID MEASURE.

There are several varieties of English liquid measure, and provincial variations in their scales ; but the principal unit of liquid measure is the imperial gallon, which contains 277·274 cubic inches, and of which a cubic foot contains 6·2321, or nearly $6\frac{1}{4}$. The unit of French liquid measure is the litre, or cubic decimètre, the thousandth part of a cubic mètre, equivalent to 61·028 cubic inches, somewhat less than the imperial quart, which contains 69·3185 cubic inches.

TIME MEASURE.

60 seconds = 1 minute.
60 minutes = 1 hour.
24 hours = 1 day.
7 days = 1 week.

The French measurement of time is the same.

TEMPERATURE.

There are three scales of temperature in use :—

1. Fahrenheit's, used in England, in which the point of water freezing is 32°, and the point of water boiling is 212°.

2. The Centigrade, used in France, in which the freezing-point of water is the zero, or 0°, and its boiling-point is 100°.

3. Reaumur's, used among some Continental nations, in which the freezing-point of water is zero, or 0°, and its boiling-point 80°.

---

[*] The reason of this rule is the following :—

One-third of 1, expressed decimally, is	·3333 &c.
One-third of ·333, &c., expressed decimally, is .	·1111 ,,
One-twelfth of ·111, &c., expressed decimally, is .	·0092 ,,
Their sum	·4536
is a near approximation to . . .	·45355

To reduce temperature by Fahrenheit to temperature by Centigrade.

Rule.—Subtract 32°, multiply by 5, and divide by 9.

Example 1.—To reduce 180° Fahrenheit to Centigrade.

180

Subtract . . 32

$$\frac{148 \times 5}{9} = 82^{\circ}{\cdot}222 \text{ Centigrade.}$$

Example 2.—To reduce 15° Fahrenheit to Centigrade.

15

Subtract . . 32

$$\frac{-17 \times 5}{9} = -9^{\circ}{\cdot}44, \text{ \&c.,}$$

or 9°·44, &c., below zero.

To reduce temperature by Centigrade to temperature by Fahrenheit.

Rule.—Multiply by 9, divide by 5, and add 32°.

Example 3.—To reduce 82°·2 Centigr. to Fah.

Multiply by . . 9

Divide by . . 5)740 nearly

148

Add 32

180° Fah.

Example 4.—To reduce — 9°·4 Centigr. to Fah.

9

Divide by . . . 5) − 85 nearly

−17

Add 32

15° Fah.

Note.—When the temperature has the mark — (*minus*) prefixed, it means *below* zero, and is to be subtracted in cases where it would be added if it had not the mark —.

Example 5.—To reduce − 100° Centigr. to Fah.

9

5) − 900

− 180

32

− 148° Fah., or 148° below zero.

To reduce temperature by Fahrenheit to temperature by Reaumur.

Rule.—Subtract 32, multiply by 4, and divide by 9.

Example 6.—To reduce 62° Fah. to Reau.

Subtract . . . 32

30

Multiply by . . 4

Divide by . . 9)120

13°·3 Reau.

Example 7.—To reduce 15° Fah. to Reau.

32

− 17

4

9) − 68

− 7°·5 Reau., or 7°·5 below zero.

To reduce temperature by Reaumur to temperature by Fahrenheit.

Rule.—Multiply by 9, divide by 4, and add 32.

Example 8.—To reduce 13°·3 Reau. to Fah.

9

4)120

30

32

62° Fah.

Example 9.—To reduce − 7°·5 Reau. to Fah.

85° Centigr.

DIVISION OF THE CIRCLE.

60 Seconds = 1 Minute 60″ = 1′

60 Minutes = 1 Degree 60′ = 1°

90 Degrees = 1 Quadrant or right angle, often marked $\frac{\pi}{2}$

360 Degrees or 4 Quadrants = 1 Circumference, often marked 2 π.

THE FRENCH DIVISION IS

100 Seconds = 1 Minute.

100 Minutes = 1 Degree.

100 Degrees = 1 Quadrant.

4 Quadrants = 1 Circumference.

The quadrant, right angle, or quarter of the circumference, is the same for the French and English systems, and 100° French are therefore equivalent to 90° English.

To reduce French degrees to English.

Rule.—Subtract $\frac{1}{10}$th.

Example 1.—To express 73° French in English measure.

Subtract one-tenth . 7·3

65·7 65° 42′ English.

Multiply by . . 60

To find minutes . 42 0

Example 2.—To express 26° 7′ 35″ French in English measure.

The French number would be written 26°·0735

Subtract one-tenth . . . . . 2 ·60735

23 ·46615

60

27 ·969

60

58·14

Ans. 23° 27′ 58″·14 English.

To reduce English degrees to French.

Rule.—Add $\frac{1}{9}$th.

Example 3.—To express 65° 42′ English in French measure. $42' = \frac{42}{60}$ or 0°·7; therefore the English, expressed decimally, is 65°·7

Add one-ninth . 7 ·3

73°· French.

Example 4.—To express 23° 27′ 58″·14 English in French. The quantity, decimally expressed, is

$$\begin{array}{lr} & 23^{\circ}\cdot46615 \text{ English.} \\ \text{Add one-ninth} \quad . & 2\ \cdot60735 \\ \hline & 26^{\circ}\cdot0735 \text{ French.} \end{array}$$

The circumference of every circle is 3·1416 times its diameter, or 6·2832 times its radius or half diameter.

Hence to find the circumference of a circle whose diameter or whose radius is given,

Rule.—Multiply the diameter by 3·1416, or the radius by 6·2832.

Example 1.—To find the circumference of a pulley whose diameter is 4 feet 6 inches.

4 feet 6 ins., or 54 ins. × 3·1416 = 169·6464 ins., or 14 feet 1⅝ inches nearly.

Example 2.—To find the circumference of the pitch circle of a wheel, the pitch radius being 11 inches.

11 ins. × 6·2832 = 69·1152 ins., or nearly 69⅛ ins.

Since the decimal ·1416 is nearly equal to $\frac{1}{7}$th (which is accurately ·142587), we have the approximate rule for finding the circumference of a circle.

Rule.—Multiply the diameter by $3\frac{1}{7}$, or (since $3\frac{1}{7} = \frac{22}{7}$) multiply the diameter by 22 and divide by 7, or multiply the radius by 44, and divide by 7.

Example 3.—To find the circumference of a pulley 4 feet 6 inches diameter.

$$\begin{array}{lr} \text{4 feet 6 ins.} \times 3 & = \text{13 feet 6 ins.} \\ \text{4 feet 6 ins.} \times \frac{1}{7} (\text{or} \div 7) = & 7\tfrac{5}{8} \text{ ins. nearly.} \\ \hline \text{Circumference} & \text{14 feet } 1\tfrac{5}{8} \text{ ins. nearly.} \end{array}$$

Example 4.—To find the circumference of a wheel whose radius is 11 inches.

$$\frac{11 + 44}{7} = 69\tfrac{1}{8} \text{ ins. nearly.}$$

The circumference of an ellipse is that of a circle whose diameter is a mean between the two axes of the ellipse.

Example 5.—To find the circumference of an ellipse having a longer axis 18 ins., and a shorter axis 12 ins.

Mean $\frac{18+12}{2}$ = 15 ins. × 3·1416 = 47·124 ins. or 3 feet 11⅛ ins.

The converse operation of finding the diameter of a circle having a given circumference is,

Rule.—Divide the circumference by 3·1416, or multiply it by ·31831, the reciprocal of 3·1416.

Example 6.—To find the diameter of a pulley whose circumference is 14 feet 1⅝ in. or 169·625 ins.

$$\frac{169\cdot625}{3\cdot1416} = 54 \text{ ins., or 4 feet 6 ins. very nearly.}$$

or 169·625 × ·31831 = 54 ins. nearly.

The following approximation is generally sufficiently seen for practical purposes.

Rule.—Multiply the circumference by 7, and divide by 22, the quotient is the diameter.

Example 7.—To find the diameter of a wheel having 23 teeth, each of 3 ins. pitch.

23 × 3 ins. = 69 ins. the circumference of the pitch circle, and $\frac{69\times7}{22}$ = 22 ins. nearly.

The pitch radius is ½ of 22 ins. = 11 ins.

Mensuration of Superficies.

The object of Mensuration of Superficies is to discover the number of square units in a figure, the form and dimensions of whose boundary are known. The simplest kind of figure is that bounded by three straight lines, the triangle.

To find the area of a triangle.

Rule.—Multiply the length of any one of the sides by that of the perpendicular let fall upon it from the opposite angle (or, briefly, multiply the base by the height), and halve the result.

Example 1.—To find the area of a triangle having base 2 feet 3 ins., and height 1 foot 8 ins.

2 feet 3 ins. = 27 ins., and 1 foot 8 ins. = 20 ins.

$$\text{Area, } \frac{27\times20}{2} = 270 \text{ sq. ins.}$$

Example 2.—To find the area of a triangular field, having base 23 chains 8 links, and height 14 chains, 73 links.

$\frac{23\cdot08 \text{ ch.} \times 14\cdot73 \text{ ch.}}{2}$ = 169·9842 sq. chains; or 16·99842 acres, very nearly 17 acres.

The parallelogram is a figure bounded by four straight lines, the opposite sides being equal and parallel to one another. When the angles of the parallelogram are right angles, or, as it is said in ordinary language, when the sides are *square* to one another, the figure is called a rectangle or oblong.

To find the area of a parallelogram.

Rule.—Multiply the base by the perpendicular height. —When the figure is an oblong, we say, multiply the length by the breadth.

Example 3.—To find the area of a parallelogram, base 2 feet 3 ins., height 1 foot 8 ins.

27 ins. × 20 ins. = 540 sq. ins.

Example 4.—To find the surface of a cylinder, diameter 4 feet, length 14 feet.

The surface of a cylinder, if developed or unrolled, would form a rectangle whose length is the length of the cylinder, and breadth the circumference. Its area is therefore found by multiplying the length by the diameter, and by $3\frac{1}{7}$.

14 feet × 4 feet × $3\frac{1}{7}$ = 176 sq. feet.

The trapezoid is a figure bounded by four straight lines, two of which are parallel. To find the area of a trapezoid.

Rule.—Multiply half the sum of the two parallel sides by their perpendicular distance apart.

Example 5.—Required the area of a trapezoid having parallel sides, respectively 5 feet and 7 feet, 3 feet apart.

$$\frac{5+7}{2} \times 3 = 18 \text{ sq. ft.}$$

Any figure bounded by straight lines may be divided into triangles; and the sum of the areas of all the triangles into which it is divided, is the area of the whole figure.

Of surfaces bounded by curved lines, the most regular and frequent is the circle.

To find the area of a circle.

Rule.—Multiply the square of the diameter by ·7854. Or, multiply the circumference by the radius, and halve the product.

Example 6.—Required the area of a circle 4 ft. diam. 4 × 4 × ·7854 = 12·5664 sq. feet.

Otherwise, the radius is 2 feet, and the circumference is 4 × 3·1416 = 12·5664, and the area is

$$\frac{12\cdot5664 \text{ circumf.} \times \text{rad.}}{2} = 12\cdot5664 \text{ sq. ft.}$$

The following method furnishes a near approximation to the area.

Rule.—Multiply the diameter by itself.

Take half the product, to which add its half, and the seventh part of that half.*

Example 7.—Required the area of a circle 4 feet diameter.

$$\begin{array}{rl} 4 \times 4 = 16 \text{ and } & \frac{1}{2} \text{ of } 16 = 8 \\ & \frac{1}{2} \text{ of } \ 8 = 4 \\ & \frac{1}{7} \text{ of } \ 4 = 0\cdot57 \\ \hline \text{Area} & 12\cdot57 \text{ sq. ft. nearly.} \end{array}$$

Example 8.—Required the area of a circle 37⅝ ins. diameter.

---

* This approximate rule is thus derived:—

$$\begin{array}{lr} \text{Since one-half, decimally, is} & \cdot5000 \\ \text{One-half of } \cdot5000 & = \cdot2500 \\ \text{One-seventh of } \cdot2500 & = \cdot0357 \\ \hline \text{Their sum} & = \cdot7857 \end{array}$$

which is nearly equal to ·7854, the proper multiplier of the square of the diameter.

$37\frac{5}{8}$ or 37·625 × 37·625 = 1415·64 sq. ins.
$\frac{1}{2}$ of 1415·64 = 707·82 nearly.
$\frac{1}{2}$ of 707·82 = 353·91
$\frac{1}{7}$ of 353·91 = 50·56

Area 1112·29 nearly.
The correct area is 1111·84

Error in the approximate method 0·45 sq. ins.

The converse operation of finding the diameter of a circle when its area is given, is the following :—

Rule.—Divide the area by ·7854, or multiply the area by 1·273 (the reciprocal of ·7854), and extract the square root of the result.

Example 9.—Required the diameter of a circle having 12·5664 sq. ft. area.

$\frac{12\cdot5664}{\cdot7854}$ or 12·5664 × 1·273 = 16 ; and the square root of 16 is 4 feet.

Approximate method.

Rule.—To the given area add its fourth part, and $\frac{1}{10}$th of that fourth, or the fourth with one decimal place pointed off, and extract the square root.[*]

Example 10.—Required the diameter of a circle whose area is 1111·84 sq. ins.

Area = 1111·84
Add $\frac{1}{4}$ of 1111·84 = 277·96
$\frac{1}{10}$ of 277·96 = 27·796

1417·596

The square root of which is 37·65, or $37\frac{5}{8}$ inches nearly.

The area of an ellipse is ·7854 times the product of its two axes.

Example. 11.—Required the area of an ellipse whose axes are 2 feet 3 inches and 1 foot 8 inches respectively.

27 ins. × 20 ins. × ·7854 = 424·116 sq. in.

or, $\frac{424\cdot116}{144}$ = 2·9452 sq. feet.

The area of a sector of a circle is the same part of the area of the whole circle, as the arc of the sector is of the whole circumference.

Example 12.—Required the area of a sector ; radius 12 ins., and arc 67° 30′.

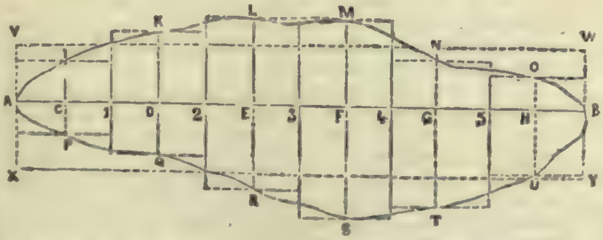
The area of the whole circle is 12 × 12 × 3·1416 = 452·39 sq. ins.

$$67^\circ\ 30' \text{ is } \frac{67\frac{1}{2}}{360}, \text{ or } \frac{67\frac{1}{2} \times 2}{360 \times 2} = \frac{135}{720},$$

or $\frac{135 \div 45}{720 \div 45} = \frac{3}{16}$ths of the whole circumference ; therefore

Area of sector is $\frac{3}{16}$ths of 452·39 sq. ins. = 84·823 sq. ins.

Fig. 270.



In measuring the area of figures bounded by lines of irregular curvature, as A L B S, the most convenient method is to draw through the figure a straight line A B, the longest possible, and to divide it into numerous equal parts at the points 1, 2, 3, 4, 5. If we bisect each of those parts at C, D, E, F, G, H, and draw perpendiculars to the line A B, meeting the curve in I, P, K, Q, &c., by drawing parallels through these points, meeting perpendiculars through the points A, C, D, &c., we form a number of rectangles, each of which is very nearly equal, in area, to the part of the curve contained between its two perpendicular sides. The area of the whole curved figure is, therefore, very nearly equal to the sum of the areas of all those rectangles. Now, as the area of each rectangle is equal to its base multiplied by its perpendicular height, and as the bases of all are equal, the area of all the rectangles is equal to the length of one of the bases, such as C D multiplied by the sum of all the heights I P, K Q, L R, &c. It is to be observed, that the distances A C and B H of the first and last perpendiculars from the extremities of the line, are each half the distance C D or D E between any two perpendiculars. Or, we may view the question in another way, thus :—Having divided the line A B as before, and set off the perpendiculars I P, K Q, &c. (technically called *offsets*), we may find a mean or average V X or W Y, by adding together the lengths of all the perpendiculars, and dividing their sum by their number, and then the whole rectangle V W Y Z has very nearly the same area with the curved figure. Hence the following—

Rule I.—Multiply the sum of all the offsets by the distance between two adjoining offsets ; or,

Rule II.—Add together the lengths of all the offsets, divide by their number, and multiply by the whole length of the base line.

Example 13.—The length of A B is 24, and the offsets are I P = 3, K Q = 5, L R = 7, M S = 8, N T = 6, O U = 4 : required the area.

By *Rule* I.—There are six offsets ; therefore the distance between any two adjoining is $\frac{24}{6}$ = 4 (note, A C and B H are each 2), and the area is

$$(3 + 5 + 7 + 8 + 6 + 4) \times 4 = 132.$$

By *Rule* II.—The mean of all the offsets is

$\frac{3 + 5 + 7 + 8 + 6 + 4}{6}$ = 5·5, and the area is 5·5 × 24 = 132.

The surface of a cone may be developed, or unrolled, into the form of a sector of a circle, and its area found by the rule. Or thus,

Rule.—Multiply the diameter of the base by the length of the side (from the apex to the edge of the base), and by 1·5708.

Example 14.—Required the surface of a cone, having a base 12 inches in diameter, and 18 inches length of side.

12 × 18 × 1·5708 = 339·2928.

The surface of a sphere is 4 times that of any of its circular sections passing through the centre. Hence, to compute the surface of a sphere—

Rule.—Multiply the square of the diameter by 3·1416.

Example 15.—Required the surface of a sphere 18 inches diameter.

18 × 18 × 3·1416 = 1017·8784 square inches.

MENSURATION OF SOLIDS.

By mensuration of solids we discover the number of cubic units in a body of given form and dimensions. A parallelopiped, or prism, has two opposite sides equal and parallel to one another. Either of these is called a base, and their perpendicular distance apart is called the height or altitude of the prism. A cylinder has a circular base.

For finding the solid contents of a prism or cylinder

Rule.—Multiply the area of the base by the height.

Example 1.—Required the capacity of a cistern, whose base is a rectangle 4 feet long by 3 feet wide, and whose height is 2 feet 6 inches.

---

[*] This rule, like the former, is thus derived,—

1 = 1·000
$\frac{1}{4}$ of 1 = 0·250
$\frac{1}{10}$ of 0·25 = 0·025

1·275, which is nearly 1·273.

Area of base $4 \times 3 \times 2\frac{1}{2}$ height = 30 cub. feet, or $30 \times 6{\cdot}2321 = 187$ gals. nearly.

Example 2.—Required the solid contents of a roller 22 ins. diameter and 42 ins. long.

$22 \times 22 \times {\cdot}7854 \times 42 = 15965{\cdot}6$ cubic inches.

When the prism or the cylinder is hollow.

Rule.—Subtract the area of the internal part of the base from that of the whole base, and multiply by the height.

Example 3.—Required the weight of a cast-iron hollow cylinder 5 feet high and 30 inches diameter internally, having metal 1 inch thick (reckoning 3·8 cubic inches of cast-iron equivalent to 1 lb.) The external diameter is the internal diameter increased by twice the thickness of metal; it is, therefore, 32 inches, and its area would be $32 \times 32 \times {\cdot}7854$. The area of the internal would be $30 \times 30 \times {\cdot}7854$; and, subtracting, we have $(32 \times 32 - 30 \times 30) \times {\cdot}7854 = 97{\cdot}436$ sq. inches for the area of the section of metal. The solid contents are

$$97{\cdot}436 \times 60 \text{ ins.} = 5846{\cdot}16 \text{ cub. ins., and } \frac{5846{\cdot}16}{3{\cdot}8} = 1538{\cdot}46$$

lbs., or 13 cwt. 2 qrs. $26\frac{1}{2}$ lbs.

When the diameter of a hollow cylinder is large in proportion to the thickness of its material, as in the case of a boiler, which may be several feet in diameter, while the thickness of its metal is less than half an inch, we may multiply the area of its surface by the thickness of material to ascertain the quantity of material. In this calculation the following points must be observed.

Boilers are generally made of wrought-iron plate; and it happens that a square foot of iron plate, $\frac{1}{8}$th of an inch thick, weighs 5 lbs. In order to ascertain the weight in pounds of a wrought-iron boiler $\frac{1}{8}$th of an inch thick, we should then have to multiply its surface by 5; and were the thickness $\frac{2}{8}$ths or $\frac{1}{4}$th, we should multiply by 2×5 or 10; for thickness $\frac{3}{8}$ths, multiply by 3×5 or 15, and so on. But in constructing boilers, there are many plates used, which overlap each other at their joints; and at the corners there are angle-irons, and numerous rivets are used to make the joints tight. Making allowance for all these additions to the weight, we may estimate the weight per superficial foot at about 6 lbs. for every $\frac{1}{8}$th of an inch in thickness, or 3 lbs. for every $\frac{1}{16}$th of an inch. Again, as $\frac{6}{112}$ is nearly $\frac{1}{20}$th, we may roughly approximate the weight in cwts. by the following rule :—

Rule.—Multiply the surface (in square feet) by the thickness (in $\frac{1}{8}$ths of an inch), and divide by 20 for the weight (in cwts.)

Example 4.—Required the weight of a Cornish boiler, external diameter 4 feet, diameter of flue-tube 2 feet, length 12 feet, thickness $\frac{3}{8}$ and $\frac{1}{16}$ of an inch (or $3\frac{1}{2}$ eighths of an inch).

$$\begin{array}{lll}
\text{External circumference . . } & 4 \times 3\frac{1}{7} & \\
\text{Circumference of flue . . . } & 2 \times 3\frac{1}{7} & \\
\hline
\text{Both . . . . } & 6 \times 3\frac{1}{7} & = \overset{\text{nearly}}{18{\cdot}9} \times \overset{\text{length}}{12} = \overset{\text{surface of casing and flue.}}{226{\cdot}8} \\
\text{Area of end of boiler . } & 4 \times 4 \times {\cdot}7854 & \\
\text{Area of flue . . . . } & 2 \times 2 \times {\cdot}7854 & \\
\hline
\text{Difference . . . . . } & 12 \times {\cdot}7854 & = 9{\cdot}4 \times 2 \text{ (ends)} = \overset{\text{surface of ends.}}{18{\cdot}8} \\
 & & \qquad\qquad\qquad\quad \overline{245{\cdot}6} \text{ total surface.}
\end{array}$$

$$\text{And } \frac{245{\cdot}6 \times 3\frac{1}{2}}{20} = 43 \text{ cwt. nearly, or 2 tons 3 cwt.}$$

The cubic contents of a sphere are $\frac{2}{3}$rds of that of a cylinder of the same diameter and altitude. But the altitude being equal to the diameter, and $\frac{2}{3}$rds of ·7854 being ·5236, the contents of the sphere may be found by the following method :—

Rule.—Multiply the cube of the diameter by ·5236.

Example 5.—Required the number of cubic inches in a ball 12 inches diameter.

$12 \times 12 \times 12 \times {\cdot}5236 = 904{\cdot}7808$ cubic inches.

When the sphere is hollow,

Rule.—Subtract the cube of the internal diameter from the cube of the external diameter, and multiply by ·5236.

Example 6.—Required the weight of a hollow ball of iron, 30 inches diameter externally, metal $1\frac{1}{2}$ inch thick, reckoning 3·8 cubic inches to the pound.

$$\begin{array}{ll}
\text{External diameter } 30 \times 30 \times 30 = & 27000 \text{ cubed} \\
\text{Internal diameter } 27 \times 27 \times 27 = & 19683 \\
\hline
\text{Difference . . . . } & 7317
\end{array}$$

$$\text{And } \frac{7317 \times {\cdot}5236}{3{\cdot}8} = 1008 \text{ lbs. or 9 cwt.}$$

The cubic contents of a cone are $\frac{1}{3}$rd of that of a cylinder of equal base and altitude. Hence, to find the contents of a cone :—

Rule.—Multiply the square of the base by the height and by ·2618.

Example 7.—Required the solid contents of a cone, having a base 18 inches diameter, and a height of 22 inches.

$18 \times 18 \times 22 \times {\cdot}2618 = 1866{\cdot}11$ cubic inches.

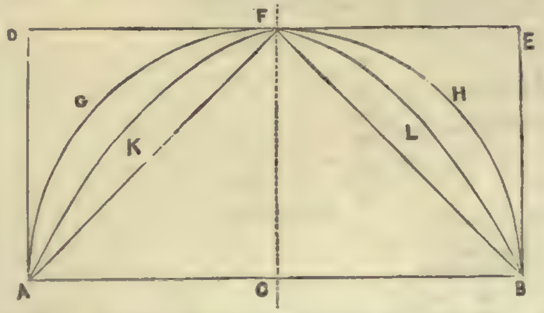
The solids with which the practical mechanic has to deal are chiefly those called solids of revolution, or such as may be conceived to be produced by the revolution of some figure round an axis. Any work that is formed in a turning-lathe is a solid of revolution. An imaginary line extending between the centres of the lathe is the axis; and if the solid were cut across by a plane passing through this line, the section or surface exposed on the removal of the half cut off, is symmetrical on each side of the axis or centre line. One-half of this symmetrical figure, or the part lying on either side of the axis, is called the generating figure. Thus, a cylinder is generated by the revolution of an oblong or rectangle round one side. A cone is generated by the revolution of a right-angled triangle round its perpendicular. A sphere is generated by the revolution of a semicircle round its diameter. A spindle, by the revolution of a segment of a circle, or other curve, round its chord. In the same way, other mathematical figures, such as the ellipse, or the parabola, are capable of producing solids of revolution by causing them to revolve round their axis. When the ellipse is supposed to revolve round its shorter axis, the solid produced is called an oblate or shortened spheroid; when it revolves round its longer axis, the solid is an oblong spheroid. The parabola, by revolution, produces the paraboloid.

There are singular relations among some of these solids of revolution, one of which it is useful to remember. If A B E D (Fig. 271) represent the section of a cylinder, whose base has a diameter A B double its height, or axis, C F—A F B the section of a cone on the same base, and of the same height with the cylinder—A G F H B the section of half a sphere,—and A K F L B the section of a paraboloid; then

The solid contents of the cone are $\frac{1}{3}$rd of that of the cylinder.
„ „ hemisphere are $\frac{2}{3}$rds „ „
„ „ paraboloid are $\frac{1}{2}$ „ „

As the paraboloid comes midway between the cone and the hemisphere in form of section, so its capacity comes midway between them in amount. In many cases of mensuration of solids of revolution, when the form of section is something between that of a cone and of a hemisphere, it may be taken as a paraboloid, and its capacity may be found thus :—

Fig. 271.



Rule.—Square the diameter of the base, multiply by the height and by ·3927 (half of ·7854). Or, multiply the area of the base by half the height.

Example 8.—Required the solid content of a paraboloid, base 2 feet 6 inches diameter, height 1 foot 8 inches.

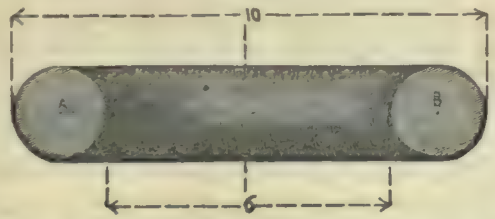
Area of a circle 2 feet 6 inches, or
30 inches diameter . . . . . 707 sq. ins., nearly.
Half of 1 foot 8 inches, or 20 inches 10

Solid content 7070 cubic inches.

In general, the capacity of any solid of revolution may be found by multiplying the area of its generating figure by the circumference described by the centre of gravity of that figure. In a ring, for instance, generated by the revolution of a circle round some centre without it, if we know the diameter of its generating circle or section, and the distance of its centre from that round which it revolves, we can compute its solid contents, as we may show by an example.

Example 9.—A ring of circular section measures 10 ins. external diameter, and 6 ins. internal: required its solid contents. Subtracting 6 from 10, there are left 4 ins., which must be double the diameter of the ring's section, giving 2 ins. as the actual diameter of the section, which has therefore an area 2 × 2 × ·7854 = 3·1416 sq. ins. Again, adding 6 to 10, and taking half, we get 8 ins. as the distance between A and B (Fig. 272), the centres of the circular sections, and the circumference of a circle 8 ins. diam. is 8 × 3·1416 = 25·1328 ins. The solid content of the ring is therefore 3·1416 sq. ins. × 25·1328 ins. = 78·9572 cub. ins. In this particular case, it happens that the centre of gravity of the section coincides with the centre of figure. When this is not the case, the position of the centre of gravity may readily be found by the following mechanical process :—

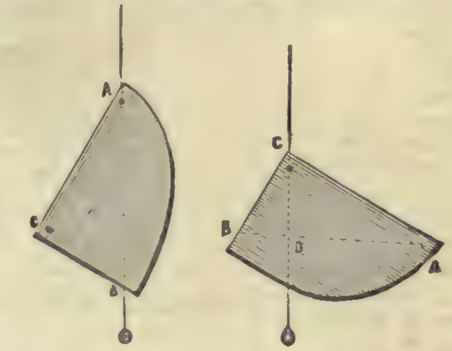
Fig. 272.



Draw upon a card or piece of thin wood, or plate of metal such as zinc, the figure, either of its full size or to any convenient scale ; and having cut it out to the shape, make two small holes in it, such as A and C (Fig. 273). Suspend it by a thread from one of the holes, and along the face of it let a plumb-line hang and mark B, the point where the plumb-line crosses its edge, tracing a line A B coinciding with the plumb-line. Suspend it now by the other hole C, with the plumb-line crossing the line formerly traced at D. The point where the lines cross is the centre of gravity, or that round which all parts are balanced. The position of the centre of gravity thus ascertained may be laid down upon the drawing of the work to be estimated, and the solid content may be found by the rule we have given.

For the measurement of a solid of irregular form, the most convenient method is to suppose it divided by numerous parallel planes into sections of equal thickness—to measure the area of each of those sections, and find the mean or average of them by summing them all and dividing by their number. This average area multiplied by the total thickness, measured perpendicularly across the planes of section, will give the solid content. In many cases of the measurement of cylindrical bodies, such as timber or round bars of metal, it is more convenient to use the girth or circumference as a known dimension for estimating the cubic contents. A near approximation to the capacity may be made thus :—

Fig. 273.



Rule.—Multiply the square of the girth by the length, and by 8, and point off two decimal places.

Example 10.—Required the cubic contents of a round log, having an average girth of 6 ft. 3 ins., and 12 ft. long.

6 ft. 3 ins., decimally expressed, is 6·25, and 6·25 × 6·25 × 12 × 8 = 3750. Pointing off two decimal places, the solid content is 37·5 cub. ft. The ordinary rule for timber gives a considerably smaller result, and is intended, not to furnish the accurate contents, but the contents estimated according to trade custom. It is,

Rule.—Multiply the square of ¼th the girth by the length.

According to this rule, the contents of the log. in *Example* 10 would be (¼th of 6·25 being 1·5625) 1·5625 × 1·5625 × 12 = 29·3 cubic feet.

DUODECIMALS.

In the mensuration of surfaces and solids, a system of computation is frequently adopted, called the duodecimal system, because the notation is reckoned by twelves (Latin, *duodecim*), instead of the ordinary decimal scale of tens (Latin, *decem*).

According to the duodecimal system, a square foot is supposed to be divided into 12 equal parts, each containing 12 square inches : and each of those parts again into twelfths, each 1 square inch ; and these again into twelfths. So, also, a cubic foot is divided into 12 equal parts, each 144 cubic inches ; each of those into 12 parts, each 12 cubic inches ; and each of those into 12 parts, each 1 cubic inch. To multiply a certain number of feet and inches by some other number of feet and inches, the one quantity is written below the other, as in ordinary multiplication.

1. The inches are multiplied by inches, the product divided by twelve, the remainder written one place back from the inches, and the quotient carried to the next operation.

2. The feet are multiplied by inches, and the number carried from the former operation added, the result divided by twelve, the remainder written in the place of inches, and the quotient written in the place of feet.

3. The inches are multiplied by feet, the result divided by twelve, the remainder written in the place of inches, and the quotient carried.

4. The feet are multiplied by feet and the carried number added, and the whole written in the place of feet.

5. The result of the two multiplications are added, carried by twelves.

For cubing, the same process is repeated, remembering that in the cubed result, or the result of multiplying three quantities of feet and inches, there are four places—viz., cubic feet; twelfths, each 144 cubic inches; twelfths of twelfths, each 12 cubic inches; and cubic inches.

Example.—Required the cubic contents of a cistern, the base of which is 4 ft. 8 ins. long by 3 ft. 10 ins. wide, and the height 5 ft. 7 ins.

We first find the area of the base.

4 ft. 8 in.
3 10
3*c*. 10*b*. 8*a*.
14*e*. 0*d*.
17 ft. 10 pts. 8 ins.

Operation. 8 ins. × 10 ins. = 80 sq. ins. and $\frac{80}{12}$ = 6 pts. 8 ins.
carry 6 and write 8, *a*.
4 ft. × 10 ins. = 40, add 6 = 46, and $\frac{46}{12}$ = 3 ft. 10 pts. *b*, *c*.
8 ins. × 3 ft. = 24, and $\frac{24}{12}$ = 2 ft. 0 pts.
carry 2, and write 0, *d*.
4 ft. × 3 ft. = 12 ft., add 2, 14 ft., *e*.
Sum the two lines.

We now multiply the area of base by the height.

	ft.	pts.	ins.	
Area	17	10	8	
		5	7	
	10	5	2	8
	89	5	4	
	99	10	6	8

Operation. 8 × 7 = 56, and $\frac{56}{12}$ = 4 ft. 8 ins., carry 4.
10 × 7 + 4 = 74, and $\frac{74}{12}$ = 6 ft. 2 ins., carry 6.
17 × 7 + 6 = 125, and $\frac{125}{12}$ = 10 ft. 5 ins.
8 × 5 = 40, and $\frac{40}{12}$ = 3 ft. 4 ins. carry 3.
10 × 5 + 3 = 53, and $\frac{53}{12}$ = 4 ft. 5 ins., carry 4.
17 × 5 + 4 = 89. Add up the lines.

The cubic contents are therefore

99 cub. ft. 10 twelfths, 6 hundred and forty-fourths, 8 cub. ins., or 99 ft. 1520 cub. ins., because 10 twelfths, each of 144 cubic inches . . . . = 1440 cubic inches.
6 hundred and forty-fourths, each 12 cub. ins. = 72 ,,
8 cubic inches . . . . 8 ,,
1520

Water is generally taken as the standard of specific gravity, and it fortunately happens that 1 cubic foot of water weighs very nearly 1000 ounces. By reference to any table of specific gravities, the weight of a cubic foot of each material is given in ounces; and from this may be readily derived—

1. The weight of 1 cubic foot in lbs., viz., $\frac{1}{16}$th of the specific gravity or weight in oz., because 1 oz. = $\frac{1}{16}$ of 1 lb.

2. The weight of 1 cubic inch in ounces—viz., the specific gravity divided by 1728, because there are 1728 cubic inches in 1 foot—and the weight of 1 cubic inch in lbs, viz., the specific gravity divided by 1728, and the quotient by 16, or the specific gravity divided by 27648.

3. The number of cubic inches in 1 lb., viz., 16 times 1728, or 27648 divided by the specific gravity.

4. The number of cubic feet in 1 ton, viz., 2240 lbs. × 16 oz., or 35840 oz. divided by the specific gravity.

Example 1.—Required the weight in lbs. of 7 cubic feet of English oak.

Spec. grav. $\frac{900}{16} \times 7 = 393\frac{3}{4}$ lbs., or 3 cwt. 2 qr. $1\frac{3}{4}$ lbs.

Example 2.—Required the weight of 178 cubic inches of cast-iron.

Spec. grav. $\frac{7200}{1728} \times 178 = 742$ oz.

Or $\frac{7200}{27468} \times 178 = 46\frac{1}{3}$ lbs.

Example 3.—Required the number of cubic inches in 2 cwt. (or 224 lbs.) of gun metal.

$\frac{27648}{\text{Spec. grav. } 8800} \times 224 = 703\frac{3}{4}$ cubic inches.

Example 4.—Required the number of cubic feet in 20 tons of granite.

$\frac{35840}{\text{Spec. grav. } 2700} \times 20 = 265\frac{1}{2}$ cubic feet.

In estimating the weight of wrought-iron cylindrical bars, the following method is a very near approximation:—

Rule.—Square the diameter reduced to eighths of an inch, multiply by the length in feet and by $4\frac{1}{7}$, and point off two decimal places for the weight in lbs.

Example 1.—Required the weight of a cylindrical bar of wrought-iron $5\frac{7}{8}$ ins. diameter, and 7 ft. 7 ins. long.

$5\frac{7}{8}$ ins. = 47 eighths, and 7 ft. 7 ins. = $7\frac{7}{12}$ ft.

$47 \times 47 \times 7\frac{7}{12} \times 4\frac{1}{7} = 69401$.

The weight is therefore 694 lbs., or 6 cwt. 0 qr. 22 lbs.

For wrought-iron bars of rectangular section:—The width of these advances by quarters, and the thickness by eighths of an inch.

Rule.—Multiply the breadth in quarters of an inch, by the thickness in eighths, by the length in feet, and by $10\frac{1}{2}$, and point off two decimal places for the weight in lbs.

Example 2.—Required the weight of a bar of wrought-iron $2\frac{1}{4}$ inches wide, $\frac{3}{8}$ in. thick, and 3 feet long.

Width 9 qrs. × thickness 3 eighths × length 3 ft. × $10\frac{1}{2}$ = 850; therefore the weight is 8·5 lbs.

For wrought-iron plates.

Rule.—Multiply the area in square feet by the thickness in eighths of an inch, and by 5 for the weight in lbs.

Example 3.—Required the weight of 123 square feet of boiler-plate $\frac{1}{4}$ and $\frac{1}{16}$ in. thick.

Thickness $\frac{1}{4}$ and $\frac{1}{16}$, or $2\frac{1}{2}$ eighths of an inch.

$123 \times 2\frac{1}{2} \times 5 = 1538$ lbs., or 13 cwt. 2 qr. 26 lbs.

For cast-iron balls.

Rule.—To the cube of half the diameter (in inches) add its eleventh part for the weight in lbs.

Example 4.—Required the weight of a cast-iron ball 6 ins. diameter. Half the diameter is 3 ins.

And 3 × 3 × 3 . . = 27
Add one-eleventh of 27 = 2·5
Weight . . . . 29·5 lbs.

SIR J. F. W. HERSCHEL, BART., F.R.S.

SECTION X.

ASTRONOMY.

CHAPTER I.

HISTORY OF THE SCIENCE, AND ITS DEFINITIONS.

Astronomy is that science which teaches the distribution and arrangement of the heavenly bodies ; their true and apparent motions in space ; their magnitude, distance, and physical condition ; and its history presents some of the most brilliant examples of the development of the human mind.

Astronomy essentially owes its existence as a science, as well as its present degree of perfection, to continuous observations of the heavenly bodies, from the first watchings of the Chaldean shepherds, to the refined instrumental measurements of the astronomers of the nineteenth century. But if the accumulated observations of centuries, which the genius of man would naturally endeavour to preserve, had not been made subservient for the prediction of recurrences of the same phenomena, Astronomy would exist only in name, and cease to hold its high position among the accurate sciences. Its course, however, has not always been progressive : it is only within the last few centuries that the errors of antiquity have been completely eradicated. To the invention of the telescope, and its application to graduated instruments, we are in a great measure indebted for this progress, which, in a physical point of view, it is impossible to over-estimate, for it has permitted great and permanent advances to be made in the accurate observations of the heavenly bodies. By the latest improvements in these instruments, astronomers have been enabled to note, with an incredible degree of precision, the apparent places of the fixed stars and planets. In this manner, as the accuracy of observation increased, the errors of the ancient theories exhibited themselves more clearly, and the mind of man has been enabled to explain, on sound and natural principles, the new phenomena which have been revealed. The discovery of the aberration of light and of the nutation of the earth's axis, two of the greatest discoveries of any age, have thus resulted, and afforded to Dr. Bradley the means of investigating, by accurate observation of the places of the stars, the preceding discovery by Roemer, of the successive transmission of light, which he had determined by observations of the eclipses of Jupiter's satellites.

The total overthrow of the Ptolemaic system is owing to the same cause—the observations of Tycho Brahé having furnished means of clearly exhibiting to Kepler, the errors of a circular hypothesis, in the same manner as the errors of the Alphonsine tables, based also on the Ptolemaic theory, pointed out to Copernicus the errors of the ancient philosophy, when it was discovered, about the epoch of 1500, that they differed more than two degrees of the truth. Calculation has also lent its aid in reducing to law, and in grappling with difficulties, problems, which the happy invention of logarithms has rendered accessible, and which, in other respects, without this assistance, would be almost insurmountable.

We find that, amongst the most ancient nations of antiquity, the appearance of the heavens was attentively watched. And, in the first place, the motions of the sun and moon commanded attention, in regard both to the duties of the husbandman, and appointments for the assemblage of large masses of the people. The Egyptians and Chaldeans discovered that the motions of these bodies, and the planets, were all performed within a certain compass of the heavens, which was termed the Zodiac ; the names of the constellations through which this belt passed, having especial reference to the motions of the sun. We also find that eclipses of the sun and moon were recorded with superstitious veneration ; whilst, in connection with the foolish study of judicial astrology, the positions of the planets, with reference to bright stars, were also carefully noted. The Egyptians and Chaldeans were acquainted with the time of the revolutions of the moon's nodes—an epoch which they termed the *Saros*—which would give them the means of predicting eclipses, recurring, as they naturally would, in the same eras. The Chaldeans were also acquainted with the lunar-solar period of 600 years, which Josephus attributed to the ancient patriarchs, although Pliny cites Hipparchus as its author. Their primitive observations appear to have consisted in the heliacal rising of bright stars, and probably in the use of the gnomon or sundial.

Thales, of Miletus, in Asia Minor, who had studied the astronomy of the Egyptians, is supposed to have predicted, by a knowledge of the period of 223 lunations, or the Saros, the famous eclipse which occurred about 585 B.C., and which is recorded by Herodotus.

Thales, on his return from Egypt, founded the Ionian school (B.C. 640). This school had for its followers Anaximander (B.C. 610), Anaximenes (B.C. 530), and Anaxagoras (B.C. 500). The first is known by a most useful invention, viz., that of geographical charts. The others added some fanciful notions, in addition to those of Thales, on the construction of the universe ; and they all appear to have believed in the plurality of worlds. The most enlightened disciple of this school, however, was Pythagoras (B.C. 580), who, having been advised by Thales to travel into Egypt to perfect his studies, became initiated in the secret mysteries of the priests in a greater degree than any of his predecessors. He founded a school in Italy on his return, where the doctrines of the Ionian school were more fully promulgated. He appears to have been acquainted with the earth's rotation on its axis, its annual revolution, and its spherical figure—doctrines which, in imitation of the Egyptian priests, were kept secret from the multitude.

But the first approach to a scientific system of astronomy was that of the Alexandrian school, where we find observations carried on regularly, and a theory which, though founded in error, rudely satisfied the observations of the period. The most distinguished members of this school were Aristarchus of Samos (B.C. 281), Eratosthenes of Cyrene (B.C. 276), and Hipparchus of Bythinia (B.C. 140). Aristarchus is famous for having made an approximation to the distance of the sun from the earth, by the angular measurement of the distance of the sun and moon, at the time at which the moon is half illuminated. Having found that the moon's angular distance at this period was 87°, he thence concluded that the sun was distant eighteen or twenty times that of the moon. This method, however ingenious, fails in consequence of the roughness of the moon's surface. By careful observations of the sun's path, he also made an approximation to the diameter of this body, which he considered to be $\frac{1}{720}$th part of the whole daily motion—an observation not very far from the truth. His tract on the magnitude and distances of the sun and moon has been preserved. In addition to the tenets of the Alexandrian school, he was of opinion that the stars were at distances immensely greater than the sun, on which account this astronomer must hold a high rank among those of antiquity.

Eratosthenes of Cyrene, who lived B.C. 276, is known for a determination of the obliquity of the ecliptic, by observations of the altitude of the sun at the summer and winter solstices—an observation of great value, as showing the progressive diminution of this element when compared with modern observations. He also made an approximation to the magnitude of the earth, on correct principles, by the measure of the celestial arc, included between Syene and Alexandria, combined with the known distance between the two places. Syene was one of the most southern cities of ancient Egypt, where it happened that at the summer solstice the sun was exactly vertical, which he determined by the fact that a deep well was wholly illuminated. At Alexandria, which was situated in the same meridian, and at the same period of time, the sun's zenith distance was 7° 12′, or one-fiftieth part of the whole circumference. The distance of the two places was known to be 5,000 stadia, whence he concluded that the circumference of the earth was 250,000 stadia. The great uncertainty of the length of the stadium does not permit us to make use of this determination, or to compare it with the method pursued with more accurate instrumental means by modern astronomers.

Apollonius of Perga deserves also to be mentioned as having invented the system of deferents and epicycles, for the purpose of accounting for the direct, stationary, and retrograde appearances of the planets.

But one of the greatest astronomers of antiquity, Hipparchus (B.C. 140), now appeared, famous alike as an accurate observer and geometer. To this distinguished man we are indebted for the discovery of the "precession of the equinoxes." The appearance of a new star led him to form a star catalogue, by a comparison of which, with a former catalogue of the same school, this important element became evident. He was also acquainted with the unequal motion of the sun in its orbit, and the inequality of the solar rays. The former he endeavoured to explain by a modification of the preceding system of deferents and epicycles, which will be explained in its proper place.

The revolution of the moon's nodes, and the inclination of its orbit to the ecliptic, were also known to Hipparchus, as well as the eccentricity of the sun's orbit and the motion of the apsides. By a comparison of his observations of the sun with the former astronomers, he determined the length of a tropical year. His solar tables were held in high estimation by Ptolemy three centuries after their construction.

Ptolemy (B.C. 130) collected the observations of the Alexandrian school in his *Almagest*, a work which existed as a text-book among astronomers for centuries. He is famous for having discovered the *evection* of the moon, imperfectly known to Hipparchus; and by a comparison of observations of eclipses, and at the other parts of the moon's orbit, he empirically determined its amount with a great degree of accuracy. He confirmed the value of the precession of the equinoxes, previously discovered by Hipparchus. He also proportioned the magnitude of the deferents and epicycles, for the purpose of explaining the planetary motions, which had been previously invented by Apollonius and Hipparchus, whence the name of the "Ptolemaic System." In his Geography, he collected the longitudes and latitudes of all known places. He also left behind him many other works, testifying to his skill and genius as a philosopher.

After the death of Ptolemy, the Alexandrian school existed only in name. During five centuries, the discoveries of Hipparchus and Ptolemy were not extended; and the labours of its followers consisted principally in commenting on their works, and in noting extraordinary phenomena.

After the dissolution of the Alexandrian school, the science of astronomy in Europe had almost disappeared; but among the Arabs, it had been cultivated with some success under the auspices of the more enlightened caliphs. The *Almagest* of Ptolemy was translated into their language, and their annals transmit to us many observations of the sun, moon, and planets, as well as the measure of a degree of latitude. Among the Arabian astronomers, Albategnius deserves honourable mention as an industrious and accurate observer. He confirmed and corrected the rate of the precession of the equinoxes, and also determined the obliquity of the ecliptic, which, from several collateral circumstances, is entitled to great confidence. He also paid considerable attention to the theory of the sun, and determined the eccentricity of its orbit with accuracy. He also found that the apogee of the sun was subject to a small annual displacement, according to the order of the signs, and determined its position at that period to be in the constellation Gemini, which, when compared with the modern elements, does not differ more than 40′ from the truth. The astronomy of the Arabians does not open to us any new theories, but is merely an extension of the system of Ptolemy. In the art of observation they had, however, improved; larger instruments and more refined calculations had been introduced by them, on which account their investigations are entitled to hold a high rank in the history of astronomy.

After the Persians had thrown off the yoke of the Arabians, Holeg Ilecoukhan, one of the Persian sovereigns, founded an academy of astronomers, where they formed new tables based on the Ptolemaic system, with trifling changes in their elements. But the greatest praise is due to Ulugh Beigh, one of their princes, who was a great patron of this science, as well as an observer, and who formed a catalogue of stars, and improved the solar and planetary tables. He also determined the obliquity of the ecliptic, and the precession of the equinoxes.

The next epoch of the history of astronomy commences with its revival in Europe, when, after the overthrow of the Arabian empire, it again became cultivated in Spain. Alphonso, the tenth king of Castile, collected a body of astronomers at Toledo; and having made use of the observations of the Arabians for the purpose of correcting the planetary motions, published the Alphonsine tables, which are more correct than any which preceded them in some respects; but their accuracy was not commensurate with the great trouble and expense they occasioned. The great confusion of the Ptolemaic system, caused Alphonso to say, "that if he had been consulted at the Creation, he could have devised a better arrangement." In Austria, the study of astronomy was cultivated under the auspices of Albert, the third duke, and Frederick the second emperor. In the 15th century, Purbach, Regiomontanus, and Waltho lived, known as assiduous cultivators of this science. Ephemerides of the planets and eclipses were published for the meridian of Vienna from 1475, first by Regiomontanus, who, being also an observer, was well acquainted with the errors of the Alphonsine tables, the place of Mars being above 2° in error. The art of measuring time received an important improvement by the substitution of clock-work motion for the clepsydræ of the ancients, which also increased the accuracy of observations; and about this period the true system of the universe forced itself on the attention of Copernicus.

This distinguished astronomer—who saw clearly the errors of the Ptolemaic system, and who, after thirty-six years of study, published, in a clear and connected form, the present system of the world—was born at Thorn in Prussia, in 1473, four years before the death of Regiomontanus. The ancient systems of astronomy, as related by Plutarch and Cicero, had, by their extreme simplicity, captivated his mind; and to this circumstance we owe his explanation of the celestial motions; an explanation which, however imperfect in several respects, shows his originality. In his system, he adopted the hypothesis of the earth's rotation on its axis, its annual revolution round the sun, in common with the other five known planets, whose distances from the great central body he proportioned. As regards the "precession of the equinoxes," he conceived it to arise from a small motion of the earth's axis. In consequence, however, of his ignorance of the elliptical motions of the planets, he was unable totally to abolish the system of epicycles. The work which contained his explanations was dedicated to Pope Paul III.; and it was owing only to the urgent representations of his scientific friends, that he was induced to publish it in the form of an hypothesis. He had only revised the last proof sheet when death put an end to his labours in his seventieth year.

One of the most important inventions ever introduced by the genius of man, was afterwards applied to the observations of the heavenly bodies by Galileo. This was the telescope, which has enabled the astronomer to overcome the feebleness of his natural vision, and to examine leisurely, and attentively, the physical constitution of the celestial bodies. Galileo, an ardent follower of Copernicus, was immediately convinced of the truth of the system, when, having observed the phases of Venus, he traced their connection to their elongation from the sun, and found that the orbit of this planet was included within the earth's orbit. Galileo also discovered the four satellites of Jupiter, and was acquainted with the existence of spots on the sun, from which he concluded the rotation of that body on its axis. He appears also to have first applied the pendulum to the clock.

The overthrow of the Ptolemaic system followed quickly on the footsteps of Copernicus and Galileo, but not till the new system had encountered much opposition. Tycho Brahé, who was born in 1546, is celebrated in having supplied observations of greater excellence than any of his predecessors. The cultivation of practical astronomy had made but little progress since the time of the Arabs, and the new theory required accurate observations to test its correctness. Tycho thus paved the way for Kepler to make his splendid discoveries. Personally, however, he resisted the Copernican theory, and invented an hypothesis of his own, retaining the earth as the centre of the universe, but making the sun the centre of the planetary motions. This system had few admirers; but the accuracy and number of his planetary observations, his star catalogue, his discovery of the "variation" of the moon, and his table of refractions, give him a position among the astronomers of his period. From the planetary observations of Mars, the immortal discovery of the elliptic motions of the planets has resulted. Kepler placed such confidence in the observations of Tycho, that he affirmed his belief that the true system of the universe might be founded on them. Taking at first the Copernican doctrine of a circular hypothesis, he found that a difference of 8′ existed between the theory and observation of Mars, which difference, from the accuracy of the observations, he had no doubt was attributive to an erroneous hypothesis. After labour infinitely great, extending over a period of twenty years, he discovered his three famous laws which serve as the foundation of modern astronomy. Kepler appears also to have had some notions on gravity; and he left also some tracts on optics. The laws which he had determined for the sun and planets, were found also to extend to the satellites of Jupiter, they having been just discovered by Galileo, Huygens, and Cassini.

Among the distinguished men who followed Kepler, mention must be made of Huygens, Hevelius, Cassini, and Roemer. The first, in addition to his optical and mechanical improvements, described the ring surrounding Saturn as well as one of its satellites, and is said to have applied the pendulum to clocks—a discovery also claimed for Galileo. Hevelius is known as a persevering observer. But all his observations were made with the naked eye; and although he was able to estimate angular spaces by these means to a wonderful degree of accuracy, which Dr. Halley confirmed by direct comparison, his observations cannot be made use of in any delicate inquiry. His researches on comets, and his tables of the sun, rank him in a high position among practical astronomers. Cassini formed tables of Jupiter's satellites from observation, and determined the rotation of Jupiter and Mars. He also occupied himself with refractions, and made a theory of the libration of the moon, which had been left in an imperfect state by Hevelius. Roemer is known as the inventor of the transit instrument and meridian circle, with which instruments he carried on a series of observations of the heavenly bodies for several years; but only those of three days have been preserved, the others having been destroyed in the great fire which occurred at Hafnia. Roemer also discovered, by comparison of Cassini's tables of Jupiter's first satellite, the successive transmission of light. The discovery of universal gravitation by Newton, at the latter end of the seventeenth century, produced a total revolution in astronomy, and enabled its illustrious author to account for the previous empirical deductions of Kepler.

Since the discovery of gravitation by Sir Isaac Newton, astronomy has been much advanced by the establishment of observatories. And, in this respect, England has great reason to be proud of her position, her astronomers having followed up this immortal discovery by a series of observations unexampled for their extent—an object which is essentially necessary, in order to continue the comparison of theory and observation, for the correction of the elements of the system. The accuracy of the science has been considerably increased by the institution of the Royal Observatory at Greenwich, both with regard to the eminent men who have directed this establishment, and to the continuous mass of observations which it has furnished. Founded by King Charles II., in 1675, it has had for its directors, successively, Flamsteed, Halley, Bradley, Bliss, Maskelyne, Pond, and Airy.

Flamsteed is known as the greatest observer of the age in which he lived. Patronised by Sir Jonas Moore, to whom the foundation of the Greenwich Observatory is due, he carried on for many years continuous observations of the planets and fixed stars, and contributed materially to furnish Sir Isaac Newton with the observations on which his system of the world is based. He was succeeded by Dr. Halley, an astronomer to whom we are indebted for many useful investigations, but whose province did not so much lie in practical astronomy as that of his predecessor. This distinguished man has the merit of adding considerably to our knowledge of cometary astronomy, and the lunar theory. But one of his greatest triumphs, which will always render his name illustrious, is his proposition of determining the sun's distance, by the transits of Venus over its disc.

Dr. Bradley, the next in succession, enriched this science by two important discoveries—viz., the aberration of light, and a more exact knowledge of the nutation of the earth's axis. Distinguished as the most accurate astronomer of his age, he reobserved, with better instruments, all the stars of Flamsteed, as well as the sun, moon, and planets, the former observations of which, have been incorporated in the *Fundamenta Astronomiæ* of Bessel. His observations of the moon and planets, are included in the Greenwich planetary and lunar reductions.

The same important class of observations was continued by Dr. Maskelyne, from 1765 to 1811, extending over an interval of forty-six years. In addition to other important works, this astronomer has the credit of establishing the *Nautical Almanac* for the use of mariners, and of introducing in that work, tabular elements for the improved method of finding the longitude at sea.

On the same regular system have been carried on, at the Royal Observatory, observations of the sun, moon, and planets, under the superintendence, successively, of Mr. Pond and Professor Airy. If it were necessary to discuss the importance of the immediate comparison of theory and observation, it would be merely requisite to mention, that the discovery of the planet Neptune has thus resulted—a discovery which, in the opinion of all competent judges, deserves to be ranked among the most brilliant triumphs of the human mind.

In the field of telescopic research, the labours of Sir W. Herschel deserve particular mention. His discovery of the planet Uranus and its satellites, as well as his investigation on Saturn's rings—his theory of the motion of the solar system in space and its direction, which have been verified recently by several independent researches, are sufficient monuments of his skill and industry.

In France, the cultivation of practical astronomy in the eighteenth century was well sustained by the celebrated astronomers Lalande and La Caille, the latter having observed the stars of the southern hemisphere about the epoch 1750; the publication and reduction of which, have since been undertaken by the British Association. He is also known as having determined the *constant* of lunar parallax, by corresponding meridional observations at the Cape of Good Hope and at European stations. Besides these important undertakings, he was an energetic calculator of ephemerides, and useful investigations on refraction, the figure of the earth, &c.

Lalande is known as an industrious and indefatigable observer. His immense catalogue of stars bears sufficient evidence of his unremitting industry for many years. The catalogue of stars formed from his observations, have been reduced and published by the British Association.

In Sicily, the labours of Piazzi have been principally occupied in an extensive catalogue of stars, the epoch of which is the beginning of the present century, and which is now one of the standard works of the day. His zeal was rewarded by the discovery of Ceres among the asteroids, in 1801. The discoveries of these bodies, during the last ten years, are too numerous to be mentioned here.

The progressive improvements of instruments during the last century, have been rewarded by increased accuracy of results. At Greenwich, the mural arc of Flamsteed is now replaced by the magnificent transit circle; and the aid of galvanism has been brought to bear on an essential and delicate element of time—viz., that of right ascensions. All these circumstances produce a corresponding improvement in theory. Successive comparisons of theory and observation engage the attention of our analysts; and to this we are in a great measure indebted for the important discoveries of the various inequalities, which have enriched the science of astronomy.

ASTRONOMICAL DEFINITIONS.

Having thus shown how the investigating disposition of man has been occupied in its endeavour to obtain a more correct and perfect knowledge of the universe, we proceed to explain the laws which have been established.

Astronomy is usually divided into three parts:—1. Spherical Astronomy, which teaches the knowledge of the various points and circles of the celestial sphere, the constellations, the position of the stars with respect to these points and circles, and the phenomena occurring in the sphere of the heavens.—2. Theoretical Astronomy, which enables us to determine, from observation, the path of the heavenly bodies.—3. Physical Astronomy, which gives the laws by which the heavenly bodies are regulated, teaches how their motions are to be calculated according to the rules of mechanics, and combines all that is known of their physical characters. Without the formality of so dividing our subject, which our space does not permit, we shall endeavour to combine all the useful and practical portions of the subject.

In order to facilitate the study of the heavens, artificial representations have been made, similar to those of the surface of the earth. These are called celestial globes, on which the stars are depicted in their natural positions, the observer being supposed to be in the centre, viewing them in the concave surface.

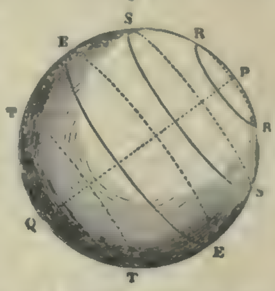
To represent the apparent diurnal motion of the heavenly bodies, the celestial globe must be turned from east to west.

Circles.—To designate with precision the situation of the sun, moon, and stars, imaginary circles have been considered as drawn in the heavens, most of which correspond to, and are in the same plane with similar circles supposed to be drawn for similar purposes on the surface of the earth. If a line be drawn on the sphere (Fig. 1) of the earth P Q, the plane cuts the surface of the sphere, and forms a great circle E E, which is the celestial equator, the sphere being divided in this circle into two hemispheres, in which one of the poles forms a central position; these form the northern and southern hemispheres.

A plane is that which has surface, but not thickness. The plane of a circle is that imaginary surface which the circle bounds.

The axis of the earth, P Q, is an imaginary line passing through its centre, north and south, about which its diurnal revolution is performed; the poles of the earth are the two extremities of the axis, where it is supposed to cut the surface. The axis of the heavens is the earth's axis, produced both ways to the concave of the sky; the poles of the heavens are two imaginary points exactly above the terrestrial poles.

Fig. 1.



Great circles are those which divide the globe into two equal parts, as the equator, the ecliptic, and the colures. R R, S S, and T T (Fig. 1) are small circles which divide the globe into two unequal parts, as the tropics, polar circles, and parallels of latitude.

Every circle is supposed to be divided into 360 equal parts or degrees. A degree is further subdivided into 60 equal parts or minutes; and a minute into 60 seconds. Degrees are marked°, minutes′, seconds″. The space included by a degree of a great circle in the heavens, is equal to nearly twice the apparent diameter of the sun or moon, when considerably above the horizon.

The equator of the earth, E E (Fig. 1), is an imaginary great circle passing round the globe, east and west, everywhere equidistant from the poles, dividing it into northern and southern hemispheres. The equator of the heavens, or the equinoctial, is the plane of the terrestrial equator extended to the concave surface of the heavens, and called the equinoctial, because, when the sun appears in it, the days and nights are equal all over the world.

The Ecliptic is the *via solis*, or sun's path, the great circle which he appears annually to describe among the fixed stars; though, more properly, it is the track which the earth actually describes among the stars, as viewed from the sun. The ecliptic is so called, because solar and lunar eclipses only can happen when the moon is in or very near this circle. It cuts the equinoctial obliquely at two opposite points, making an angle with it of 23½°, which is called the obliquity of the ecliptic. One half lies on the north side of the equinoctial; the other half on the south side. The points of crossing are the equinoctial points. A zone or girdle extending 8° on each side of the ecliptic, or 16° in breadth, is the zodiac, in which are the orbits of all the planets, with the exception of some of the asteroids. The ecliptic and zodiac are divided into twelve equal parts, called signs, each containing 30°. Their names, with the days on which the sun enters them, are as follows;—

Northern signs, being north of the equinoctial.

Spring Signs.	*Summer Signs.*
Aries, the Ram, March 21.	Cancer, the Crab, June 21.
Taurus, the Bull, April 19.	Leo, the Lion, July 23.
Gemini, the Twins, May 20.	Virgo, the Virgin, Aug. 22.

Southern signs, being south of the equinoctial.

Autumnal Signs.	*Winter Signs.*
Libra, the Balance, Sept 23.	Capricornus, the Goat, Dec. 21.
Scorpio, the Scorpio, Oct. 23.	Aquarius, the Water-bearer, Jan. 20.
Sagittarius, the Archer, Nov. 22.	Pisces, the Fishes, Feb. 19.

The Colures are two great circles passing through the poles of the heavens, dividing the ecliptic into four equal parts, and marking the seasons of the year.

One passes through the equinoctial points, Aries and Libra, and is therefore called the equinoctial colure. When the sun is in either of these points, the days and nights on every part of the globe are equal to each other. The other passes through the solstitial points, Cancer and Capricorn, which mark the sun's greatest declination, north and south of the equator, and is thence called the solstitial colure. When the sun is in or near these points, his meridian altitude undergoes scarcely any sensible variation for several days; and hence the term solstitial applied to them.

The Horizon is a great circle, whose plane passing through the centre of the earth, and extended to the sphere of the fixed stars, divides the heavens into two hemispheres, of which the upper is the visible, and the lower the invisible hemisphere. This is the rational or true horizon, which determines the rising and setting of the sun, planets, and stars. It is represented by the wooden horizon of the artificial globe. The sensible or apparent horizon is the circle which bounds our view, where the land, or water, and sky, seem to touch each other; more or less extensive according to the position of an observer.

The sensible horizon of a person changes as he moves, and, in an open country, enlarges or contracts as his station is high or low. Standing on a plain, the eye having an elevation of 5 feet above the surface, the radius of the sensible horizon will be less than 2¾ miles. At an elevation of 6 feet it will be just 3 miles.

Rule, to find the distance when the height is known—Increase the height in feet one half, and extract the square root for the distance in miles.

Thus, in the preceding case the eye is supposed to have an elevation of 6 feet above the surface of a plain, and 6 with its half is 9, the square root of which is 3; that gives the distance in miles which a person will be able to see in a right line upon that surface.

Again—a tower, 32 yards above the level of the ocean, may be seen along that level from a distance of 12 miles. For 32 yards = 96 feet, increased one half = 144, the square root of which is 12.

The poles of the horizon are the zenith and the nadir. The zenith is the point in the heavens which is directly over our heads; the nadir, that which is exactly under our feet. The zenith to us is the nadir to our antipodes, and the nadir to us is their zenith. Circles drawn through the zenith and nadir of any place, cutting the horizon at right angles, are called azimuth or vertical circles; and that which passes through the east and west points of the horizon, is the prime vertical.

Meridians are imaginary great circles passing through the terrestrial and celestial poles, cutting the equator and equinoctial at right angles.

A meridian is supposed to pass through every place on the earth, and every point in the heavens; but only 24 are drawn on the globes through every 15° of the equator and equinoctial, including altogether 360°. These meridians mark the space which, in consequence of the earth's diurnal rotation, the heavenly bodies appear to describe every hour through the 24 in the day. They are sometimes called, therefore, hour or horary circles. As 15° answer to an hour, 1° answers to four minutes of time, ½ to two minutes, and ¼ to one minute.

Longitude on the earth is distance east or west from a fixed meridian measured on the equator. The Fortunate Islands, supposed to be the Canaries, supplied the ancients with their first meridian. The western extremity of Africa, as then known, was taken by Abulfeda, the Arabian geographer. The meridian of Terceira was used by the Spanish and Portuguese in the sixteenth century; and that of Ferro by all nations in the seventeenth and eighteenth centuries. We now adopt the meridian of the Greenwich, and the French that of the Paris, observatories.

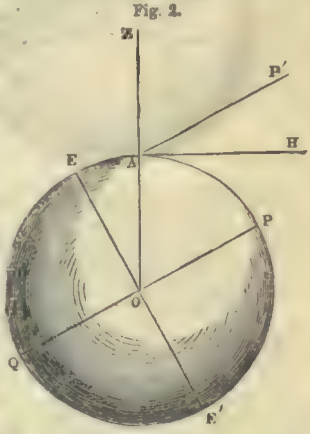
Longitude in the heavens, is distance east from the great meridian which passes through the first point of Aries, or the equinoctial colure, measured on the ecliptic.

Right ascension, is distance east from the same meridian measured on the equinoctial.

Terrestrial longitude being reckoned in two directions from a fixed point, east and west, can only extend to 180°. Celestial longitude, and right ascension, are only reckoned in one direction, east from the prime meridian, and may, therefore, extend to 360°.

Parallels of Latitude are small circles supposed to be drawn on the surface of the earth, north and south of the equator, and parallel to it, dividing the globe into two unequal parts. Let us suppose A (Fig. 2) to be placed under consideration, and P, E, Q, E′ its meridian, E E′ the line intersecting the equator, and P Q the line of the poles, it is here the arc A E, or, which is the same thing, the angle A, O, E, which represents the latitude sought. P, O, E being a right angle, the latitude is the complement of the angle A, O, P; but the angle A, O, P, is only another thing for the zenith distance Z, A, P, of the pole of the celestial sphere. For to an observer placed at A, P Q is a parallel to the earth's axis; the latitude of the point A then is the complement of the zenith distance from the pole at that point, to the height P′, A, H, of the pole above the horizon, A H, being equal to the distance Z, A, P′. We can, therefore, say that the latitude of a place is equal to the height of the pole above the horizon of that place. Parallels of declination are such circles produced in the heavens, north and south of the equinoctial, and parallel to it.

Fig. 2.



Latitude on the earth is the distance of a place from the equator, measured on a meridian, north or south.

Declination is the distance of the heavenly bodies from the equinoctial, measured on a meridian, north or south.

Latitude in the heavens is distance from the ecliptic, at a right angle, north or south.

Terrestrial latitude and declination may extend to 90°. The sun has no declination when in the equinoctial. His greatest declination is 23½° north or south. He has no latitude, being always in the ecliptic. The greatest declination of a planet is 30½°, and latitude 8° north or south, with the exception of the asteroids. It is more convenient to describe the position of the heavenly bodies by their declination and right ascension, than by their latitude and longitude, the former corresponding to terrestrial latitude and longitude.

The Tropic of Cancer is a small circle 23½° north of the equator, and parallel to it; and the tropic of Capricorn is a similar circle, at the same distance, on the south. The polar circles are also small circles, each 66½° from the equator, and at the same distance from the poles as the tropics are from the equator.

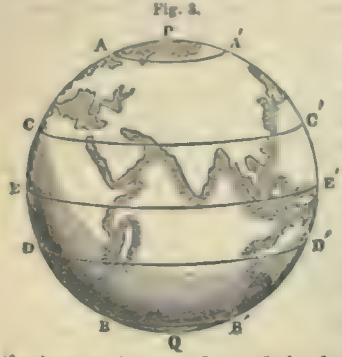
The tropics on the celestial sphere, mark the limits of the sun's farthest declination, north and south.

The tropics on the terrestrial sphere, divide the torrid from the two temperate zones, and the polar circles divide the temperate from the two frigid zones.

Zones.—Twice in the year the sun is vertical to those who dwell in the torrid zone. Consequently, at noon they deflect no shadow, and are hence styled *ascii*, meaning shadowless. At other times their shadows fall at noon, north or south, according as the sun is north or south of them. They are then called *amphiscii*, signifying that their shadows fall both ways.

The variation in the temperature has led to the division of the earth into zones. Between the latitude 66° 32′ north and south, the sun rises and sets every day. In all higher latitudes, however, there are certain periods of the year when the sun never rises, and others when it never sets. The two parallels of latitude A A′, B B′ (Fig. 3), which correspond to the latitude 66° 32′, divide the surface of the earth in three parts. The two zones at A P A′, B Q B′ are called the frozen zones. The circles A A′, B B′ are the polar circles; A A′ is the arctic; while the other is the antarctic circle: in the points between these two are the several zones, in which the sun sets and rises daily.

Fig. 3.



Those who dwell in the temperate zones have their shadows at noon always cast towards the north in the north temperate zone, and towards the south in the south temperate zone. They are styled *heteroscii*, meaning, that they have their shadows at noon, either north or south.

The inhabitants of the frigid zones are called *periscii*, signifying a shadow turning about, as, during a revolution of the earth on its axis, their shadows are projected towards every point of the compass.

The Disc of a planet is its apparent face, seemingly perfectly flat, though really spherical. The planets exhibit discs as seen with the telescope. The diameter of the disc of the sun and moon is considered to be divided into twelve parts called digits.

The Orbit of a planet is the path described by it in one revolution round the sun.

The Plane of a planet's orbit is an imaginary surface cutting through the centre of the sun and the planet, and reaching out to the stars.

Fig. 4.

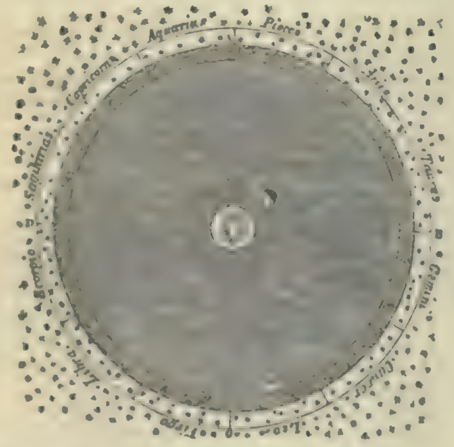


Figure 4 shows the plane of the earth's orbit. The stars to which it extends form the constellations of the zodiac. The circle A, B, C, D, is the ecliptic, the sun's place in the heavens, as seen from the earth, and the earth's place as seen from the sun.

The Inclination of the orbit of a planet is its plane referred to the plane of the earth's orbit, to which it is inclined.

If we suppose the shaded part of the diagram to be a surface of water, a ring hoop held inclined so as to be half immersed, will describe the relation of the planetary orbits to that of the earth. They are all inclined towards it, one half being below, and the other half above it. The angle of inclination varies, but exhibits, at the greatest, only a slight divergence.

Mercury . .	7°	0′	9″	Jupiter .	1°	18′	51″
Venus . .	3	23	28	Saturn . .	2	29	35
Mars . .	1	51	6	Uranus .	0	46	28

The Nodes of a planet are the two opposite points where its orbit appears to cut the orbit of the earth, or the ecliptic. Where the planet appears to rise above the orbit of the earth, it is called the ascending node; the opposite point, where it appears to go below it, is called the descending node.

Conjunction and *Opposition* are terms used to denote certain situations of the planets with respect to the sun and to each other.

A planet directly between the earth and the sun, is said to be in inferior conjunction with the sun. This can only take place in the case of Mercury and Venus, but along with them the earth may be in inferior conjunction with the sun to Mars, and with Mars to Jupiter, &c.

A planet with the sun directly between it and the earth, is said to be in superior conjunction with the sun. The terms inferior and superior refer to the smaller or greater distance of the planet from the earth.

A planet, with the earth directly between it and the sun, is said to be in opposition. This can never take place in the case of Mercury and Venus, whose orbits are included in that of the earth.

Planets are said to be in conjunction with each other when they are in the same sign and degree. This is a common occurrence in the case of two; but the very rare phenomenon of Mercury, Venus, Mars, Jupiter, and Saturn being in conjunction between the wheat ear of Virgo and Libra, took place, September 15, 1186. It will be ages before they cluster again in that part of the heavens. Venus, Jupiter, and the moon, were in conjunction in Leo in 1801.

The aspect of the planets to each other is said to be sextile, when they are two signs apart, or the sixth part of the zodiac; quartile, when they are three signs distant, the fourth part of the zodiac; trine, when they are four signs distant, the third of the zodiac; and in opposition, when they are six signs, or half the zodiac, from each other.

Apogee is that point of the moon or a planet's orbit which is farthest from the earth.

Perigee is that which is nearest.

Aphelion is that point of the orbit of the earth, or of any planet and comet, which is farthest from the sun.

Perihelion is that which is nearest. A straight line joining the points of aphelion and perihelion, is called the line of the apsides.

Culmination is the act of coming to the meridian in the case of any star or planet, when it attains, on any given day, its greatest altitude in the heavens.

Daily Acceleration is the interval of time that the stars rise, culminate, and set, sooner every succeeding day than on the one preceding. It amounts to about four minutes daily, or two hours a month.

Rotation.—Besides the apparent diurnal motion of the stars, caused by the earth's rotation upon its axis, they appear to have a motion westward, in consequence of the earth's orbital course eastward. They gain, therefore, on the sun, rising, culminating, and setting sooner, day after day. Thus, those stars and constellations that, on any given evening, rise at ten o'clock, will, at the same hour, a month afterwards, be 30° above the horizon; and three months afterwards, they will be advanced over our heads; and six months afterwards be setting in the west, having accomplished half of their apparent annual revolution.

Hence the same constellations are not always visible to us through the year. Some, not visible before, successively rise to view in the east; while others sink in the

Planisphere containing the Zodiacal signs … Southern constellations according to Kircher

… Planisphere containing the Zodiacal signs and the Northern constellations according to Kircher west, and are not seen again, until, having passed through the lower hemisphere, they reappear in the east.

Rising and Setting.—Cosmical, achronical, and heliacal rising and setting of the stars and planets, are phrases of the old poets, who spoke of the phenomena in reference to the rising and setting of the sun. A star or planet rising and setting with the sun, was said to rise and set cosmically. A star or planet rising at sunset, or setting at sunrise, was said to rise and set achronically. A star or planet appearing a little before the sun, in the morning, after having been so near him as to be hid by his effulgence, was said to rise heliacally, and to set heliacally when it ceased to be visible after him in the evening, on account of its proximity to his orb.

Apparent Solar Day is the time included between the centre of the sun leaving the meridian of any place, to its return to the same meridian again.

It varies continually in length, owing to the unequal motion of the earth in its orbit, and the obliquity of the ecliptic, being sometimes more and sometimes less than twenty-four hours. The greatest variation occurs about November 1, when the solar day is 16′ 17″ less than twenty-four hours, as shown by a well-regulated clock.

Mean Solar Day is the time which would elapse between consecutive returns of the sun to the meridian of any place, if moving in the plane of the equator, with an equable motion. It is the mean of the true solar days throughout the year, and consists of twenty-four hours, as measured by a time-piece, which, on some days of the year, is as much faster than the sun-dial, as on other days the sun-dial is faster than the time-piece.

Sidereal Day is the time which elapses between consecutive returns of any fixed stars to the same meridian, or, in other words, the period which the earth takes to accomplish one rotation on its axis. This period is unvarying and immutable—23 hours, 56 minutes, 4 seconds—which would always be the length of the solar day, if the earth stood still in space, and only turned upon its axis.

In comparison with the immense distance of the stars, the diameter of the earth's orbit is but a point; and, consequently, in relation to them, the diurnal rotation is performed precisely the same as if our globe had no translation in space. This is not the case in relation to the sun, a nearer neighbour; and owing to the earth's change of place, somewhat more than one diurnal revolution, or twenty-four hours, is required to bring the sun round again to the same meridian.

Astronomical Day is reckoned from noon to noon; and, consisting of the same length of twenty-fours in all latitudes, is called a natural day.

Artificial Day is the time between sunrise and sunset, and varies with the latitude of places.

Solar or Tropical Year is the time which the earth takes in moving in its orbit, or, apparently, the sun in the ecliptic, from one equinox or tropic to the same again, consisting of 365 days, 5 hours, 48 minutes, 49 seconds.

Sidereal Year is the time occupied by the earth in moving in its orbit, or, apparently, the sun in the ecliptic, from a determinate point in relation to any fixed star, to the same point again, and consists of 365 days, 6 hours, 9 minutes, 12 seconds.

[The accompanying folio plate illustrates some subjects mentioned in the preceding pages, in reference to the history and technicalities of the science.—Fig. 1 represents an armillary sphere, showing the position of the equator, the ecliptic, and other circles found drawn on celestial globes. The general appearance of one of them is shown in Fig. 2.—Fig. 3 gives the names and positions of the equator, poles, zones, &c., of the sphere referred to in the foregoing definitions.—Figs. 4 and 5 afford an interesting illustration of the zodiac, and northern and southern constellations, as drawn and used by the ancient Egyptians.* At the present day, the representation of each sign used by astronomers, is almost identical with that figured in the plate.—Ed.]

CHAPTER II.

ON THE EARTH.

The earth, which to the eye of its inhabitants appears an immense plane, stretching out to an indefinite extent in all directions, is, by a variety of circumstances appealing to our reason and our senses, shown to be of a spherical form.

On the Figure of the Earth.—The notions of the ancients on the figure of the earth were very uncertain and vague. Xenophanes, who lived 500 or 600 years before the Christian era, supposed the earth to be a plane of indefinite extent, whose foundations were infinite in depth. There appears to have been a great repugnance to admit that a planet could remain suspended in space as the earth is; but as science progressed, and the art of observation became more certain, the ancient astronomers became well acquainted with its spherical figure. The shadow of the earth, projected by the moon in an eclipse of that body, clearly demonstrated its spherical form; and, on the other hand, the measures of its circumference, which the Grecian and Arabian astronomers have recorded, indicate clearly that, when reduced to a common modulus, their agreement is sufficiently striking to show that they possessed some knowledge of its dimensions. The natural pride of man, however, placed it in the centre of the universe; and according to the doctrines of the Ionian school, the solid crystalline orb, to which the stars were supposed to be attached, revolved around it in the space of 24 hours. The celebrated Aristotle, whose philosophy reigned for many centuries, was of this opinion, but he supposed that the motions of the sun, moon, and planets were performed with solid heavens, but at a nearer distance; and to explain their proper motions, he considered that a presiding genius was placed in each planet.

The usual arguments brought forward in favour of the spherical figure of the earth, are, that navigators sail round it, setting out in an easterly, and returning in a westerly, direction; but a happy illustration is given in the appearance of a vessel as it approaches the shore, or in leaving a harbour, or a succession of steam-vessels at sea. In the first case, we see at a distance the upper parts of the vessel, and gradually the lower parts, till finally the hull, which is the most conspicuous part of the vessel, in other circumstances, appears from beneath the waters. In the case of leaving a harbour, the contrary appearance takes place.

These appearances arise from the convexity of the water, between the eye and the object; for if the surface of the sea were a dead level, the largest objects would be visible the longest.

Other arguments are adduced:—Upon the bosom of the ocean, or in the midst of an extensive plain, the boundary of vision is a well-defined circle, and this circular horizon is a certain indication of the circular figure of the body to which it relates.

Navigators proceeding in the same general direction, east or west, have arrived at the same point from whence they have started. This enterprise, now so common, was first undertaken by Ferdinand Magellan, who sailed westerly from Seville, in Spain, August 10, 1519, passed the extremity of the South American continent, entered the Pacific, and reached the Philippine islands, where he was killed in a skirmish; but one of his ships arrived at St. Lucar, near Seville, September 7th, 1522.

Voyages of circumnavigation demonstrate the convexity of the earth, east or west, or that its form must be either globular or cylindrical. The convexity of the surface, north and south, is shown by the gradual declination and rise of the north and south circumpolar stars as the equator is approached and receded from, which proves the figure of the earth not to be that of a cylinder, but of a sphere.

---

* See *ante*, p. 859.

Though spherical, like the other planets, whose round discs are defined by the telescope, yet the earth is not a perfect sphere, whose circumference is everywhere at an equal distance from the centre. It is more convex within the tropics than towards the poles, the equatorial diameter being longer than the polar; so that its general shape is that of an oblate spheroid, bulging out in the middle, and flattened at the two opposite sides.

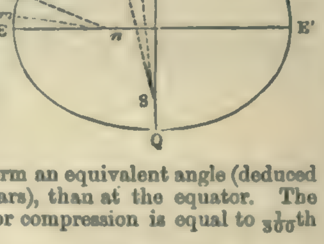
This proposition of Newton, the result alone of theory, has been amply confirmed by accurate measurements conducted by the most eminent mathematicians in various places, from the equator to the polar circle. He conceived that the velocity of the earth's daily rotation upon its axis being the greatest at the equator, the consequent greater action there, of the centrifugal force, would produce a bulging out of the surface in the equatorial regions, and a flattening at the poles. But as one of the first fundamental principles of astronomy consists in an accurate determination of the figure and dimensions of the earth, we shall briefly describe the methods adopted by astronomers for this purpose. The problem requires that all our operations must be carried on at the surface, as we cannot remove ourselves from the earth. In shifting our positions on the surface, we will take, as a point of reference, the successive appearances of the fixed stars. These bodies are so immensely distant, that at all positions on the earth, the rays emitted by them may be considered as parallel. If we shift our latitude 10° more southerly, other objects, invisible at the former station, will come under our notice near the southern horizon, whilst those near the north horizon will vanish from our view. If the difference of distance on the same parallel of longitude be measured, to produce a change of 10° in the apparent altitude of a star, we shall find, roughly speaking, that for this variation there will be a corresponding distance on the earth's surface of nearly 695 miles. And this is the principle on which the first recorded attempt of one of the ancient astronomers was founded.

Modern astronomers proceed on the same principle in a more accurate manner, and with every possible precaution to insure a correct result. In England, the first measurement of a degree was that by Norwood, in 1635, who found its length at the mean latitude of London and York, or 52° 45′, equal to 367,196 English feet, or 69 miles, 288 yards. This determination, however, is not entitled to much weight, as it appears that his latitudes were obtained by the solstitial zenith distances of the sun observed with a five-feet sextant; and it is feared, from other circumstances, that he was not sufficiently careful in his reductions to the meridian. Snell, Picard, and Cassini determined the length of a degree of latitude with a considerable accordance. It does not, however, appear that the deviation of the earth from a strictly spherical form was noticed till 1672, when Picard found that the pendulum of his transit clock, which beat seconds at Paris, required to be made shorter to beat seconds at the station at the island of Cayenne (latitude 4½° N.) This deviation of the earth from a spherical form was that which Newton and Huygens predicted, from the theoretical considerations of a revolving body, would be the case. But it is not from theoretical considerations alone that the form of the earth is adduced. In 1735, the French Academy fitted out an expedition for the purpose of determining its figure, with better instruments and methods than had been previously in use. Their proceedings became celebrated for the additions made to our astronomical knowledge. One of the stations fixed upon was near the equator at Peru, under the direction of Bouguer; the other at Lapland, under the superintendence of Maupertius, Clairault, and other celebrated men. All the measures taken by these astronomers denoted a decided ellipticity, but still the observations were not sufficiently numerous to infer its amount. At the Cape of Good Hope, in latitude 33° 18′ south, the celebrated La Caille measured an arc of the meridian; and in North America, in the plains of Pennsylvania, near the Alleghany Mountains, Mason and Dixon also measured a degree of the meridian in north latitude 39° 12′.

In Italy we have two measures of degrees—the first we owe to Boscovid and Le Maire, the other to Beccaria.

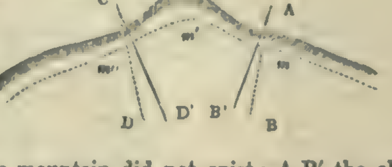
The surveys undertaken in places near the neighbourhood of mountains are very often affected by the attractions of those mountains. Thus, in the South American surveys, the attraction of the Chimborazo Mountains affected the deviation of the plumb-line by a quantity equal to 7½″. In latter times, in a survey undertaken by Plana and Castini, in Italy, the plumb-line was affected in a very perceptible manner, so much so that the resulting value of 1° in measure was 674 toises too large, from the known ellipticity of the earth deduced from a combination of observations at France and Peru. From all recorded measures, the length of a degree was greatest at the poles, and diminished gradually at the equator. If we lay down graphically the length of a degree from the different observations, we shall find that the intersections of these radii will form a curve, which will differ from the centre of the sphere in the following manner:—At the pole, the intersection or radius will touch the axis; it will afterwards recede from it, the convexity being averted to the polar axis; till, finally, at the equator, it will be perpendicular to that at the poles. The curve thus traced is termed the *evolute*. In the annexed (Fig. 5), P Q and E E are the minor and major axes of the ellipsoid of revolution; *m m′* and *n n* are measurements of a degree of latitude at the equator and the pole, which show that a longer arc, *n n′*, is required at the latter to form an equivalent angle (deduced from observations of stars), than at the equator. The effect of this flattening or compression is equal to $\frac{1}{300}$th part of the diameter.

Fig. 5.



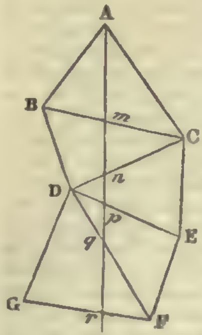
The practical method, then, of determining the length of a degree at the different positions of the earth's surface, is to find, first of all, the angle included between the verticals of the two stations, by the differences of zenith distances of certain selected stars. This is performed by means of a zenith sector, the stars being chosen near the zenith, in order to eliminate any uncertainty with regard to atmospherical refraction. But the adjustments of a zenith sector essentially depend on the accurate verticality of the plumb-line, which has been, as already stated, considerably affected by the attraction of neighbouring mountains. In Fig. 6, C M A is a surface of the earth; M a mountain; A B the direction of the plumb-line if the mountain did not exist; A B′ the observed direction of the plumb-line. In a similar manner, C D should be the real direction of the plumb-line, and C D′ the observed direction of the plumb-line. The effect of this attraction will be easily seen to affect observations by the zenith sector; and we may infer, from this circumstance, that the irreconcilable differences in the results of some surveys have been thus occasioned.

Fig. 6.



The measurement of the distance between the two stations, extending the whole length of a kingdom, is effected by a series of triangulations in the following manner :—In the figure (Fig. 7), the length of the meridian A *r* is required ; and for this purpose we select certain stations A, B, C, D, &c., as clock-towers or elevated objects. Conceive these to be joined as in the figure, and thus to form a series of triangles, as A B C, B C D, C D E, &c.

Fig. 7.



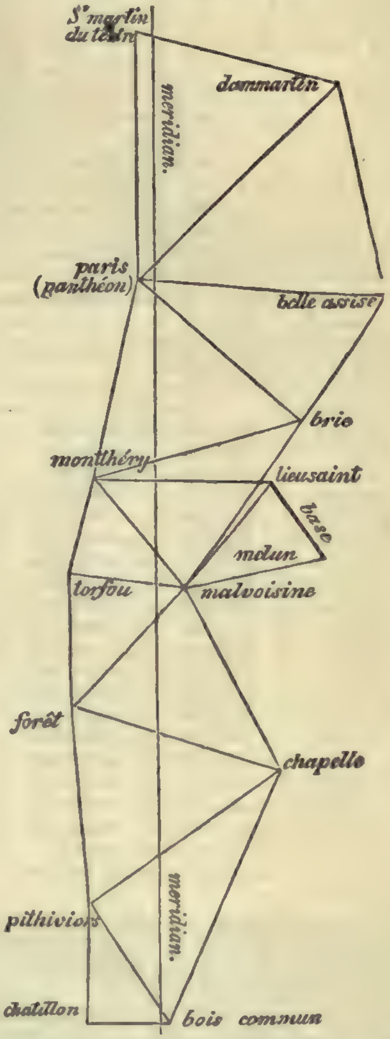
If we know all the sides and all the angles of these different triangles, as well as the angle formed with the meridian A *m n*, with the side A B, we can conclude easily the lengths of the different parts, A *m*, *m n*, *n p*, of this meridian. In fact, in the triangle A B *m*, we know the side A B, and the two adjacent angles A B *m*, B A *m*, whence we can readily find the side A *m*, which forms the first portion of the meridian, as well as B *m*, and the angle B *m* A. In the triangle *m* C *n* we know the side C *m*, which is the difference between B C and B *m*, and the two adjacent angles *m* C *n*, C *m n*, the second being equal to B *m* A, previously determined. We arrive at the same conclusion with the side *m n*, which forms the second portion of the meridian, and at the same time the side C *n*, and the angle C *n m*. In the same manner the triangle D *n p* will show us the third part of the meridian, and by this proceeding we have determined all the parts of the meridian of the point A.

But we do not require a measurement of all the sides —it will be necessary only to measure a certain part termed the *base*. Suppose that the side A B be the part measured, then the triangle A B C is entirely known, since we know one side and the three angles, and we can find the lengths of the two sides, A C, B C. In the same manner, the knowledge of the three angles of the triangle B C D, and of the side B C, that we find, permits the determination of the length of each of the two sides B D and C D ; and proceeding in this manner, we find all the sides and angles of all the triangles as well as if we had measured these lines directly.

In determining an arc of the meridian, we know well the point of departure, but we do not know where the second extremity is situated. We can find, it is true, after having determined conformably to what precedes, the length of the portion F *r* of the side F G, by measuring the distance F *r* ; but besides that this often presents great practical difficulties, it will frequently happen that the point *r* would not be favourably placed for erecting an instrument such as a repeating circle or theodolite. We have also sometimes occasion to know the latitude of the point *r*, as well as that of the point A, in order to deduce the angle included between the verticals drawn through the two points. To attain this, we observe the latitudes of the two extremities F G of the side on which the point *r* is situated ; we can easily compute the latitude of the point *r*, by the knowledge that we have ascertained of the distances comprised between this point *r* and the two points F G. Having the length of the line F G, relatively to the dimensions of the earth, we can admit that in going from F to G, along the line F G, the latitude varies proportionally to the distance passed over on this line.

MERIDIAN OF FRANCE.—One of the greatest measurements of an arc of the meridian was that performed at the end of the last century, by the celebrated astronomers Delambre and Méchain. The arc which they measured took its departure at Dunkirk and across France at its greatest length, terminating in Spain, near Barcelona, the Pantheon, at Paris, forming the summit level. Part of this survey is contained in the following figure ; the base line, on which the success of the whole measurement depends, was measured with every possible precaution by means of rods of platinum, and was found to be 6075·98 metres. The angles of the triangles were measured by means of the repeating circle, and the lengths of the different sides of the triangles were successively determined by the method before mentioned.

Fig. 8.



In order to have some independent check on the result, a second base was measured near Perpignan ; that is, near the southern extremity of the series of triangles. The length of the second base, reduced to the level of the sea, was found to be 6006·25 metres. In comparing the length thus obtained to that of this same base, deduced from the successive calculations, we have not found a greater difference between the two results than 10 inches 8 lines (cent. metres, 288). So small a difference on a length of more than 6,000 toises, is surprising, especially when we consider the immense distance which separates the base of Melun and Perpignan, a distance of more than 450,000 toises. This certainly shows that the operations had been executed with great care.

The results arrived at by these measurements showed at once, that the value of a degree was different at the equator and the poles, being least at the equator, and greatest near the poles.

From a judicious combination of the observations at all the stations, Bessel deduces the following elements of the earth's figure :—

Equatorial diameter, 41847199·9966 feet, or 7925·606 miles.

Polar diameter, 41707314·3324 feet, or 7899·113 miles.

Which shows an ellipticity of $\frac{1}{300}$th.

The following are the principal results on which the above elements are founded, viz. :—

Name of Place.	Mean Latitude.	Length of a Degree in English ft.
Peru	1° 31′ 1″ . .	362,808
India	12° 32′ 21″ . .	363,013
France and Spain .	46° 8′ 6″ . .	364,649
England	52° 2′ 20″ . .	364,914
Lapland	66° 20′ 10″ . .	365,782

In European latitudes, actual observation gives:—

Stations.	Mean Lat	English ft.
Formentera . . .	40° 0′ 50″ . .	364,206
Mountjouy . . .	42° 17′ 29″ . .	364,239
Carcassonne . . .	44° 41′ 49″ . .	364,347
Evaux	47° 30′ 46″ . .	364,935
Paris—Pantheon .	49° 56′ 29″ . .	365,052
Dunkirk	51° 15′ 25″ . .	365,116

From Bessel's Elements the next table is formed:—

Lat.	Length of a Degree in Latitude. English Feet.	Length of a Degree of Long. English Feet.	Radius Vector.	Angle of Vertical.	
°				′	″
0	362,749	365,186	1·000000	0	0·0
5	362,776	363,805	0·999975	1	59·5
10	362,858	359,674	0·999899	3	55·5
15	362,992	352,821	0·999778	5	44·3
20	363,174	343,296	0·999612	7	22·7
25	363,398	331,168	0·999407	8	47·9
30	363,658	316,524	0·999170	9	57·1
35	363,946	299,472	0·998907	10	48·3
40	364,254	280,135	0·998626	11	19·8
45	364,572	258,657	0·998336	11	30·5
50	364,590	435,198	0·998045	11	20·5
55	365,199	209,933	0·997763	10	49·7
60	365,489	183,052	0·997499	9	59·1
65	365,752	154,759	0·997259	8	50·2
70	365,979	125,271	0·997052	7	25·1
75	366,163	94,812	0·996884	5	46·3
80	366,300	63,620	0·996759	3	57·0
85	366,382	31,568	0·996683	2	0·3
90	366,411	0	0·996657	0	0·0

The elements of the earth's figure, deduced by Professor Airy,* are—

Equatorial diameter in miles .	7925·648
Polar diameter in miles . . .	7899·170.

The equatorial circumference being a little less than 25,000—accurately, 24,899.

To illustrate the very trifling proportion which subsists between the inequalities of the earth's surface and its entire volume, we may suppose an artificial ball eighteen inches in diameter, to represent our globe, when the proper proportionate elevation to be assigned to its highest mountains would be $\frac{1}{80}$th of an inch.

ROTATION OF THE EARTH.—Two principal motions belong to our planet; one of rotation upon its axis, called its diurnal motion, producing the succession of day and night; and another of progression in space, or revolution round the sun, called its annual motion, causing the vicissitude of the seasons. Both of these motions are to be understood of the whole earth, its interior substance, its superficial masses of land and water, the surrounding atmosphere, and the clouds in suspension over it; and both motions are in the same direction from west to east.

The exact time occupied by the diurnal rotation is 23 hours, 56 minutes, and 4·09 seconds. This forms a sidereal day; so called, because, in that time, the stars appear to complete one revolution round the earth. A star which is on the meridian of a place at a given period, will be on the meridian again after that interval. But as, while the earth rotates upon its axis, it is also moving in its orbit round the sun, it will require twenty-four hours, upon an average, throughout the year, for the sun to pass from the meridian of a place to the same meridian again. This forms a solar day, longer than a sidereal; and consequently, in the course of the earth's annual revolution round the sun, while we have 365 of the former, we have 366 of the latter, or that number of complete rotations of the earth upon its axis. Hence the well-known fact, that, in travelling round the globe, a person finds, on arriving at the point whence he set out, that he has gained or lost a day in his reckoning of time, according as he has travelled east or west, as compared with the reckoning of those who have remained at rest.

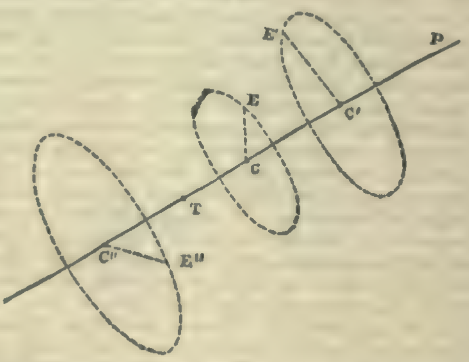
The earth's motion upon its axis is perfectly uniform and equable. Sidereal days, therefore, are always of the same length, every rotation being accomplished in the same time; but the motion of our planet in its orbit being unequal, sometimes faster, sometimes slower, solar days vary in length at different times of the year. Hence the hour shown by a well-regulated clock and a true sundial is scarcely ever the same; the difference between them, sometimes, amounting to 16¼ minutes, being called the equation of time. About the 21st of December, the solar day is half a minute longer, and about the 21st of September nearly as much shorter than 24 hours; which is an average of all the solar days throughout the year.

The rotation of the earth upon its axis is not susceptible of ocular evidence like that which the observation of spots upon the sun, and some of the planets, affords of the same fact in relation to those bodies. Nevertheless, the truth of the doctrine is established by various considerations.

Either the globe revolves upon an axis every twenty-four hours, or the whole universe, including the sun, moon, comets, and fixed stars, accomplishes a revolution round the earth in the same time. No third opinion upon the subject can possibly be held. In the latter case it is evident, from the distance of the celestial bodies, that their diurnal revolution around our planet must involve a rate of motion that is utterly inconceivable. The sun must travel at the rate of 400,000 miles a minute, the nearer stars with the velocity of upwards of 1,000,000,000 of miles a second, and the more distant with a rapidity which no numbers can express. It is absurd to suppose this, when the end to be gained requires only our little globe to revolve upon itself.

The following considerations present themselves. If the diurnal movement which we see, were attributable to a movement of the stars, E, E′, E″ (Fig. 9) would describe uniformly a circle situated in a plane, T P, perpendicular to the plane of the poles and the centres of the circle, C″, C, C′, for the reduced perpendiculars of the stars upon this line; that is to say, the most distant points from the earth T. But we know that when a body describes a circle with a uniform motion, it is attracted towards the centre of the circle by a constantly acting force, of which the magnitude depends at once upon its rate of motion and the radius of the circle which it describes. The stars E, E′ E″ cannot move in the circle of which we speak without being attracted towards the points C, C′, C″, situated upon the line of the poles.

Fig. 9.



But something like demonstrative proof of real circumstances may be adduced. If the earth rotate, the summit of a high tower, having a larger circle of rotation to describe in the same time than the base, must obviously move with greater rapidity; a stone, therefore, dropped from the summit, leaving it with a greater momentum, will move faster through the whole of its descent than the base, and reach the ground a little in advance, or easterly, of the foot of the perpendicular, the direction of the earth's rotation. Owing to the small height of buildings suitable for the purpose, this is a very difficult matter to test; but experiments have been conducted with this result, in 1804, in St. Michael's Tower, at Hamburg, and, in 1805, in a coal-pit at Schlebusch, in the county of Mark. Let the circle E (Fig. 10) be the equatorial circumference of the earth, the line T a tower perpendicular to C the centre, the circle M will then be the circumference described by the summit of the tower S, in the course of one rotation of the earth upon its axis. If we suppose the base of tower *b* to pass to *c*, the summit S will in the same time pass to *a*; and this being the larger arc, it follows that the summit must travel faster than the base. If then the earth rotate eastward, a ball dropped from the summit will leave it with its momentum, and move faster eastward through the whole of its descent than the base. The result will be that it will deviate a little from the plumb-line, and fall a little to the east of *c*.

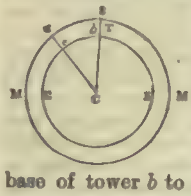
Fig. 10.



Again: a pendulum of a given length, which makes 86,535 vibrations in a day at London, will make only 86,400 in the same time if transported to the equator. This shows that the force of gravity which produces oscillations must be least where the movement is the slowest, or less at the equator than at London. Now assuming the earth's rotation, its equatorial regions, where the circle of the circumference is the greatest, must revolve with greater velocity than those which are situated towards the poles; consequently, the tendency to fly off from the centre is greater there, which proportionally neutralises the force of gravity, and accounts for the unequal action of the pendulum.

At the equator, the rate of the rotation is about 1,042 miles an hour, or 17 miles a minute; at 30° of north latitude it is 14 miles a minute; at 45°, or about the centre of France, it is 11.

ANNUAL MOTION OF THE EARTH.—The annual motion of the earth, or its orbital movement round the sun, occupies a period of 365 days, 5 hours, 48 minutes, 49·7 seconds. This forms the solar year, or the period which the sun appears to take, through the actual procession of our planet, in passing from a particular point of the ecliptic, say the first point of Aries, where the ecliptic and the equator intersect, to the same point again. It is also called the tropical year, because it is the interval occupied by the sun, in visiting the tropics and returning to the equator. The sidereal year, or the space of time which the sun takes in apparently passing from any fixed star till it returns to it again, is 365 days, 6 hours, 9 minutes, 9·7 seconds; rather more than 20 minutes longer than the tropical year, which is due to a slow annual displacement of the equinoctial points.

If the mean distance of the earth from the sun is 95,000,000 of miles, the diameter of the orbit is 190,000,000 of miles, and its linear extent near 600,000,000 of miles. This enormous distance is traversed at the rate of 68,000 miles an hour, or 19 miles in a second. This is the mean velocity for the year; but in January the earth travels at the rate of 69,600 miles an hour; which is more than 3,000 miles an hour its rate of motion in July, when it is only 66,400 miles an hour. This results from the second law of Kepler, to which we shall afterwards return.

Hipparchus, two thousand years ago, was the first who closely approximated to the true length of the solar or tropical year. His determination of 365 days, 5 hours, 55 minutes, 12 seconds, exhibits a value but slightly in excess of the truth.

The earth's motion of translation in space, like that of its rotation, is imperceptible by us; resembling that we experience in calmly floating down a stream, when surrounding stationary objects appear to be in movement, and our senses are lulled into complete forgetfulness of our own progression. It appeals not to the eye, as in the case of the other planets, which are seen to be constantly changing their place; but, besides the evidence of strong probability in its favour, it has received sensible confirmation from the discovery of the aberration of the stars.

In its annual revolution round the sun, the axis of the earth, inclined 23½° from a line perpendicular to the plane of the orbit, maintains invariably the same position, causing the phenomena of the seasons. An attempt is made in the following engraving to delineate the annual revolutions of the earth about the sun, and the other phenomena attending it. (See Fig. 11).

By measuring the distances of the earth from the sun, at different times of the year, the shape of its orbit has been ascertained. These distances, as they were unequal, could not, of course, be semi-diameters of a circle, but they corresponded, taken together, to the radii vectores of an ellipse. The straight line connecting the perihelion and aphelion, passing through the centre of the sun, is the line of *apsides*. The inclination of the earth's orbit to its equator, or the so-called *obliquity of the ecliptic*, amounts to 23° 27'. The velocity of the earth is greatest at the perihelion, and least at the aphelion. It is further to be observed, that the mean distance of the earth from the sun is equal to half the major axis of the earth's orbit, and the line of apsides is itself the major axis. There are four noteworthy points in the earth's orbit in the engraving, viz., those which mark the beginning of the four seasons. Two of these points are called the *solstices*—they mark the beginning of winter and summer. The straight line uniting them, passing through the centre of the sun, is called the *solstitial colure*. The two other points are the *equinoxes*, vernal and autumnal, marking the commencement of spring and autumn. The straight line cutting them at right angles, and passing through the centre of the sun, is the *equinoctial colure*. This

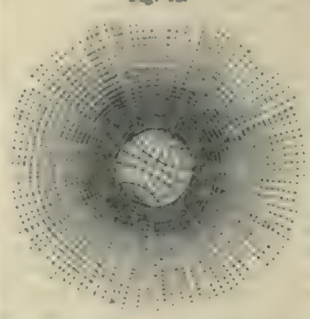
The earth is represented on the first day of each of the twelve months of the year, the solar distances corresponding to these twelve positions, and the shape of the earth's orbit. The deeper circle surrounding the pole at a short distance, is intended to represent the parallel of latitude of Europe, or the hour circle of that place divided into twenty-four hours. Although at the end of December the earth is nearest the sun, yet, at that time in the northern hemisphere, the heat is less than at any other. The reason of this lies in the fact of the short days and long nights, as well as that the sun's rays fall very obliquely on the earth, traversing a longer path through the atmosphere, and consequently losing much of their heating power. At the beginning of July, on the contrary, although then the earth is at its greatest distance, the temperature of the northern hemisphere is greatest, on account of the long days and short nights, and the great altitude of the sun at noon. It must not be forgotten, however, that owing to the precession of the equinoxes, these signs no longer correspond to the constellations of the same name, so that now the sign Pisces corresponds to the constellation Aries, the sign Aries to the constellation Taurus, &c. It is further evident, that if the earth at the beginning of spring, summer, autumn, and winter, should be in the signs Aries, Cancer, Libra, and Capricornus, respectively, then the sun, as being always directly opposite in the ecliptic, will be in the signs Libra, Capricornus, Aries, and Cancer.

An atmosphere—the region of the winds, lightning, and meteoric corruscations—upon which respiring beings depend for vitality, surrounds our globe, and is one of its most important attributes; chiefly interesting to the astronomer, on account of its effect in displaying to us the heavenly bodies, and diffusing the rays of light in every direction around us. The extent of this wonderful and benign envelope is not precisely known; but its density diminishes as we ascend from the surface, and, at a very inconsiderable elevation, it becomes so rare as to interfere with the functions of existence. The diagram represents the engirdling atmosphere of our planet, various strata of air resting upon it, the upper pressing upon the lower, and causing the interior to be more dense than the exterior strata.*

Fig. 12.



The density of the earth is $4\frac{9}{10}$ that of water, so that our globe would counterpoise $4\frac{9}{10}$ globes of the same size, composed of materials of the same specific gravity as water. Yet, abandoned to the solar attraction, it would require 64 days, 13 hours, to fall upon the sun.

The varying intensity of the force of gravity at the surface of the earth, as shown by the unequal action of the pendulum, which vibrates slower at the equator than in other places, is as 1 at the equator to $1\frac{1}{194}$ at the poles. A body, therefore, weighing 194 pounds at the equator, would weigh 195 pounds at the north pole.

The place of the earth in the system is a favoured one, where nearly all the planets are visible to the naked eye. While they appear in our heavens, Jupiter, Venus, and occasionally Mars, shining with great splendour, our planet may be presumed to return the compliment, exhibiting to Venus, at the time of her inferior conjunction, when she is nearest to us, a full orb resplendent through her whole night. The apparent size of the earth will be greater than that of Venus to us.

CHAPTER III.

ON THE SUN.

THIS stupendous luminary, to which we are indebted for many of the blessings we enjoy—the source of light and heat, and which also contributes materially to the development of vegetation—will now claim our attention. It also serves as a standard for the regulation of our calendar. The orbit which it appears to describe about the earth fixes our year, whilst its displacements in the ecliptic regulate our seasons. A little attention will show us, that its motions in the heavens from day to day differ from that of a fixed star. We have only to mount firmly any line of sight, properly protected by coloured glasses from the glare of sun-light, and we can readily determine, by means of a watch or chronometer, that the interval between the successive returns of the sun will be different at different times of the year; whilst the invariable constancy of the returns of the fixed stars, on the other hand, impresses us at once with the notion that the earth rotates on its axis. The apparent path of the sun, however, in the heavens is not so easily traced as that of the moon or planets, whose position can be readily compared with the fixed stars. For any accurate investigations, we are obliged to make use of a transit instrument and mural circle, which will be described hereafter. By these instruments we find two elements necessary to define its path, namely, its right ascension and declination. Its diameter can also be readily known. We thus find, that, in addition to its diurnal motion, it partakes of a proper motion always in the same direction from west to east, and that it is six months above, and six months below the *equator*. Its path in the heavens is termed the ecliptic, and passes through the twelve constellations. Its orbit is inclined to the equator by an angle of 23° 27′, termed *the obliquity of the ecliptic*. The intersections of its orbit with the equator occur at two points, termed the vernal and autumnal equinoxes. The points at which the greatest and least declinations of the sun take place, are called the solstices.

MOTION OF THE SUN IN ITS ORBIT.—In order to obtain the accurate path of the sun in the ecliptic, it will be necessary to convert the right ascension and declination, obtained by means of the transit instrument and mural circle, into longitudes, which can be readily done, having given the obliquity of the ecliptic. It will then be easily seen that the arc described in the space of a day is not uniform, varying in amount at different parts of his orbit. The maximum change occurs on the 1st of January, when it amounts to 61′ 10″, and which gradually diminishes to the 1st of July, when the value is 57′ 12″, after which its motion is again quicker. The average velocity of 59′ 11″ takes place at the commencement of April and October. The observed diameter obtained by means of the passage of his eastern and western limb over the meridian, or the vertical diameter measured by the mural circle, will also exhibit fluctuations; the maximum occurring at the time of its greatest angular velocity. It would by this appear that its distance from the earth varied. The variable velocity of the sun in its orbit engaged the attention of Hipparchus, who lived about 140 years before our era, and who appears to have been a more accurate observer of the solar motions than his predecessors. This celebrated philosopher, who was of opinion that the motion in a circular orbit was the more natural, invented an *eccentric hypothesis*, which explained the greater angular velocity, and the smaller angular velocity, but which failed at the intermediate positions. He considered that the earth was removed some distance from the centre of the sun's motion, as in the annexed diagram. If the earth be supposed to be placed at T (Fig. 13), instead of at O, the centre of the circle M E N E, it will follow that the equal arcs described by the sun in equal times will not appear uniform, and thus the motion will be slower at N than at M, and will gradually increase from the former to the latter point. Hipparchus explained this change in the angular velocity of the sun, by means of the epicycle. Supposing that the earth is placed at T (Fig. 14), with a radius T C, describe the circle C C′ C″. If the sun be fixed at S, in the smaller circle C S (which is called the epicycle), and makes a complete revolution in the direction of the arrow, in the same time that the circle itself passes round the earth; it would follow that the sun would always remain at equal distances from the point T, as at a', a'', a'''. But if the sun be supposed to travel uniformly, and always preserve the same direction C S, C′ S′, C″ S″, &c., it is plain that its distance will vary from the point T. If we make T O equal to C S, and describe a circle from the centre O, this circle will pass through all the points S S′ S″ S‴. This agrees with the preceding explanation; for whilst the sun describes a circle round O, the earth T is placed eccentrically in this circle. The amount of this eccentricity may be determined by comparing the angular velocities of the sun when at apogee and perigee; and we thus find T M : T N :: 3431·5 : 3670·1; whence it would result that the greatest, the mean, and the least, distance, supposing the earth's orbit to be circular and the motion uniform, would be 1·0338 : 1·0000 : and 0·9662 respectively; the eccentricity of the earth's orbit would be 0·0338, or $\frac{1}{30}$th. We may also arrive at a knowledge of the eccentricity e, by comparing the diameters of the sun at different epochs.

---

* See *ante, Mechanical Philosophy, Pneumatics*, p. 770.

Fig. 13.

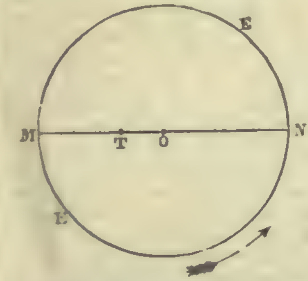


Fig. 14.

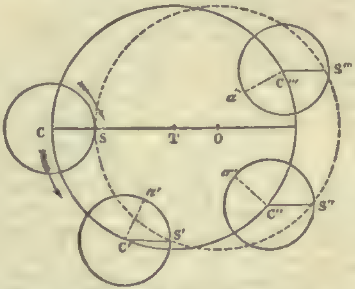


Thus, let d be the least diameter, D the greatest diameter, and δ the mean diameter, then

$$d = \frac{\delta}{1+e},\quad D = \frac{\delta}{1-e},\quad \frac{\delta}{D} = \frac{1-e}{1+e},\ \text{and}\ e = \frac{D-d}{D+d}$$

In this case D = 1955″·6, d = 1891″, and the resulting eccentricity is 0·0168; consequently the greatest and least distances would be 1·0168 and 0·9832. It would follow from this, that the motion of the sun in its orbit cannot be uniform, but that it must move really more rapid when at perigee than at apogee. The variation of its angular velocity is about twice as great as that of its distance. We may arrive at a knowledge of the true orbit of the earth round the sun by marking off the longitudes daily, and the proportional radii (estimated from the observed diameters). It will thus be found that the figure, roughly traced, will differ considerably from a circle, and will be an ellipse, having the earth in one of its foci. It was not, however, by these simple means that Kepler made the great discovery of the elliptic motion of the earth and planets, but by a long and laborious discussion of the observations of Mars, made by his master and patron, Tycho Brahé.

By further consideration on the motions of the planets, Kepler discovered that their angular velocity diminishes in the same proportion as the square of the distance increases, and that the areas described by the radius vector are proportionate to the times of description. If we suppose a planet to pass through M M′ (Fig. 15) and N N′ in the same space of time, it would follow from this that the areas M, T, M′, and N, T, N′, are equal, and that the angular velocities are greatest at perigee and least at apogee. The form of the ellipse which the earth describes about the sun, differs but little from that of a circle, as the distance O T is only one-sixtieth part of the semi-major axis O M; and if such an ellipse were described of a yard in diameter, the difference between the major and minor axis would be almost invisible.

The direction of the line of the apsides of the earth being known, its position in respect to the fixed stars has next to be determined. The line to which this is referred is that of D B of the equinoxes. At the present time, the inclination between the major axis M N of the earth's orbit, and the line D B of the solstices, is nearly 10°, and is gradually increasing—the major axis increasing in the same direction as the sun's motion, at the rate of 62″ annually. The duration of the seasons is consequently unequal, as may be seen by comparing the areas, a T b, b T c, c T d, and d T a, which being proportionate to the times, the sun will consequently remain longer in the quadrant b T c, than in d T a, &c. Whilst, therefore, the length of the year is constant, the duration of the seasons is subject to a slight change from year to year. At the present time, the lengths of the different seasons are as follows :—

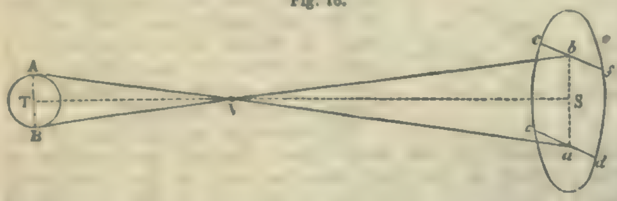
Fig. 15.

	d.	h.	m.
Spring	92	20	59
Summer	93	14	13
Autumn	89	18	35
Winter	89	0	2

The sun, therefore, remains nearly eight days longer in the northern than in the southern hemisphere. By taking into account the rate of the progressive motion of the apsides, M N, which is 61″·9 per annum, according both to theory and observation, the time when the line of solstices, D B, coincided with the line of apsides may be determined; and it has been concluded that this occurred in the year 1250. At that time the autumn and winter quarters were of equal length, and likewise the spring and summer; but the summer was longer than the winter.

Distance of the Sun.—Before we make any very accurate progress in the motion of the sun in its orbit, we must first discover the sun's actual distance, or the angle which the earth subtends at the sun. This angle is termed the parallax, and it is obtained by observing a transit of Venus, across the sun's disc, in the manner illustrated in the following diagram (Fig. 16).

Fig. 16.



The relative distances of the earth and Venus from the sun's centre are accurately known. Let us suppose that when Venus is situated between the sun and the earth, its distance from the former is 0·73, the earth's distance being 1·00. The earth being situated at T, and two observers stationed at the opposite diameters A and B, the observer at A will perceive Venus, V, crossing the sun's disc from *c* to *d*, whilst the observer at B will see it passing from *e* to *f*. The breadth of this zone, *a b*, will be considerably greater than the diameter of the earth, A B, in consequence of the greater proximity of the planet to the earth, V S being 2·7 times greater than the line V T, and consequently the line *a b* is 2·7 greater than the diameter of the earth, A B. If the angular measure *a b* could be obtained, this would therefore be 2·7 times greater than the earth's apparent diameter as seen from the sun, or 5·4 times the sun's horizontal parallax. This angular measure can be found by the observers A and B taking the distance of the limb or centre of Venus from the sun's limb. The line *a b*, as here represented, is drawn much greater than it really is, for the resulting diameter of the earth is only $8\frac{1}{2}$ seconds of arc; and consequently the breadth of this zone is only 46″·4, or about three-quarters of the diameter of Venus at the time of inferior conjunction, or $\frac{1}{42}$ of the mean diameter of the sun.

It is not only, however, by observing micrometrically the distance of Venus from the sun's limb that the relative distance *a b* may be deduced; it can likewise be determined by the *time* which the planet remains on the sun's disc at the several stations, or the interval elapsed between its entry at *c* and *e* to its disappearance at *d* and *f*. The motions of Venus are accurately known by means of the tables, and thus the lengths of the chords *c d* and *e f*, and therefore the distance *a b* also. It is usual, in these cases of the passage of the planets Venus and Mercury over the sun's disc, to note the time when the limbs of the planet and sun come in contact, and also, after the ingress has occurred, to note the time when they are last in contact. The same must be done at its egress. The times of interior contact can be perceived much more exactly than the exterior. If the transit be central, the duration of its passage may extend from 7h. 52m. to 7h. 54m.; and according as it is more distant from the centre, the chord will be shorter, and the time in the same proportion. In the passage of 1769, the duration at Wardhus was 6h. 29m.; at Hudson's Bay, 6h. 22m.; at California, 6h. 14m. 3s.; and by Captain Cook, at Tahiti, at 6h. $6\frac{1}{2}$m. From these measures the horizontal parallax of the sun was calculated by the astronomers of the time at 8″·5693; but the results differ considerably, the entrances being 8″·2 and 9″·2. The small altitude of the sun in the northern latitude, and its consequently bad definition, made it difficult to estimate the exact moment of entrance on the solar disc. Some observers saw it as much as twenty seconds sooner than others; but the effect of this would only entail an error of one-sixtieth, or probably of only one-half of that amount, on the total parallax; so that instead of 8″·5693, we should have 8″ 640 or 8″·498. These calculations have been performed anew with the utmost accuracy, by Professor Encke, of Berlin. From the first transit of June 5, 1761, that celebrated astronomer has obtained the value 8″·490525 comprised between the limits of 8″·429813 and 8″·551237. The discussion of the second passage of June 3, 1769, gives 8″·5776, not greatly different from the above: it is the value now generally adopted by astronomers. The resulting mean distance of the earth from the sun would, consequently, be

$$\frac{1}{\sin.\ 8''\cdot5776}, \text{ or } 24046\cdot9 \text{ radii of the terrestrial equator,}$$

which corresponds to 82,667,200 miles, of 60 to a degree. To pass through this distance light employs 8m. 13 15s., and in consequence we see the sun 20″·252 behind its real position. The radius of the sun at its mean distance being 960″·9, the real diameters of the two bodies will be in proportion to their apparent diameters, or as 8 578 to 960·9, or the diameter of the sun is 112·024 times greater than that of the earth. Their volumes being proportionally as the cubes of their radii, it would follow that the bulk of the sun is 1,405,845 times that of the earth.[*]

Passage of Venus across the Sun's Disc.—This phenomenon can only take place at intervals of eight years and 105 years, and the two next times will occur on Dec. 8, 1874, and Dec. 6, 1882. Since Venus comes nearly to the same point of the heavens every eight years, it may be expected that if it transits over the sun at one given epoch, it will pass over it on the eighth following year, and this generally takes place. As Venus, however, changes her latitudes during this period of eight years, it is impossible that three can follow each other in succession, as it must then pass beyond the disc of the sun, which is only 32′ in diameter; and as they can only take place when the plane is very near its nodes, it follows that for some centuries this will occur either in the months of June or December.

---

[*] Although the calculations of the parallax of the sun, deduced from the transits of Venus in 1761 and 1769, were subsequently made with all possible care by Professor Encke, affording 8″·5776, still there was reason to doubt the accuracy of the data on which that value was founded. It was, therefore, extremely desirable to check the results thus obtained; and beyond the reasons just mentioned, the motion of the nodes of Venus, considered in relation with the other planets, the speed of light, as determined by M. Foucault, and other questions, required more accurate solution of the inquiry.

In 1857, Professor Airy called the attention of observers to the oppositions of Mars, occurring in 1860 and 1862. The former year was unfruitful, owing to the state of the weather precluding observations; but in 1862, sufficient data were gathered to show that the value 8″·5776 was underrated. In that year, observations of the parallaxes of Mars at Greenwich and Williamstown, gave 8″·94; whilst those of Pulkova and the Cape of Good Hope, resulted in 8″·97. Subsequently, M. Leverrier arrived at the conclusion, that 8″·95 would represent the solar parallax.

If this modified value be adopted, considerable differences will arise in the estimate of the distances, &c., of the planets. That between the sun and the earth must be reduced by about 4,030,000 miles, affording a mean distance of 91,330,000 miles. The mean distance from the sun, of the other planets, would consequently be, in round numbers—Mercury, 35,500,000; Venus, 65,500,000; Mars, 139,000,000; Jupiter, 475,000,000; Saturn, 871,000,000; Uranus, 1,752,000,000; and Neptune, 2,742,000,000. The diameter of the sun would be about 850,000 miles, and his volume 1,340,000 times that of the earth. The mass of our globe would be increased by one-tenth; the circumference of our orbit would be 599,194,000, and the mean hourly velocity of the earth, 65,460 miles. Each planet would be similarly affected in its mass, volume, &c., by changing the estimate of solar parallax from 8″·5776 to 8″·95.

No transit of Venus will occur, by which these results can be tested, until the years 1874 and 1882. Meanwhile, the care bestowed on the calculations, giving the new value, having been made by so eminent an astronomer as M. Leverrier, entitle them to the highest respect, if not the fullest confidence of observers. Indeed, incidentally, they receive considerable confirmation from the investigations of M. Foucault into the velocity of light. That philosopher, from careful experiment, proposes to reduce the estimated speed of light from 192,000 to 185,000 miles per second. For those not acquainted with the value of such data, in an astronomical point of view, we may observe, that in an eclipse, we never see the eclipsed body at the moment of last contact or emersion, obtained by calculation. It does not reappear for some time, owing to the fact that its light has to travel to the eye, and, in doing so, occupies frequently many minutes. By noting the time which elapses between the moment ending the eclipse, and that when the body reappears to the observer, the difference in seconds, multiplied by the speed of light, gives the distance of the body. On the other hand, if the known distance of the body be divided by the number of seconds which elapse between the actual and apparent conclusion of the eclipse, the speed of light, in miles per second, is obtained. The eclipses of the satellites of Jupiter afford an illustration of this fact, and will be referred to at page 961, *et seq.*, in connection with the laws of the aberration of light.—Ed.

The solid mass of the sun is found to be 354,936 times greater than that of the earth; and, comparing this with its volume, we find that the latter is only equal to one-fourth of that of the sun.* The gravity on the surface of the sun is 28·36 times greater than that on the surface of the earth; or a body which weighs one pound on the surface of our planet, weighs twenty-eight one-third pounds on the surface of the sun; and, consequently, a body will fall with twenty-eight one-third times the velocity during the first second of time.

Form of Sun's Disc.—In measuring the disc of the sun with the heliometer, or any graduated instrument, it is necessary to take precautions that it be favourably situated, and not too near the horizon, where the refraction has a very sensible effect in elevating the lower part of the disc in a greater degree than the upper. When the sun is 45° above the horizon, the difference between the vertical and horizontal diameters only amounts to 1″; but when it touches the horizon, the vertical diameter is one-sixth part of the whole diameter less than the horizontal. The figure which the sun takes under these circumstances will be seen by Figs. 17 and 18, which have been constructed with exact proportions. The refraction causes the sun, when really at S, to appear at S′, with its apparent lower limb touching the horizon. This is the usual effect of refraction; but at the horizon, many irregular local causes tend to produce changes, and it is generally found to be serrated, and with a continual whirling motion, due to the irregular motions of the atmosphere. It appears strange that the discs of the sun and moon, which, if anything, are smaller under those circumstances than when at a great altitude, are commonly remarked to be larger at the horizon than elsewhere. The ancient astronomers sought to explain this optical illusion, by the effect which the atmosphere had upon the luminous rays of the sun. It is, at the present time, more naturally attributed to the effect which a comparison with the various objects seen at the horizon produces; and, as we suppose the sun to be removed an immense distance beyond those bodies, its diameter appears greater than it really is. A similar effect takes place when the apparent areas of the constellations are compared at the zenith and the horizon; in the latter position, they appear considerably more extensive than they really are. It is, probably, due to a similar cause, that if we attempt to measure an altitude of 45° from the horizon, or the point half-way between the zenith and horizon, it frequently happens that when we come to measure it with an instrument, that which we consider to be the central point is situated some degrees nearer to the horizon than it appears to be.

Fig. 17.

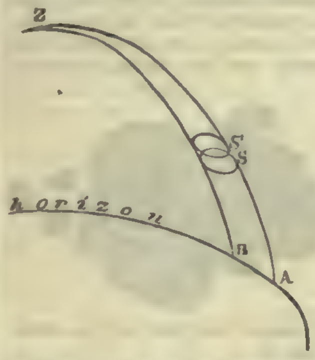


Fig. 18.

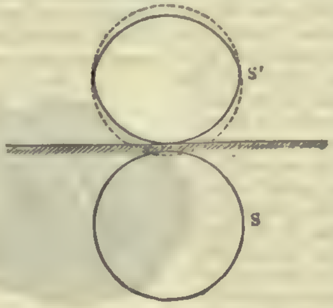


Telescopic Appearance of the Sun.—An observer, viewing the sun's surface with an instrument of moderate power, would probably not perceive any marked difference of light and shade over its general surface; but with higher powers, and a better telescope, a steady mottled appearance would become apparent, dark and light specks being softly intermingled, but not strikingly apparent when seen for the first time, or under favourable circumstances. Whilst the *ground* is not uniformly bright, there are very frequent portions which are decidedly brighter than the general surface, and others, which are much more remarkably darker, being as dark and black as the surrounding heavens, when viewed with the coloured glasses made use of. It is by means of these fleeting *maculæ* and *faculæ*, as they have been called, that nearly all our knowledge of the solar nature, its rotation, and the position of its axis, as well as the structure of its lurid and changeable atmosphere, is derived. These spots have constantly been perceived ever since the discovery of the telescope, and there is little doubt but that they were frequently seen before that time with the unaided eye, as they have occasionally been seen since. They sometimes cover large portions of the sun's surface, and are strikingly apparent from the contrast they afford with the bright surface surrounding them.

By whom these spots were first seen, after the invention of the telescope, is a matter which has found its way into the debateable land of scientific history. It would be most natural to suppose that Galileo, who had first scanned the heavens with the optic tube of his invention, and who was so capable of distinguishing every phenomenon which was apparent, would have been the first to notice these irregular appearances; but the first publication of them is due to Fabricius, who perceived them early in the year 1611; and his work, published in the same year, has a dedication bearing date June 13, 1611. In so far, however, as the mere observation of the spots is taken into account, they were seen by our countryman, Harriot, some time previous to any date fixed upon by the regular claimants to the discovery. Galileo appears to have seen them in April or May, 1611. Scheiner informs us that he perceived them during the same months, but he did not take them into consideration before the October of that year.

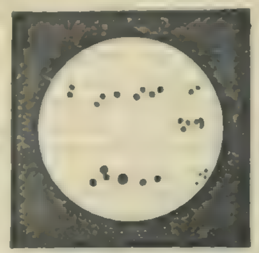
In the annals of China, it would appear that a large spot was visible on the sun in the year 321 of our era. In the year 807, a large spot was visible on the sun for the space of eight days, which was supposed by many to be a passage of Mercury over the sun's disc; but the length of time during which it remained visible is, of course, quite incompatible with such a supposition. Large spots which were seen by Averrhoes, Scaliger, and Kepler, were likewise supposed to be passages of this planet; but when it is remembered that a spot of the dimensions of Venus, with a diameter of five times that of Mercury, could not be detected on the sun's disc, we may be quite certain of their nature. Since that period, they have been frequently seen with the naked eye. It was, however, from telescopic observation of these spots, that the fact of the rotation of the sun on its axis was made apparent; and Fabricius was the first who surmised that they adhered to the sun, judging from their slow motion when they arrived at the edge of that luminary. This rotation, and its duration, were subsequently confirmed by Galileo. The inclination of the solar equator to the plane of the ecliptic was determined by Scheiner to be seven degrees.

---

* This may be put in the following form:—To obtain a body having an attractive force equal to that of the sun, would require that 354,936 spheres each as large, and having the same specific gravity, as our earth, should be combined. The MASS of matter, however, forming the sun, occupies four times the BULK, or SPACE, of such imaginary spheres; and hence, the volume of the sun is equal to about 1,405,845 times that of the earth.—Ed.

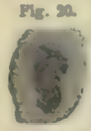
It has been remarked that the spots are confined to a certain equatorial zone, and that they rarely, if at all, extend beyond it. Their disposition in this respect may be seen from the accompanying diagram. By Galileo they were seen as far as 29 degrees of latitude north and south, but Scheiner extended this to a zone of 60 degrees in breadth, called by him the *royal zone*. They have frequently been seen, however, even beyond this limit, Messier having seen one of 31½ degrees, and Mechain one of 40½ degrees of north latitude; whilst another observer has detected one of 60 degrees of latitude. This, however, may have been one of the dark *pores*, as Herschel calls them, with which the whole surface of the sun is dotted, and tend to produce that mottled appearance which he compared to the skin of an orange. The rarity of the spots seen beyond 30 degrees of latitude quite confirm the limited nature of the equatorial zone, which the multitude of spots constantly seen on the sun renders more remarkable. It was surmised by Cassini that more spots were seen in the southern than in the northern hemisphere of the sun; but there does not appear to be any foundation for this, as they are generally equally disposed on each side of the equator. (See Fig. 19).

Fig. 19.



In the large dark spots, or *maculæ*, properly so called, it has constantly been noticed, that the very dark central portion, termed the nucleus, is fringed and surrounded on all sides with a shade of less intensity (Fig. 20), known by the name of the penumbra (pene-umbra), and which is nearly of the same degree of darkness throughout. Herschel found that even the largest of these spots commenced with one of these minute dark points, or pores, in the bright surface of the sun, which became larger and larger by degrees. When two spots were within a short distance of each other, they appeared to have a tendency to unite, and continued to expand until the moment of reunion. When the nucleus of a spot was going to disappear, it was noticed by Scheiner that the penumbra encroached gradually, but irregularly, upon it, so that the nucleus vanished before the penumbra. In modern times, and with better instruments, this breaking-up of a spot in the manner here specified, has been repeatedly noticed; the interior edge of the penumbra becomes ragged and irregular, the nucleus breaking up irregularly, and separating into many distinct nuclei, and presenting the appearance as if the luminous matter of the sun flowed in upon the dark spot. The exterior edges of the penumbra, although taking all shapes, are most frequently rounded off, and seldom appear with sharp projecting promontories. This, however, is not always the case, as was believed by Scheiner, since Herschel, on one or two occasions, perceived some prominent branches in the nucleus, which were equally apparent in the penumbra. Whilst observing it with his usual attention, he perceived six branches suddenly appear instead of the two at first observed, whilst a corresponding change took place in the penumbra. The same cause, therefore, may be regarded as having affected both equally. In regard to the proportional dimensions of nucleus, and penumbra, it is generally noticed that the latter is about three times the breadth of the former. It sometimes, though very rarely, happens, that even large nuclei are unaccompanied with any penumbra, and this was confirmed by Herschel on one or two occasions. A large path of penumbra was, on another occasion, perceived by him without any nucleus. It is but rarely that these phenomena take place in large spots; the smaller ones, on the contrary, seldom have any penumbra about them. Occasionally, the spot covers such a large space on the surface of the sun, that when, by virtue of the rotation, it comes near the edges, and is about to disappear, behind the disc, it forms a dark notch on its limb. This was seen in 1703, 1719, 1800, and 1846. It has been determined by Herschel, in respect to the relative brightness of the nucleus and penumbra, that the former may be estimated at 7, and the latter at 469; the intensity of the solar light being 1000. Many observers have noticed that the interior edge of the penumbra, or that immediately contiguous to the nucleus, is sometimes fainter than the exterior portion. At times, this is so apparent, that the nucleus appears quite detached from the penumbra, which has the appearance of a separate annulus. In many regularly round spots, the penumbra has been noticed to take a decidedly radiating appearance, like the iris of the eye, and the nucleus itself observed to be riddled with minute pores, presenting the appearance of wire gauze. Mr. Dawes has made still further observations on the telescopic appearance of the spots, and by means of eye-pieces, having a very small field of view, by which he gets rid of the surrounding glare of the sun's light, he has detected, within the part generally called the nucleus, a smaller spot, which may be considered as the nucleus proper. From his observations it would appear as if what has been termed the nucleus and penumbra, had a rotary motion around the nucleus power.

Fig. 20.



Figs. 21, 22, 23, are representations of spots really seen on the sun's disc, and it will be perceived under what irregular forms they appear. The long train of spots represent it as much broken up, with the nuclei and penumbra intermingled, and it is in this manner they are noticed when about to disappear. In Fig. 21, a bright streak of the surface of the sun is perceived in the central part. The spots are very capricious in their appearance, being sometimes very plentiful; and at other times the disc of the sun is entirely free from the slightest trace. Schroeter has recorded 81 separate spots perceived on the sun's disc at the same moment. For many years together no spot of any considerable size has been seen. Their dimensions, as already noticed, are frequently very considerable; and Schroeter saw one whose superficial extent was sixteen times greater than that of the earth.

Fig. 21.

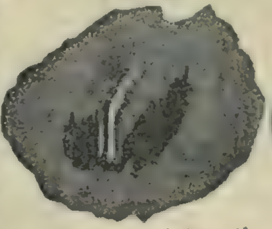


Fig. 22.

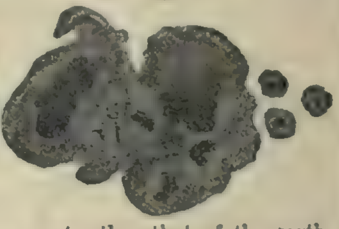

Fig. 23.

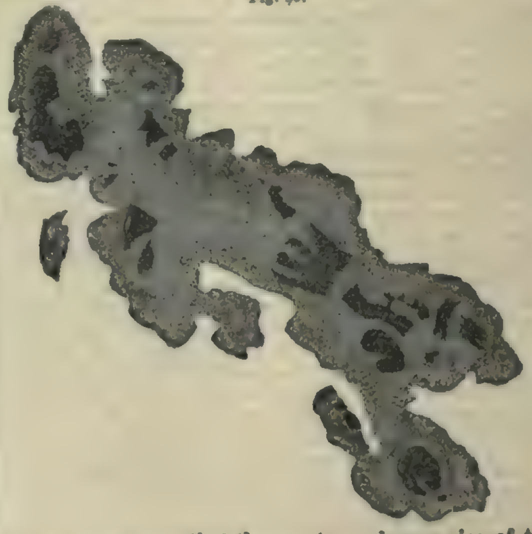
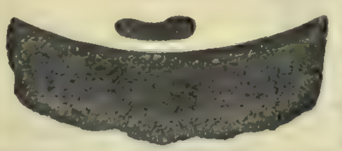


It does not appear that the great number or size of the spots have at any time been remarked to produce any degree of cold on the earth; for numerous and large as they seem to be, they bear but a small proportion to the total extent of the surface of the sun. The contrary opinion is much more generally regarded as true, and seems more accordant with the observed facts—viz., that the warmest seasons are those in which the sun is most plentifully covered with spots.

The bright spots which appear on the solar surface, either occur under the forms of long irregular veins, or minute specks, and are both perceptibly brighter than the general surface of the sun; the former being known as *faculæ*, and the latter as the *luculi*. The *luculi*, like the *pores*, are situated at all parts of the sun's disc, and assist in giving it that mottled appearance which it has. The faculæ are mostly confined to a zone of 60° in breadth, in which the spots make their appearance, and generally accompany the latter as invariably as the surrounding penumbra. The faculæ are only visible at the edges of the sun, as, when they are carried by the rotation of the sun to the centre, they are seldom, if ever visible. When the faculæ appear in great numbers and brightness on the limb of the sun, they are certain forerunners of large spots, which are almost sure to make their appearance in a few days afterwards. Cassini states that faculæ ordinarily show themselves in those places where spots have previously appeared, and that they have subsequently again become spots. Darham noticed a similar appearance, and, on one occasion, relates that he perceived changes in the spots with his eye at the telescope—a black spot appearing and disappearing successively in the centre of a brilliant faculæ. Herschel has likewise perceived extraordinary rapid changes with elongated faculæ; although Scheiner did not give credit to the existence of the *faculæ* or *luculi*, or anything on the sun brighter than its surface, yet they were detected with much less powerful instruments than he possessed, by earlier observers. Galileo first remarked the existence of the *faculæ*, and Scheiner that of the *luculi*. (See, also, page 934).

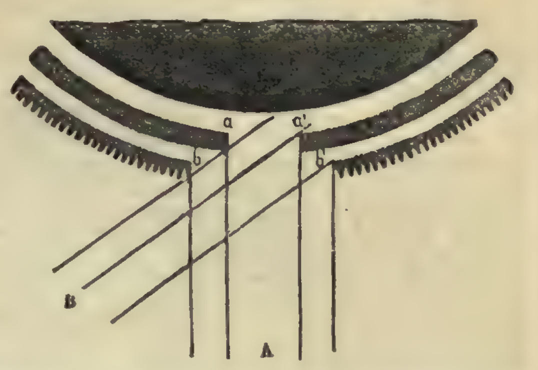
Physical Constitution of the Sun.—Until comparatively recent times, those spots were held to be the dark smoke or vapour which floated over the solar surface, although this did not explain the penumbra, or the shape which it takes when seen at different parts of the disc, when the penumbra surrounds a spot pretty equally at all sides near the centre of the sun, as at Fig. 24; for as it passes to the margin, and is received obliquely, the portion most distant would appear the narrowest. This, however, is directly contrary to observation, as it has been noticed that the nucleus and penumbra, when seen at the edge of the sun, appear as at Fig. 25, the part of the penumbra most distant from the sun's limb disappearing entirely, whilst the opposite side is only slightly diminished in breadth. Taking these facts into consideration, Dr. Wilson became convinced that the nucleus was in reality a deep hollow in the surface of the sun, and that the penumbra was the shelving sides surrounding it. If such a hollow as this be received obliquely, it is evident that it will appear as in Fig. 24. Dr. Herschel confirmed this theory in many respects; but, instead of holding the opinion that they were indentations on the surface, he considered, rather, that they were openings in the luminous atmosphere of the sun. The sun itself he considered to be a dark body surrounded by two envelopes, the interior one being formed of very luminous clouds and very bright, whilst the one lying between the photosphere and the body of the sun, is formed of clouds, very little, if at all luminous.

Fig. 24.



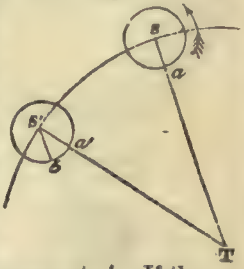
If we suppose an opening be formed in these envelopes, by a gas ascending from the body of the sun, and driving the atmosphere away, the opening at the centre of the sun (Fig. 25), to an observer at A, and the nucleus, will appear of the breadth *a a′*, surrounded equally on all sides by a penumbra, whose breadth is *b b′*. If, however, the observer is at B, he views the spot obliquely; the sides of the two openings, *a* and *b*, will coincide, and will lie in the same direction. On the opposite sides, however, at *a′* and *b′*, they will still be fully apparent. If the gas drive away the clouds of the two atmospheres, they will, of course, accumulate about the opening; and this may account for the faculæ which are to be perceived about the nucleus and penumbra. In regard to the luculi or points of light which cover the surface of the sun, they may be due to the roughness which would result from such a cloudy and irregular mass as the photosphere is imagined to be. An observation which tends to prove the unstable and cloudy nature of the outer envelope is, that they shift their positions from day to day; and it is very difficult to determine the exact period of rotation of the sun from these observations, some showing much longer periods than others.

Fig. 25.



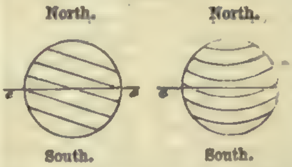
From observations on a great number of spots, M. Langier, of the Paris Observatory, has recently determined the exact period of rotation to be 25·34 days. Since, however, the earth is moving around the sun during this interval, we must wait nearly two days longer before we perceive the spot again at the centre of the sun. To explain this (Fig. 26): If T be the earth, S the sun, and *a* the spot as seen in its centre, whilst the spot appears to make a complete revolution, and to arrive again at the centre, the sun passes from S to S′; and when it arrives at S′, the spot appears at *a′*. If the sun had made exactly one revolution on its axis in the direction of the arrow, the radius S *a* would have taken the position S *b*, parallel to its first position. When it arrives in *a′*, it must, therefore, have made more than one revolution by the angle *b* S′ *a′*. To pass through 360° *plus* the angle *b* S′ *a′*, it requires 27·3 days; whilst to make a rotation on its own axis it only requires 25·34 days.

Fig. 26.



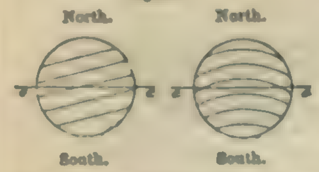
As the solar equator is inclined 7° 9′ 12″ to the ecliptic (according to M. Langier's investigations), the path which the spots appear to describe on the sun will vary at the different seasons of the year, the concavity being sometimes turned towards the north, and at other times to the south. In the beginning of December, the spots will appear to describe straight lines with reference to the ecliptic *e e*, the lines being inclined to it by an angle of 7° (Fig. 27). From the 1st of December to the 1st of June, they described curved lines, the convexity being turned to the north (Fig. 28). At the commencement of June they again describe straight lines, but in a con-

Fig. 27.



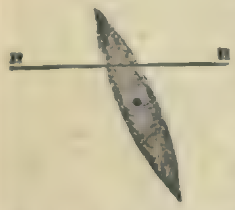
trary direction to the 1st of December. From June to December they describe curved lines, with the concavity turned to the north.

Fig. 28.



Zodiacal Light.—In the evenings of March and April, a cone of faint light is occasionally seen immediately after twilight in the western horizon, pointing in the direction, and sometimes reaching to the Pleiades, from the quarter in which the sun sets, and nearly along the ecliptic. The breadth at the base is from 20° to 30°, and its height occasionally fifty degrees. This is known as the *Zodiacal Light*, a name which was given to it by Cassini. It is very transparent, since the faintest stars can be perceived through it, equally as well as any other portion of the sky, although the glare of its bright light tends to extinguish very faint objects. Its nature is altogether unknown. It was formerly considered to be the atmosphere of the sun; but it has been proved by Laplace that this could not extend to such a distance as the zodiacal light has been observed to pass. An atmosphere to the sun could only extend to such a distance as the orbit of a planet could be situated, whose period of revolution would be equal to that of the sun on its axis, or 25 days, which would be placed considerably within the orbit of Mercury. Neither would the form of such an atmosphere agree with that observed with zodiacal light, as the equatorial and polar axes could not be beyond the ratio of three to two. Its appearance in the heavens may, however, be explained in this manner, although the cause is unknown; and it would seem as if a lenticular envelope surrounded the sun, a portion of which we see above the horizon. (See Fig. 29).

Fig. 29.

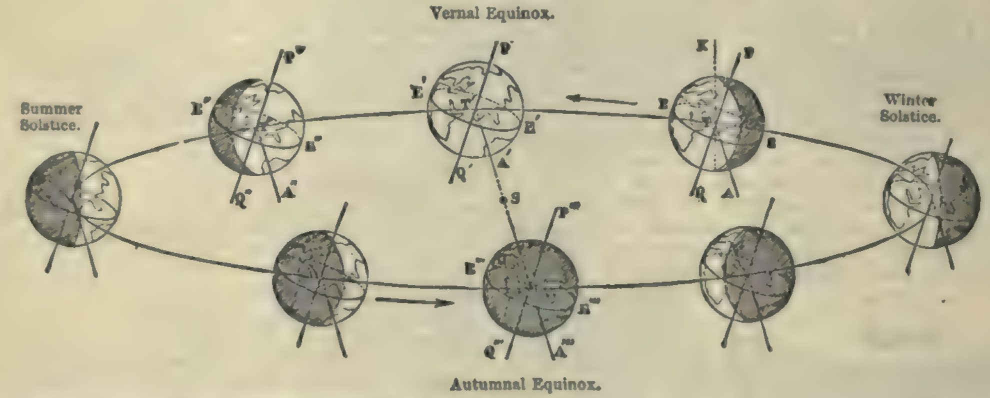


nomena of the seasons. Let S be the sun; T, T′, T″, &c., the different positions of the earth in its orbit; P Q its axis of rotation invariably parallel to itself; T A the line of the equinoxes; then at the vernal and autumnal equinoxes the sun is in the earth's equator, and the days and nights are of equal length, the sun illuminating at once one-half of the convex hemisphere. When the sun is at the winter solstice, the south pole of the earth is turned towards the sun, and the equator is above his path by an angle of 23° 27′. In our latitude, the cold northern hemisphere, the nights are longer than the days. At the summer solstice, the north pole is turned towards the sun, which is above the equator by its greatest inclination. In this latitude the days are longer than the nights. By an attentive examination of the figure, it will be seen that contrary appearances will take place in the southern hemisphere. Thus, if we consider the earth in its diurnal rotation at the summer solstice, the south pole will be constantly in darkness. At the vernal and autumnal equinoxes, the sun will shine on both poles of the earth.

Had the equator coincided with the ecliptic, the days and nights would be always equal; and had the inclination of the ecliptic to the equator been greater than at present, there would have been a corresponding difference in the seasons. Providence has wisely ordained that this inclination cannot exceed certain limits; the seasons will not, on this account, be sensibly different in occurrence and temperature.

The Earth's Equator.—In all the preceding investigations, we have supposed the pole of the earth's equator to remain fixed, but this is not the case; and, although it retains the same inclination to the ecliptic, it describes, in the course of a lapse of years, a complete revolution around the pole of the ecliptic. A very simple experiment will show, in the spinning top, that a motion of rotation around an axis may exist, without at the same time affecting its inclination, the axis of which will describe any figure. This phenomenon is termed the "precession of the equinoxes," and was discovered by Hipparchus, the astronomer, to whom we are indebted for one of our most ancient catalogues of stars. He found, by comparing the longitudes of his catalogue with those of some ancient catalogues, that whilst the latitudes of the stars were not changed, their longitudes were increased in the proportion, as he considered, of 1° in 72 years. The physical cause of the precession of the equinoxes was partly explained by Sir Isaac Newton, and afterwards more fully by the celebrated D'Alembert, and by La Place, in his *Mechanique Céleste*, on the theory of gravitation. It results from the effect of the attraction of the sun and moon on the excess of matter at the earth's equator, which produces a slow

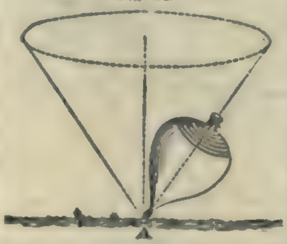
Fig. 30.



On the Seasons.—If we admit the annual revolution of the earth around the sun, its diurnal rotation on its axis, and the inclination of this axis to the ecliptic, we can readily account for the seasons, and the derivation of day and night. The annual revolution of the earth in its orbit is forced upon us by its extreme simplicity; we cannot imagine that the sun would revolve around a body 1,400,000 times smaller, as the earth is. We thus rank the earth as a planet, obeying all the laws of the other planets, describing an elliptic orbit around the sun, in the same manner as Mercury, Venus, Mars, &c. Another proof of the revolution of the earth around the sun is by the well-known existence of a phenomenon, termed the "Aberration of Light," arising from the velocity of light emanating from a star, combined with the orbital motions of the earth. The amount of this angular displacement has been determined with great accuracy by astronomers.

The above diagram (Fig. 30) will elucidate the phe-

Fig. 31.



angular motion at the plane of the equator, in a contrary direction to the earth's rotation.

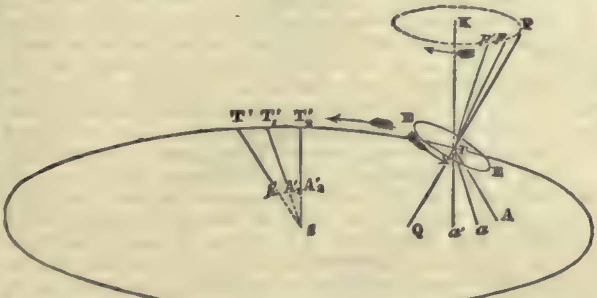
Precession of the Equinoxes.—This motion, though slow, being always in the same direction, and therefore continually accumulating, was, as we have seen, early remarked, and was one of the celestial appearances that suggested the idea of the *Annus Magnus*, or great astronomical period, by which so many days and years are circumscribed. As it affects the whole heavens, and as the changes produced are spread over a vast extent of years, it has proved a valuable guide amid the darkness of antiquity, and has enabled the astronomer to steer his course with tolerable certainty, and here and there to discover a truth in the midst of the traditions and fables of the heroic ages. The accurate analysis of the complicated effect thus produced, was a work that surpassed the power either of geometry or mechanics at the time when Newton wrote. His investigation accordingly was founded on the assumption that, though not destitute of probability, it could not be shown to be perfectly conformable to truth; and it even involved a mechanical principle, which was taken up without due consideration. The first who solved this difficult problem was D'Alembert. He employed the principle of the equilibrium among the forces destroyed, when any change of motion is produced; and by means of the equation this proportion furnished, this great mathematician was enabled to proceed with a solution that has never been surpassed for accuracy or depth of reasoning. Laplace proceeded on a more general principle, and with broader conclusions. He has shown that the phenomena of the precession and nutation must be the same; that, whatever may be the irregularity of the depth or currents of the sea, nothing can effect an alteration in the earth's rotation on its axis.

Wherever the sun, in his apparent annual course, crosses the equinoctial in spring, there is the vernal equinox; and wherever he crosses it in autumn, there is the autumnal equinox. The two points of intersection are not, however, the same year after year, but are subject to a slow annual displacement westward, so that the sun does not cross the equinoctial, spring and autumn, exactly in the same points, but every year a little behind those of the preceding year. This effect is termed the precession of the equinoxes, because it accelerates their time, though it is really their retrocession. It amounts to about 50¼″ in a year, or to 1° in 70½ years, to 30°, or a whole sign, in 2,140 years; so that in somewhat more than 25,000 years, the equinoctial points will complete a revolution westward along the ecliptic, and return to the same position.

One obvious effect of the falling back of the equinoctial points, is a progressive increase of longitude in all the heavenly bodies. Hence those stars which, in the time of Hipparchus, were in conjunction with the sun when he was in the equinox, are now 30°, or a whole sign, eastward of it; and the constellations and signs of the zodiac no longer correspond, as may be seen by reference to a celestial globe.

The annual precession of the equinoxes, apparently a change in the sun's passage across the equinoctial, is really a change in the point of the earth's orbit at which its two hemispheres are equally exposed to the sun. The cause of this remained unknown till the age of Newton, who showed that it resulted from the form of the earth, and the unequal attraction of the sun and moon on the unequal masses of matter at the equator and the poles, producing a slow reeling motion of the earth's axis from east to west, and the recession westward of the equinoctial points. Fig. 32 illustrates its effect.

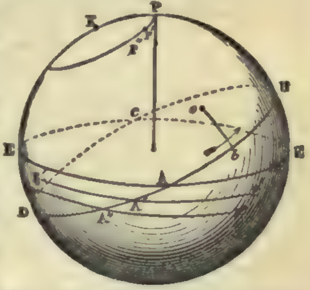
Fig. 32.



Let S be the sun, T K the pole of the ecliptic, T P the pole of the earth revolving around T K, in the direction of the arrow. In the space of one year, the revolution will change from T P, to T p; in the second year to T p'; and so on. Let E E be the earth's equator, then, when the pole of the earth moves from T P, to T p, the line of the equinoxes, or the intersection of the ecliptic and equator, will move from T A, to T a, and so on, turning slowly around the centre of the earth. It is evident that this progressive change of the direction of the poles of the earth will have a corresponding influence on the planes of the fixed stars, and on the commencements of the seasons. Thus, spring commences when the line of equinoxes is in T' A. The succeeding year would have the same commencement; but, in the meantime, the line of nodes has moved to T_1, A_1; in the following year it will have moved to T_2', A_2'—all passing through the sun S. But as the direction of the arrow shows direct motions, it is easily to be seen that the intersections *precede* at every year: for this reason this phenomenon is termed, as we have already seen, the precession of the equinoxes.

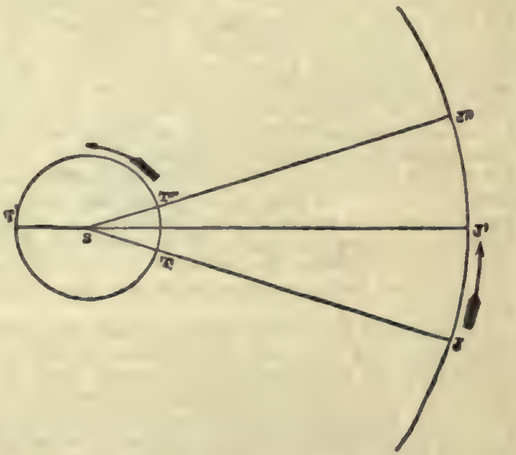
In order to exhibit the effect of this phenomenon on the planes of the stars, let E E (Fig. 33) be the earth's equator, A B C D the ecliptic, and let the intersections of the ecliptic and equator occur successively at A′, A″, &c., in an opposite direction to the sun's path. These successive changes of the equinoxes will cause corresponding changes in the pole P to P′ and P″, the right ascensions. Declinations of all bodies will be changed, as also their longitudes; but it will not have any effect on the position of the stars, the longitudes of which will be constantly the same.

Fig. 33.



On the Aberration of Light.—In ancient times it was supposed that the velocity of light was infinite and immeasurable. Roëmer, a Danish astronomer, pointed out, in the year 1675, that in comparing Cassini's tables of Jupiter's first satellite with observation, he discovered the following fact:—When Jupiter was near opposition,

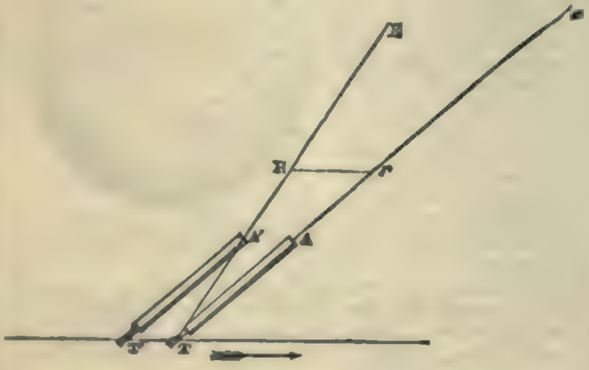
Fig. 34.



the eclipses always happened earlier than the predicted time; and when the planet was near conjunction, the eclipses happened later, the whole difference amounting to upwards of sixteen minutes. The tables of Cassini were founded on an extensive series of observations at all parts of the orbit of the planet, and would therefore give a result free from aberration at the mean distance of the planet from the earth. Thus, in Fig. 34, T T′ T″ represent the earth's orbit, S the sun, and J J′ J″ the orbit of Jupiter. Between T and T″ the planet is at opposition, and is at its least distance from the earth—the eclipses would, at this position, happen earlier—at T′ the planet is at conjunction, or at its greatest distance, when the eclipses would, of course, happen later about this period. Huygens and others confirmed this assertion of Roëmer, but the subject does not appear to have been further attended to till Dr. Bradley, in the year 1728, communicated to the Royal Society the theoretical cause of the displacement of a star, termed the "Aberration of Light." To the same astronomer we are likewise indebted for the discovery of the Nutation of the earth's axis. Without these two corrections of Aberration and Nutation, there would be a discordance in the prediction of the apparent place of a star to the amount of 1′ nearly of right ascension, and 30″ of North Polar distance. To the first of these discoveries, in chronological order, we now beg the reader's attention.

Picard, and other astronomers, in observations made for the purpose of determining the annual parallax of certain stars, found an unaccountable difference of 40″ (annually) after the application of the Prussian and all other known corrections. Dr. Bradley, who confirmed, by observations of several stars, this difference, explained the theoretical cause in the following manner:—Taking for granted that light took 8′ 3″ to pass from the sun to the earth at its mean distance, we have the motion of the earth in its orbit during this interval equal to 20″·5. In the preceding figure, when the earth is at T, the star being in the direction E T, it is evident that the telescope will not be in this position to see the star; it must have a certain inclination, T A or T′ A′, such that the cross of wires placed in T′ describe the distance T′ T by virtue of the motion of the earth, whilst that light describes the distance, A′ T. We see, in fact, that the light which passes the optical centre of the object-glass A′, when the telescope occupies the position T′ A′, arrives in T when the telescope has taken the position T A, and can, consequently, meet the cross wires, which are then found at the point T.

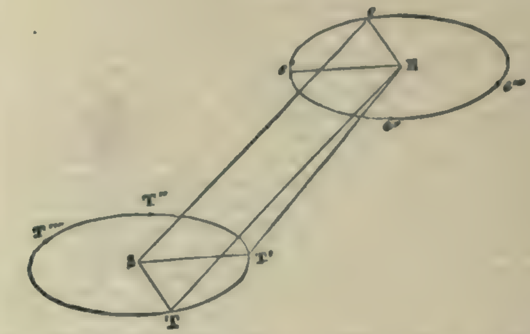
Fig. 35.



In order that the reader may see clearly the effect of the aberration of light on a star's position, we shall commence with the most simple appearances. And, in the first place, we will consider the effect of the varying position of the earth in its orbit on the place of a fixed star. For this purpose we shall take as a point of reference the place that a star would successively take, when seen from the centre of the sun, in the positions of the earth in its orbit. In the next place, we shall treat of the effect of the velocity of light combined with that of the earth in its orbit on a star's position.

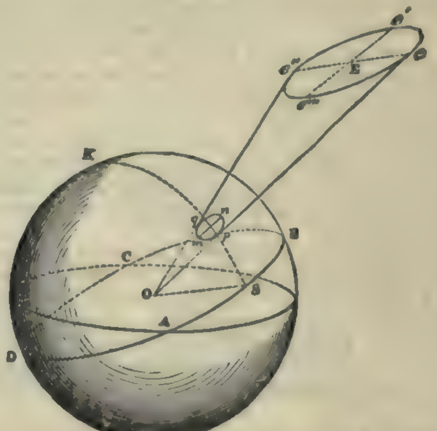
In Fig. 36 S represents the sun; T, T′, T″, &c., the earth in its orbit; E the place of a star. When the earth is at T, an observer at T will see it in the direction of T E; the corresponding direction that an observer at the sun would see it, would be found by making *e* E parallel and equal to T S, the radius of the earth's orbit; and drawing S *e* equal and parallel to T E, the star's place would then be, to an observer at S, in the position *e*: similarly when the earth has moved to T′, making *e*′ E equal and parallel to T′ S′, and completing the parallelogram, the star's place would be found in *e*′. In the same manner, tracing the position of the star throughout the year, it will be found to describe a curve equal as *e e*′ *e*″ *e*‴ is to the orbit of the earth, and parallel to its plane.

Fig. 36.



Now, to transfer these appearances to an example, let us take, in the next figure (Fig. 37), a sphere of which O is the centre, A B C D the ecliptic, K its pole, K S a circle of latitude passing through a star as γ Draconis; then, according to the preceding example, when the star is at S, the star will appear, with reference to the centre of the sphere, in a line E *e*, equal and parallel to O S, which cuts the cone in the direction *p* of the small ellipse *m p n q*. It may be remarked that each star will appear to describe an ellipse in the heavens, which will, for a star situated at the pole of the ecliptic, have its major and minor axes equal, or will become a circle, and will gradually become more and more elongated as it approaches the ecliptic, when it becomes merely a right line. The major axis, *m n*, of this ellipse is parallel to the ecliptic; and the minor axis *p q*, is perpendicular to it. We have thus found that when the sun is at S, or at the foot of the circle of latitude, the star should appear at *p*; and as the sun progresses in its orbit, it should successively be found in *n*, *q*, and *m*.

Fig. 37.

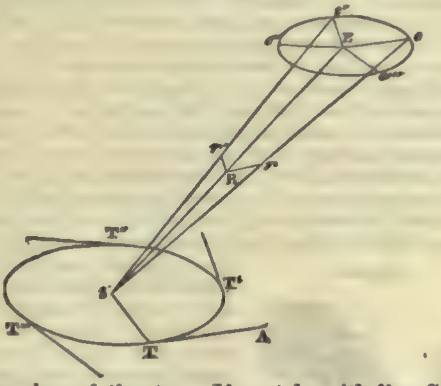


Such are the positions that Dr. Bradley calculated that the star should occupy in the annual revolution of the earth in its orbit. He was surprised to find that the most distant position of the star from the pole of the ecliptic did not occur when the sun was at S, but when it was distant 90° from this point. His observations of γ Draconis were commenced in December, 1725, when the sun would be about the position S of our figure, and the star in the position *p*; but he found that it gradually went towards the south, till it attained a position 20″ more southerly than in December. This occurred at the beginning of March, 1726. It afterwards went northerly, being in September more northerly by 39″ than it was in March. In the ensuing December the star was found in the position of the previous December, after making a proper allowance for the precession of the equinoxes.

Dr. Bradley did not, however, rest satisfied till he had repeated the observations with another instrument, made by one of the most celebrated artists of the day, Graham, which included a larger range of zenith distance. The same results as before mentioned were arrived at; the last instrument gave results identical with the three-foot quadrant of Picard, and the twenty-four foot sector of Molyneux. He endeavoured to trace the origin of the difference to the effect of refraction, or a *nutation* of the *earth's axis*, the latter of which corrections was then unknown, with the exception of the trifling effect of *solar nutation*, whose period was six months, and which at its maximum, as determined by Newton, only amounted to a fraction of a second. The cause was certainly proved by Bradley not to be owing to nutation, since a star, opposite in right ascension to γ Draconis, and at the same distance from the pole, observed at the same time of the year, exhibited differences only half the amount of γ Draconis. Had the cause been the effect of nutation of the earth's axis, the same result of fluctuation would have affected both stars by exactly the same quantity.

The effect of aberration may be thus explained. In the figure, T T′ T″, &c. (Fig. 38), represent as before; E is the place of the star. If we take with line S E, a part S R, and another line R *r*, parallel to the tangent to the earth's orbit at T, which would be the direction of the motion of the earth unless restrained by gravitation, the proportion of R *r* to S R is that of the motion of the earth in its orbit to the velocity of light. Thus when the earth is at T, the star, to an observer immovable at the centre of the sun, would, by the effect of the "aberration of light," be seen in the position S *e*, looking at the star as if he had been on the earth at T. Thus, by analogous reasoning, when the earth is at T′, by drawing R *r*′ parallel to the direction of the earth's motion, an observer at the sun will see the star in the direction S *e*′; and so on. The star would then appear to describe a curve in the heavens, *e*, *e*′, *e*″, *e*‴.

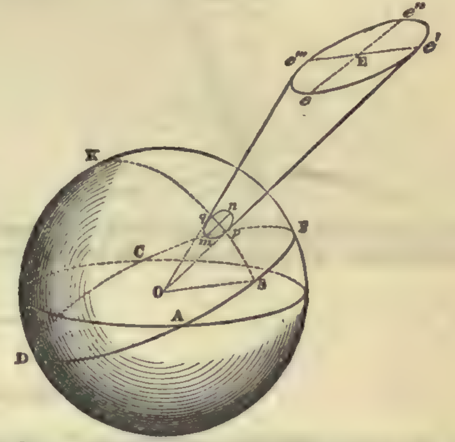
Fig. 38.



There is a great difference, therefore, between the two positions of the star, by taking into account the effect of aberration. In the former case, the direction of the visual ray was, for an observer, immovable at the sun, in a line parallel and equal to that joining the star with the earth in its orbit, and distant by the radius of the earth's orbit. In the latter case, the effect of aberration is to make the star appear in a line parallel to a tangent of the earth in its orbit, and distant by a quantity in proportion to the velocity of light, combined with that of the earth in its orbit.

Fig. 39 will show the real effect of aberration on the position of γ Draconis. By the preceding reasoning, when the sun is at S, the star should appear at *m*, in the small ellipse *m p n q*. The effect of aberration will therefore be to *retard* the position of the star by 90°, which will agree with Bradley's observation of December, 1725. At March, 1726, the star had increased its polar distance by 39″, or was found in the position *p*, and so on, the successive positions of the star agreeing precisely with observation.

Fig. 39.

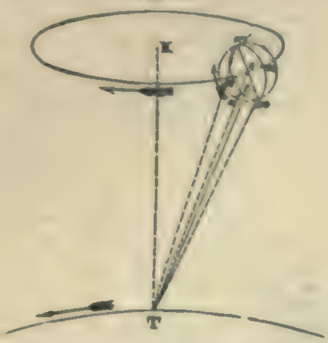


Nutation of the Earth's Axis.—After the discovery of the Aberration of Light, the indefatigable astronomer, Dr. Bradley, prosecuted his observations at Oxford and Greenwich, when his zeal and care were rewarded by the discovery of another important inequality—viz., Lunar Nutation. After applying Precession and Aberration, he found that, after a series of observations carried on from 1727 to 1745, an inequality existed, depending on the longitude of the nodes of the moon, whose period was 18 years, the existence of which had been previously mentioned by Roëmer, but of which no published account had been given. Dr. Bradley communicated this "Nutation of the Earth's Axis," in a Memoir, to the Royal Society, in 1748; in which he mentioned, that in order to reconcile it with his observations, it would be necessary to assume that the pole of the equator described a small ellipse about its mean plane, whose major and minor axes were respectively 18″ and 16″. It was afterwards explained on Sir Isaac Newton's Theory of Gravitation, as a necessary effect of the retrograde motion of the moon's nodes, by which the moon's inclination to the equator varies from 18° to 28°. By this it is evident that this variation of inclination will cause a considerable difference in the moon's attraction on the protuberant parts of the earth's equator. Nutation is, then, an irregularity of *Lunar Precession*, the mean value of which is 35″·9 annually—the remaining 14″·4 being principally due to the sun—or the whole amount of the precession of the equinoxes being equal to 50″·3.

The following explanation will clearly show the effect of a nutation of the earth's axis on the position of a star:—

It has been previously explained that the pole of the equator makes a complete revolution around the pole of the ecliptic in a term of about 25,000 years, and that it is termed the "Precession of the Equinoxes." In Fig. 40 (which is not in exact proportion to the phenomena), T K is the pole of the ecliptic, and T *o* the pole of the equator, the angle K T *o*, or the obliquity of the ecliptic, being 23° 28′. In consequence, however, of *nutation*, the pole of the equator, T *o*, does not preserve the same inclination to the pole of the ecliptic, but moves on the surface of a little cone at the elliptic base, T $m\ n\ m'\ n'$; still, however, the cone itself describing its revolution around the pole of the ecliptic, which is the "Precession of the Equinoxes," as before stated. The motion in the smaller cone, around its centre o, will evidently cause the pole of the equator to be alternately on one side and another of its mean plane. The major axis of this ellipse, $m\ m'$, is directed in the plane which passes through its axis, T o, and through the perpendicular, T K, to the plane of the ecliptic: its amplitude is 19·3″. The smaller axis of the ellipse is 14·4″. The pole, P, makes a revolution of this ellipse in the space of eighteen years, returning to m each time that the ascending node of the moon is found at the spring equinox. To know, at any time whatever, what is the position of the pole on the ellipse, we must imagine a circle described on the major axis, $m\ m'$, as a diameter, and to suppose that a point, z, describes uniformly this circle in the direction of the arrow, in a manner to come back again always to m at the times at which the pole ought to be found there. At any time whatever, the pole, P, is always situated at the point of meeting the ellipse, $m\ n\ m'\ n'$, with a perpendicular to its major axis, drawn through the position that the point z occupies at this instant. From this illustration the nature of nutation will be readily understood.

Fig. 40.



ADDENDA TO CHAPTER III.

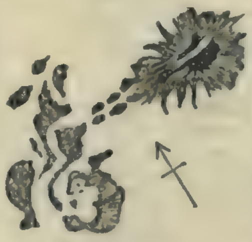
ONE of the most interesting speculations of Astronomical Science, is that which relates to the physical constitution of the sun; and we shall, therefore, venture to make some remarks in extension of those of Mr. Breen, given at page 929, on this subject.

The late advances made in Chemical and Optical Science, have not only permitted us to have a more accurate idea of the nature of solar light and heat, but, to a large extent, we have also become acquainted with some of the causes which produce them. The discovery of the polarisation of light, enables us to point out some of the characteristics of the solar luminous rays, as compared with other sources of light; but, since the year 1858, the observations of solar eclipses, and the discovery of the spectrum analysis, have proved the existence of an atmosphere encircling the sun, and shown that that atmosphere must be in a state of intense ignition. We will briefly point out how these facts have been ascertained.

At a subsequent page,* the reader will find an account of some singular appearances, which have been noticed during the eclipses of the sun that have occurred during the last few years. And as our means of observing and registering such appearances have improved,† the nature of the red flames has been directly traced to the existence of a solar atmosphere. At the time they have been noticed, they could not have occurred on the surface of the moon, because it is well known that our satellite possesses no atmosphere; and as there could be no other cause assigned for them, they were accounted for in the way we have named.

The discovery of the spectrum analysis, of which a full account will be found at the end of the section on Light, has satisfactorily set the question at rest. Our readers will understand us better if we give a brief outline of the manner of applying the spectrum method of investigation in this case.—If a ray of white light be decomposed by a glass prism, it is divided into seven colours, affording what is called the prismatic spectrum. Between each extremity of the spectrum a vast number of dark lines is distributed, which have definite positions for every ray of light. If these be viewed by means of the apparatus, illustrated and described at page 166, in the section on Light, it will be found that the vapour of any metal, passing through, or in combustion in, any luminous flame, will afford a distinctive coloured line for each metal—either of them being thus readily distinguished by its own colour and position, in the spectrum so afforded. If the reader will now peruse pages 167 and 168, in the section referred to, he will be prepared to see the application of these wonderful discoveries to the investigation of the nature of the solar atmosphere, in which, by these means, the existence of iron and other metals, in a vaporous state, has been observed. Reasoning on these facts, as we have there stated, the Astronomer Royal, Professor Airy, has pronounced a distinct opinion—that the surface of the sun is in a state of incandescence; and that immense bodies of vapour are continuously arising from it, doubtless being the cause of the intense light and heat emanating from that body. This, perhaps, is one of the most interesting applications of modern discovery with which we are acquainted.

Fig. 40*.



SOLAR SPOTS.—These curious appearances, which have been generally considered to exist *on* the disc of the sun, have generally attracted the attention of observers of late years. On July 25, 1862, a remarkable spot was noticed, having a length of 120,000 miles, and an area of 72,000,000 square miles. At its disappearance, on August 4, a distinct *notch* was afforded by the photographs of it, which seemed to prove that it was due to an indentation of the solar disc. Fig. 40* illustrates the shape of the spot as drawn on July 27.—ED.

CHAPTER IV.

ON THE MOON.

THIS object, the most valuable in relation to mankind—which serves as a guide to the mariner in the trackless path of the ocean, and whose influence, combined with the sun, produces the tides, will next claim our attention. Viewing its path in the heavens, we find its motion to be the most rapid of any other body; the earth's changes of position, which, with reference to the sun, amounted in the course of a day to 1°, will, for the moon, be more than twelve times that quantity. In consequence of this quick displacement with reference to the stars, its motions have become a most valuable means of determining, at any instant of time, the position of a vessel at sea.

Her appearance, and the breadth of her illuminated disc, vary every moment, showing that she is an opaque body which receives light from the sun. The disc, however, during each successive lunation, always presents the same physical appearances; and we have never been able to perceive the other hemisphere, which can only be seen when in conjunction with the sun, or at that time when the darkened hemisphere is directed to the earth. This arises from her rotation on an axis, in a period nearly coincident with the time of her sidereal revolution.

A most striking proof of the opacity of the body of the moon, is shown by a phenomenon frequently visible—viz., the occultation of a star by the moon. In consequence of the *proper* motion of the moon from west to east, she will pass over or occult in her march all the fixed stars in her path. Before full moon, we see the star disappear at her unenlightened hemisphere, and reappear at the illuminated limb. The time of the occultation will depend on the motion of the moon in her orbit, which can thus be calculated with great precision, and is found to agree exactly with observation.

PHASES OF THE MOON.—The phases are thus explained:—If we assume that the moon describes a circle around the earth, and that the sun is infinitely distant, we shall find that the rays of light from the sun will always be parallel, and will only illuminate one-half of the convex hemisphere limited by the line *m n* (Fig. 41). But to a spectator on the earth, at T, the illuminated portion will be limited by the line *p q*, directed perpendicularly to the radius of the moon's orbit. Thus at new moon, or A, the enlightened hemisphere is turned towards the sun, and the darkened part to the earth, when it is, consequently, invisible, except in peculiar circumstances, called "eclipses of the sun," when its diameter obscures for a time that luminary. At B a small portion of the enlightened hemisphere is seen from the earth. At C it is at its "first quarter." The enlightened portion increases gradually till it becomes a maximum, or is in opposition to the sun. At G it is again on the wane, or at its last quarter, decreasing gradually, but in a direction opposite to the first appearances. At A it is again found in conjunction. The above successive appearances are shown by the following diagrams. When the moon passes into the region of the heavens where the sun is, it is invisible. At the end of a few days, a careful observer will see the moon after sunset in the form of a crescent, with its convex side to the right, as it is represented in A (Fig. 42); this disappears, after a short period, under the horizon. For some days the same appearances present themselves, the crescent becoming broader at its centre, as in B, and remaining longer above the horizon. Six or seven days more and the crescent has nearly disappeared, and a half moon presents itself to us, as in C. At this period it is sufficiently distant from the sun, and crosses the meridian six hours after it. The moon continues to increase, first to three-fourths, and finally to a full circle, as in D and E. In another week, the waning moon, which is seen in the morning, assumes the appearance of F, G, H, and I, the concave side of the crescent being now to the left.

Fig. 41.

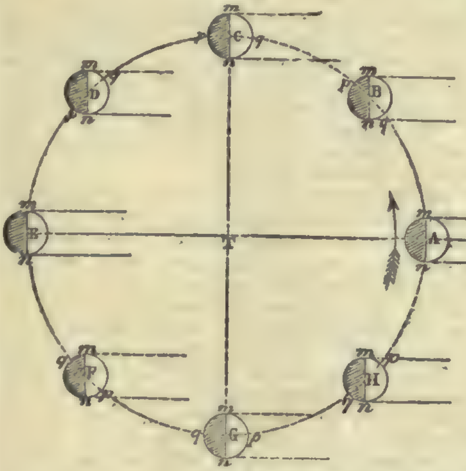

Fig. 42.

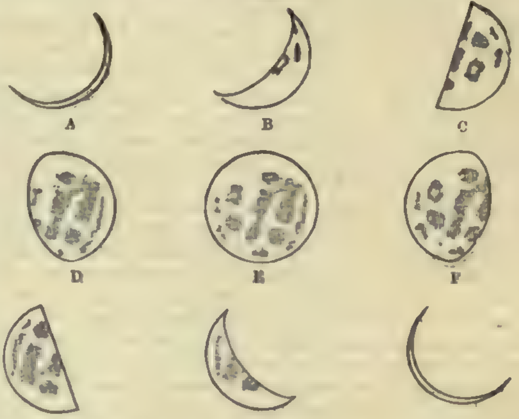
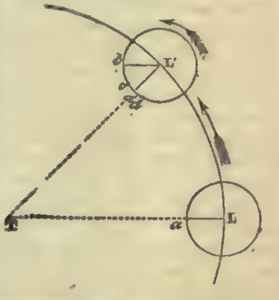


A B C
D E F
G H I

If the moon did not revolve on its axis during this progress, we should not have the same spots visible on its surface at each position in its orbit, in nearly the same direction. We are thus led to infer that the moon makes a corresponding turn on her axis, in the interval from conjunction to conjunction. Thus, if the surface were without motion, while she moved in her orbit from L to L′ (Fig. 43), the position L *a* would take a position L′ *b*; but during this time she has revolved on her axis through an angle *b* L′ *a*, equal to the angle L T L′ described in her orbit. Similarly, we find that when she has described a motion of 180° or 270°, she has rotated on her axis by an equivalent angle.*

Fig. 43.

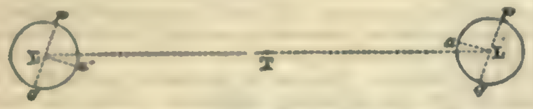


LIBRATION OF THE MOON.—Seen through a telescope, there is another phenomenon called the *libration*, which enables us to perceive a small portion of the disc, otherwise invisible. The first, or the *libration* in longitude, arises from the two motions of rotation and translation not being exactly equal, and thus the appearance of the moon's borders will likewise partake of this inequality. The second arises from the circumstance that the axis of rotation is not exactly perpendicular to the plane of its orbit, but is inclined to it by an angle of 6° 37′. This is called the *libration in latitude*. Thus, when the moon is at L (Fig. 44), we see without difficulty the pole *q*, but cannot perceive the opposite pole *p*. But when the moon is at L′ the pole *p* becomes visible, while the pole *q* vanishes from our view. The position of a spot near the moon's equator at *a*, would, therefore, to a spectator on the earth, appear in different positions; this libration is directed perpendicularly to the plane of its orbit, or nearly to the plane of the ecliptic.

---

* A somewhat acrimonious discussion was commenced some years ago, by Mr. Jellinger Symons, who stoutly maintained that the moon did *not* rotate on her axis. The idea, however, was at last given up.—ED.

Fig. 44.

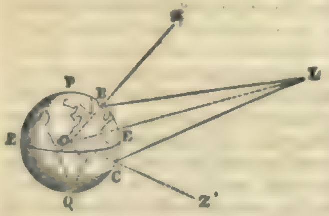


Finally, there is a third libration, called the diurnal libration, which depends on the positions of the moon to an observer on the earth's surface, in the interval from rising to setting. In consequence of the proximity of the moon, the spots will not retain the same positions at rising and passage across the meridian; but the effect at its maximum is only 32″, and is scarcely worth attention.

PARALLAX OF THE MOON.—Before attempting to deduce the orbit that the moon describes around the earth, we shall find it imperatively necessary to correct the results of observation for "Parallax." Parallax is the angle which the radius of the earth subtends at the moon. It is seen entirely in a vertical direction on the meridian, and can be determined in the following manner:—

If the zenith distance of the moon's centre be observed by two astronomers at two stations, differing considerably in latitude north and south, as Greenwich and the Cape of Good Hope, as (B and C) in Fig. 45, we shall have the angles Z B L and Z′ C L. The latitudes of the two stations, B O E and C O E, are well-known, and their difference of longitude is also accurately known. The motion of the moon in zenith distance is known to a great certainty, and thus the data are perfectly comparable. If the moon were as distant as the fixed stars, the sum of the zenith distances thus found would be precisely equal to the sum of the latitudes, north and south, of the two observatories, when proper allowance has been made for refraction. But the effect of parallax will be in both cases to increase the apparent zenith distances, and the observed sum will be greater than the sum of the latitudes by the whole amount of the two parallaxes. In this manner, by corresponding observations of the moon at her meridian passage, the constant of the horizontal parallax has been determined. (See Note at page 926).

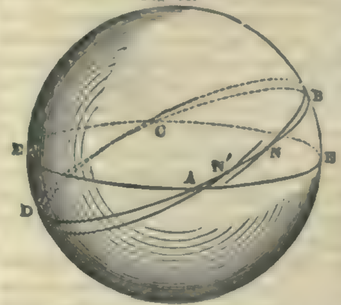
45.



In its practical application to the results of observation, it is customary to correct the zenith distances for the angle made by the direction of the plumb-line at each station, and a line drawn to the centre of the earth. This is termed the angle of the vertical; and its value, as well as the radius of the earth at the two stations, are known from the "figure of the earth." The point of reference to which horizontal parallaxes are referred, in the case of the moon, is the radius of the equator; and, in this manner, the individual results of observation are corrected for the effect of parallax in altitude, which varies as the line of the zenith distance.

THE MOON'S PATH IN THE HEAVENS.—By the transit instrument and mural circle, we are now able to trace the path of the moon in the heavens, after properly applying the corrections for parallax and semi-diameter before mentioned. We thus determine its angular displacements with respect to the equator, and find that it describes a revolution in a period of about 27 days, returning nearly to the point of departure; but if, during several lunations, its progress be watched, we shall find that its inclination to the equator differs by an angle varying from 18° to 20°. Instead, however, of referring to the equator, if we use the ecliptic, we shall find that it constantly preserves the same relation—viz., an inclination of about 5° 9′.

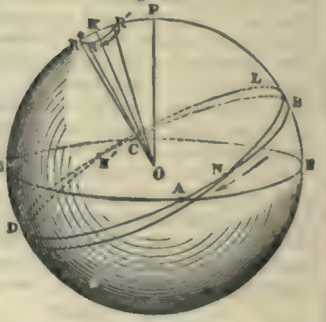
Fig 46.



The figure (Fig. 46) will show the orbit of the moon in its progress through two lunations. E E represents the earth's equator, A B C D the ecliptic, and near A B C D the orbit of the moon is seen inclined to the ecliptic by an angle of 5° 9′. The intersections of the orbit N N′ are termed the *nodes*. Supposing N to represent the node at one lunation, at the next it will be found to have retrograded to N′, and at each succeeding lunation in the same manner, always preserving the same inclination to the ecliptic, till, at the end of about 19 years, it returns to the position N. This will naturally cause a variation in its inclination with regard to the equator, which is shown by the figure (Fig. 47).

Let A B C D be the ecliptic, E E the equator, N L N′ the orbit of the moon, O P the axis of the earth, O K the axis of the ecliptic, and O R the axis of the moon's orbit. In the motion of the axis of the moon's orbit around the pole of the ecliptic, it will describe a small circle, R R′ R″, round the point K. The axis O R describes a cone of revolution, of which the axis of the figure is the line O K. In this motion the angle of O R with O K is always equal to the inclination of the moon's orbit, or 5° 9′. The inclination that the equator will make with the moon's orbit will be successively the angles P O R′, P O R, and P O R″; and as the angle P O K is the obliquity of the ecliptic, or 23° 28′, the angles P O R′ and P O R″ will be the minima and maxima inclinations, being 18° 19′ and 28° 37′ respectively. (See also Fig. 31).

Fig. 47.

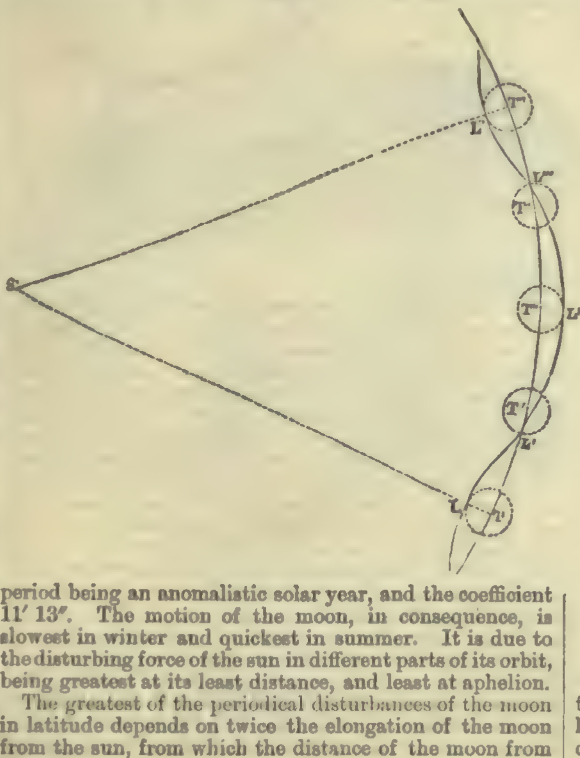


MOTION OF THE APSIDES.—The line of the apsides of the moon has been found to have a very rapid, though not uniform motion, amounting to 6′ 41″ daily, which is direct, or according to the order of the signs, and the major axis of the ellipse thus makes a complete revolution in 3,232½ days. In one hundred Julian years, or 36,525 days, the line of the apsides makes eleven complete revolutions + 109° 2′ 46″·6; and at the present time this motion decreases 50″·4203 in one hundred years. The longitude of the perigee may be calculated for any period—that in 1801, January 1 (Paris time), being 266° 10′ 7″·5. The true longitude of the moon, supposing it to move in an elliptic orbit, whose eccentricity is 0·0548442 in parts of the semi-major axis, or the greatest equation of the centre is 6° 17′ 12″·7, might thus be calculated for any period in the ordinary manner; but a great number of minute corrections must be applied to it before the tabular plane, thus obtained, would be found to agree with the observed plane of the moon.

EVECTION, VARIATION, AND ANNUAL EQUATION.—

These are the three greatest periodical fluctuations of the moon in longitude. The effect of the evection can be explained by a diminution of the equation of the centre, when the moon is at opposition and conjunction, and by an increase in its value when at quadratures; the amount of the correction in the latter case not, however, being so considerable as in the former. If we suppose the line of apsides to be in syzygy—that is, new or full moon—the observed longitude will be found to be 80′ greater than the calculation; and if the apsides are in quadratures, or first and last quarters, the observed will be found to be smaller by the same amount. The evection depends on the double of the elongation of the moon from the sun, the mean anomaly being subtracted from the product, and the coefficient of this quantity, amounting to 1° 20′ 30″. Hence, when the apsides are in syzygies, at which period the eccentricity is greatest, the greatest equation of the centre is 7° 39′; and when in quadrature, at which it is smallest, it is only 4° 58′. At the latter position of the apsides, the gravitation is greatest at apogee, and least at perigee; and in the former case, the gravitation is greatest at perigee, and least at apogee; and, consequently, the eccentricity of the orbit is increased. The discovery of the equation of the centre and evection is due to Hipparchus and Ptolemy. The more accurate observations of Tycho proved the existence of a second irregularity, which is termed the *variation*. The observed places disagreeing with the computed act of syzygies and quadratures, sometimes as much as 37′ when the line of apsides was in the octants, Tycho found that it depended on the elongation of the moon from the sun. The cause of this is the position and distance of the sun and the earth; for when the sun's disturbing force is at right angles with the radius vector, the moon's motion is accelerated from the quadratures to syzigies, and retarded in the contrary direction. The coefficient is 35′ 42″, and the increase is double the elongation of the moon and sun. The *annual equation* follows nearly the same law as the equation of the centre of the earth's orbit, only with opposite signs. This is greatest in the months of March and September, but almost vanishes in June and December. From this it derives its name—the period being an anomalistic solar year, and the coefficient 11′ 13″. The motion of the moon, in consequence, is slowest in winter and quickest in summer. It is due to the disturbing force of the sun in different parts of its orbit, being greatest at its least distance, and least at aphelion.

Fig. 48.



The greatest of the periodical disturbances of the moon in latitude depends on twice the elongation of the moon from the sun, from which the distance of the moon from its nodes being subtracted, the coefficient is 8′ 48″. In addition to this, there is another remarkable inequality, depending principally on the compression of the earth at the poles, and which may be termed the spheroidal inequality. The theory of universal gravitation has come to the aid of observation in detecting numerous inequalities, which observation alone would scarcely ever be able to discover, and has explained all those which were previously known to exist.

Motion of the Moon in Space.—The curve which the moon describes in space may be laid down in the following simple manner:—Let the earth, T (Fig. 48), pass round the sun, S′ in the orbit T, T′, T″, &c. An observer on the earth will see the moon in various positions in respect to the sun. When the earth is at T, the moon will be at L, or in conjunction; when at T′, the moon will be at L′, or at its first quarter; at L″ at full; at L‴ at last quarter; and as the earth describes its path around the sun, it follows that the curve described by the moon in space will pass through the points L, L′, L″, L‴, &c. This line is represented in the diagram as considerably more curved than it really is, the distance T L being only $\frac{1}{400}$th of the distance T S.

On the Harvest Moon.—The phenomenon of the harvest moon, when for some nights together, at that period of the year, the moon rises nearly at the same time, depends on the inclination of the ecliptic with the horizon. That part of the ecliptic in which this inclination makes the least possible angle lies in the constellation Aries (in north latitude); and when the sun is in Libra, as at the time of the autumnal equinox, the moon, when at full, will be near the first point of Aries, and but little distant from the ecliptic. It is clear that, when at this part of its orbit, as it travels from west to east, the times of successive rising must be within a short period of each other; and if the ecliptic were wholly parallel to the horizon, then it would rise exactly at the same time on each night. As the moon, however, is a little inclined to the ecliptic at some periods, this will make the difference even less. In the latitude of London, the least possible difference between the times of successive rising of the moon, has been calculated at seventeen minutes. When the constellation *Libra* rises, the ecliptic makes the greatest possible angle with the horizon, and the differences between the times of successive risings of the moon is then greatest. This takes

Fig. 49.

place with the full moon at the time of the vernal equinox, and the greatest possible difference in the latitude of London is 1h. 17m.

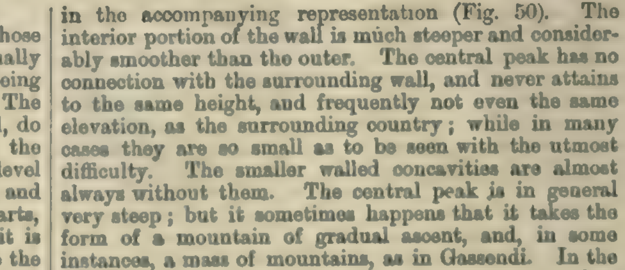
PHYSICAL CONSTITUTION AND TELESCOPIC APPEARANCE OF THE MOON.—No celestial object is better known to us, by means of the telescope, than the moon; and instruments have been constructed which shorten its distance by a thousand times, and thus brings it optically within less than two hundred and fifty miles of the earth.

In viewing it, the observer is immediately struck with the roughness of its surface, and the numerous circular formations, which appear as if surrounded by a steep and high wall: whilst those are by far the most numerous, there are also caves and hilly prominences. There exist also immense mountain chains, which for extent and height appear to surpass even those of the earth. Immense ridges, rising up from the open plains, are remarkable for their height and brightness, as well as for the numerous peaks and eminences into which the surface is separated. One of these is very visible in the interior of the crescent of the moon, when about half-full, and can even be seen as a *notch* in that portion, with the naked eye, from the shadow which it casts upon the open plain. This part is seen in the preceding representation of the moon when half-full (Fig. 49), and the mountain chain to which it belongs is a part of the *Lunar Apennines*, some of the peaks of which are calculated to be upwards of five thousand feet in height. Although, however, the general surface of the moon is rough and uneven, and the large circular mountains are extraordinarily plentiful, especially in the southern hemisphere, yet some portions are nearly level and of great extent. When the moon is full, these portions appear as dark grayish spots, and give it that appearance which has been likened to the human face; and as the moon cannot cast any shadows at this time, it follows that this must be their natural colour. These are known by the name of *seas*, and still retain that appellation; although when examined by means of the telescope, they have not any appearance of being sheets of water, but seem to be large, level, alluvial tracts of land, on which craters, peaks, cavities, and long banks are plentifully scattered. These seas take up a large portion of the lunar surface, although it is only the most extensive which are seen with the naked eye. The smaller ones are known by the names of bays, lakes, and marshes. They vary considerably in intensity of colour, and some of them have been even noticed of a grayish tinge. The greater number of these seas were named by Riccioli, who, according to the spirit of the age, called them, in the astrological manner, Mare Imbrium, Humorum, Serembates, &c. If we view the other portion of the moon when at the full, they might be mistaken for a crude, chaotic mass of crystallised or frozen fragments, without shape or termination. It is only when examined in its various crescent aspects, with good telescopes, that the various formations are seen, as it were, raised above its surface, which to all appearance they are when viewed in this bold relief.

The most remarkable of the lunar mountains are those of the circular shape, which are not, however, equally regularly defined all over its surface, some of them being quite perfect, and others misshapen and broken. The larger of the annular mountains, taken in general, do not possess the same regularity of structure as the smaller ones. For the greater part they have a level interior, which, in many instances, is very irregular; and the wall is but seldom equally high or broad at all parts, which will not, however, be perceived at first; and it is only when the sun has just commenced to illuminate the tops, that the shadows are noticed to be so rough and irregular. The exterior is frequently surrounded by high rocks, which are often more elevated than the wall. In some few instances, the interior surface is perfectly level, as in Plato, Archimedes, and the eastern portion of Stoflis; but, for the most part, they are covered with mountains, mountain chains, and craters of various depths and sizes. In several instances, the chain of mountains in the interior is quite straight and regular, and divides this surface into two parts more or less equal. These mountains are not in general so elevated as those which surround them. It is but rarely that those which are level in the interior, and may be denominated the *walled plains*, are quite circular in form. The wall which surrounds them is generally uneven, and in many parts is completely broken away: sometimes these appear as gaps, and in other cases the broken portion is completely levelled with the soil. In some cases the wall is wanting for a sixth part of the circumference; in others for one-fourth, or even one-third; but in these instances there is mostly some trace of a continuation of the real wall by a difference of brightness, or a succession of small hills. The walled plains may thus be considered to bear some affinity to the bays and some neighbouring portions of the great seas, as in the splendid *Sinus Iridum*, which, for a considerable portion of its boundary, bears a resemblance to some of the larger walled plains.

By far the greater number of the *walled plains* are seen in the southern hemisphere, where they are interlinked among each other in great plenty, and where it is a difficult matter to distinguish them properly, or to map them with the requisite distinctness. In the northern hemisphere they are less common, but appear to greater advantage from being more isolated; and it is here we see the more regular specimens of this class, as *Plato*, and *Archimedes*. It has been remarked that, in numerous instances, the walled plains appear ranged in a row in a north and south direction; and if the southern part be viewed at the first and last quarter, in that portion which separates the *Mare Nubium* from the hilly parts of the south-west quadrant, a row of these formations becomes plainly visible, some of which are of considerable magnitude and curiously entwined with one another. Similar to the circular-walled plains in shape, but mostly of smaller dimensions, are the circular-walled concavities, whose diameter varies considerably; and which, like the latter, are best seen in the northern part of the moon, though they are plentifully distributed in other parts, in the mountain chains, in the level seas, and even in the interior of the walled plains. The interior is mostly regularly concave; and in general they are furnished with a central peak, which occurs likewise, though not so frequently, in several of the walled plains, as may be seen in the accompanying representation (Fig. 50). The interior portion of the wall is much steeper and considerably smoother than the outer. The central peak has no connection with the surrounding wall, and never attains to the same height, and frequently not even the same elevation, as the surrounding country; while in many cases they are so small as to be seen with the utmost difficulty. The smaller walled concavities are almost always without them. The central peak is in general very steep; but it sometimes happens that it takes the form of a mountain of gradual ascent, and, in some instances, a mass of mountains, as in Gassendi. In the great annular mountain Tycho, which presents such a fine appearance at the time of full moon, the central peak is very steep and high. In some of the annular mountains, instead of the central part being occupied by a peak, it is frequently the locality of a deep crater, although this is not so exactly situated in the centre, as the peak generally is. It has been remarked that the very dark walled plains and concavities are mostly without any central mountain or peak, as is the case in

Fig. 50.



Julius Cæsar, Plato, Endymion, and many others of the same class. The central masses of mountains are, in general, very steep towards the summit, but are surrounded by low scattered mountains at the base. Several of the walled concavities are deficient in the same manner as the walled plains, a greater portion of the outer wall being broken down, and several gaps apparent in the circumference. The *pits* of the walled concavities are deeper than the surrounding country, the exterior height of the wall being generally one-half or one-third of the interior. But there is no proportion between the diameter and depth of the annular mountains, the smaller being sometimes deeper than the larger.

The walled mountains form but a small portion of the circular formations on the moon. Far more numerous than those, are the *craters*, by which name are designated the smaller concavities which present little or no appearance of a wall, and some of which are so minute that they can scarcely be perceived with the best telescopes. In some parts they are so numerous, that the lunar surface presents the appearance of a spongy mass covered with innumerable minute pores. Some of these craters, small as they appear, are furnished, like those of the former class, with a miniature peak in the centre. These are found at all portions of the moon, and are very plentiful in the interior of the walled concavities and plains, in the rocky chains and seas, and the level surfaces. When the moon is full, they appear as bright specks. They require a favourable time to be seen at all properly, for, unless the sun is at a favourable altitude, they can scarcely be perceived.

In viewing the moon when at full, several radiating bright streams will be noticed proceeding from many of the mountains, which pass to considerable distances from their apparent centres. None of the mountains, however, are surrounded by those bright radiating streaks to the same extent as Tycho, and many of them proceed to a distance of 500 miles. It is scarcely possible to imagine that these could be streams of lava, which flowed from the central eruption; and it is more plausibly conjectured that they must have flowed upwards through fissures, produced by the central explosion of the volcano. In either case, however, it may serve to give an idea of the tremendous force of action required in order to cause these appearances.

HEIGHT OF THE LUNAR MOUNTAINS.—The height of the lunar mountains is found either by observing the distance of the illumined summit of a mountain from the generally illuminated portion of its surface; or, otherwise, by the length of the shadow which it casts upon the plane. Both these methods will be easily understood from the following considerations. In determining their height by the former method, we find the distance of the illumined summit a (Fig. 51) from the moon's illumined edge $c\,o$, and we perceive that it is a tangent to the circle $p\,q\,r\,c'$. Knowing the two sides $o\,c'$ and $o\,a'$ of the right-angled triangles, we calculate $o\,a' = \sqrt{oc'^2 + a'c'^2}$, which is the distance of the summit of the mountain from the centre of the moon, and hence, subtracting the radius $o\,c'$, the remainder gives the height of the mountain above the surface. By this method we find its height in seconds of arcs, and this is nothing else than if we observe it resting on the limb of the moon. Its height may easily be reduced to feet. In general this method will give too small a value of the height, as the sun may have shone on the mountain for too great a length of time previously. It was by this means that Hevelius and Galileo ascertained the heights of many of the lunar mountains, some of which appeared to be as high as five English miles. More recent observations have shown them to be very high, though not of such an altitude as this.

Fig. 51.

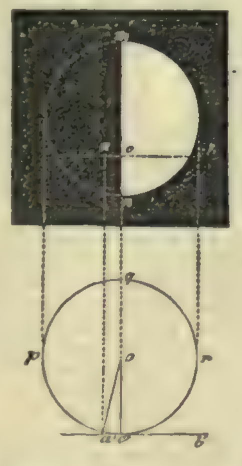


Fig. 52.

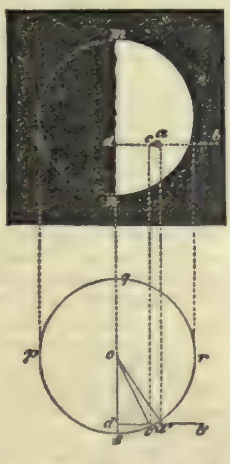


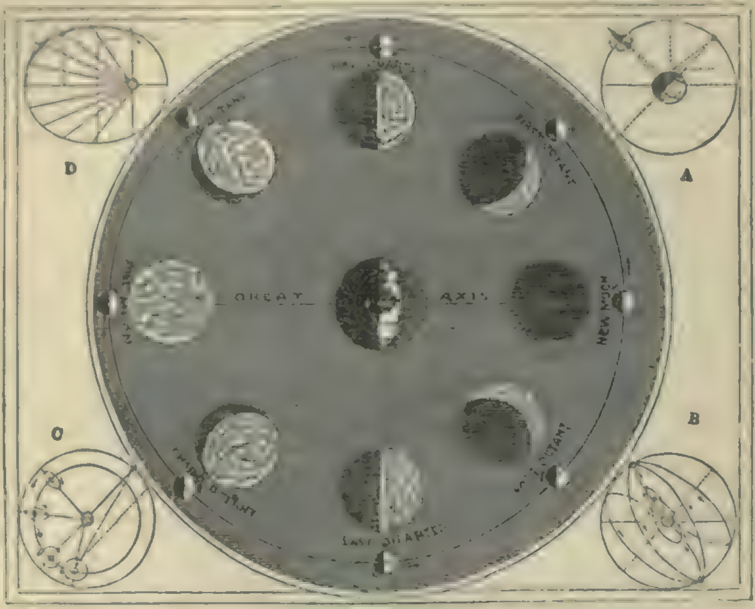
This method, however, is not applicable unless the moon is in quadrature, or half-full. The second method has been more commonly made use of on that account. As the mountain a (Fig. 52) casts the shadow $a\,c$, the length of this is measured by means of the micrometer. Describing the circle p, q, r, s, the solar ray directed towards $b\,c'$ will cut the circle in c'. The distance $c'd' = cd$ being measured, and the radius $o\,c'$ known, and the two sides of the right-angled triangle $o\,c'\,d$, the angle $o\,c'\,d$ is known, and consequently the angle $o\,c'\,a'$. In the triangle $o\,c'\,a'$ we thus know the sides $o\,c$, and $c'\,a$, and the included angle, and consequently the side $o\,a'$. Subtracting the radius $o\,c'$, the height of the mountain casting the shadow $a\,c'$ is determined.

Many observers have perceived bright spots on the *dark portion* of the lunar disc. Sir W. Herschel describes three which he once saw upon it, two of which appeared almost extinct, but the third was more luminous, and resembled a piece of burning charcoal covered with white ashes. A similar appearance was once noticed with the *naked eye* by two observers at Norwich and London. When the positions of those spots have been examined, it has been found that they are almost always situated at the brightest, and consequently the most reflective, portions of the lunar surface. When the disc of the moon is illumined by *earth-light*, as is the case when slightly crescent, or, as it is commonly called, the "old moon in the new moon's arms" (Fig. 53), those bright parts, which return most sun-light, also reflect the earth's light stronger than any others. The mountains Kepler, Tycho, and Copernicus are thus frequently visible in this manner, as also the bright mountainous districts. But, above all, Aristarchus is most commonly visible at those times. This is the brightest part of the moon, and was thought by Hevelius to be a burning volcano of sulphur and saltpetre.

Fig. 53.

In the following engraving, the cut B represents the earth when opposite the sun in the tropic of Capricorn, on the 21st of December, the longest night in the year, and moon full in the tropic of Cancer, the horizontal line being our horizon, showing that the diurnal arc of the sun is small, while the moon has a very large one to traverse. The contrary of this takes place in the summer solstice. This explains why the moon in summer seems to describe a very small, and in winter a very large arc. C represents the moon in various positions in reference to the earth and the sun. In the first and second figures she is in conjunction, or directly between the earth and the sun. In the next figures the earth is interposed between the sun and the moon. D shows how the elliptical orbit of planets is produced by the co-operation of attractive and tangential forces. The middle cut represents the phases of the moon.

Fig. 54.



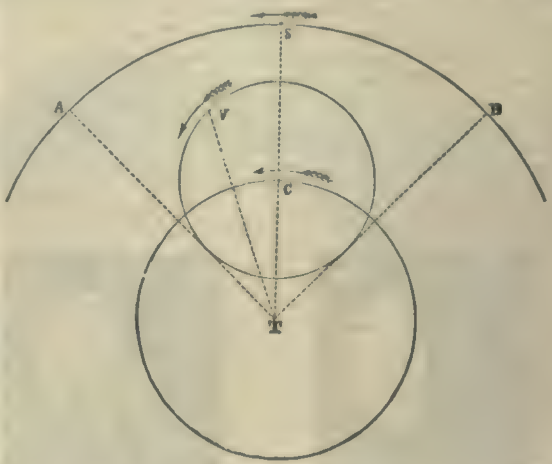
CHAPTER V.

ON THE PLANETS.

Among the more lustrous objects which arrest our observation in the heavens, are those which, since the earliest times, have been known by the name of *Planets*, from their erratic course among the fixed stars. The variable brightness of Venus, the morning and evening star, as well as those which appear at all times of the night, claim our attention equally with the sun and moon. Five of those objects were known to the ancients: Mercury, Venus, Mars, Jupiter, and Saturn; the first of which is but rarely seen with the naked eye in our latitudes, in consequence of its constant proximity to the sun, although a sparkling object, and much brighter than any of the fixed stars. These bodies, it will be perceived, do not, like the sun and moon, move in one constant direction from west to east, but sometimes direct, sometimes retrograde, and are at other times stationary. It was noticed, however, by the ancients, that whatever might be their movements in longitude, their latitudes did not depart much from the ecliptic; and a zone of 16° in breadth, or 8° north and south of the ecliptic, contained all the ancient planets. This was termed by them the zodiac, and was divided into twelve equal portions, the signs at which it cuts the equator, or the line of the equinoxes, being in the constellations Aries and Capricornus.

If Venus, the most brilliant of all the planets, be observed in its passage through the heavens, it will be seen that, in the course of a few months, it describes in the sky a very irregular circle, and that it oscillates to a certain distance on each side of the sun, sometimes rising before it in great brilliancy in the morning, and subsequently setting after it in the evening, and then for a length of time being altogether invisible to the naked eye (Fig. 55). It thus appears at an epoch nearly in the direction of the sun S; it then passes from S to A, and then returns from A to S; and having passed the sun, it goes from S to B, and finally returns to it in the contrary direction, or from B to S. When an evening star, it is seen between S and A, and between S and B in the morning. Its latitude varies in the same manner.

Fig. 55.



The greatest elongation from the sun never exceeds 47¾°, and is never less than 45°; and at those points its motion is considerably slower than when near the sun. In order to explain the oscillatory motion of Venus in respect to the sun, the ancients imagined an epicycle similar to that already mentioned in the case of the sun. If T (Fig. 55) be the position of the earth, it was supposed that V, the planet, described an orbit round the centre C, which had a motion itself around the earth, the three points, T C S, being always in a straight line. At the times of greatest elongation, the planet was in the direction of T A and T B; and in the intermediate times, its apparent motion was sometimes from west to east, and at others from east to west, or retrograde. If Venus be, however, examined with the telescope at its various distances from the sun, it will be seen that its diameter varies greatly, and that its disc undergoes a series of changes similar to those of the moon. By observing those in its different positions, it will be perfectly apparent that they agree with a motion of the planet round the sun, it being supposed that the planet is an opaque globular body, of which one hemisphere is illuminated by the sun. If the sun S (Fig. 56) be supposed to revolve round the earth T in the direction of the arrow, and the planet V around the sun, at the point V, where it is in a line with the earth and sun, and the hemisphere turned towards both illumined by the latter body, its disc will appear wholly illuminated by the latter. At the points V′ and V‴, where the angles S V′ T and S V‴ T are right angles, the planet will appear as half-full. At the point V″ the illuminated portion will be completely turned away from the east, and it will therefore be invisible, but would appear on the sun as a dark spot, and at its greatest diameter. In the positions between V and V′, and V and V‴, it will appear more or less gibbous; and between V′ and V″, and V″ and V‴, as crescentic. The appearances of the planet, and comparative sizes of its disc, under these circumstances, will be seen in the accompanying representation (Fig. 57).

Fig. 56.

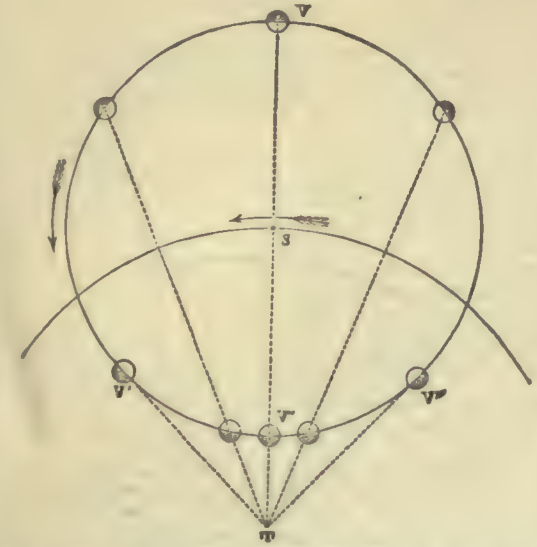


Fig. 57.

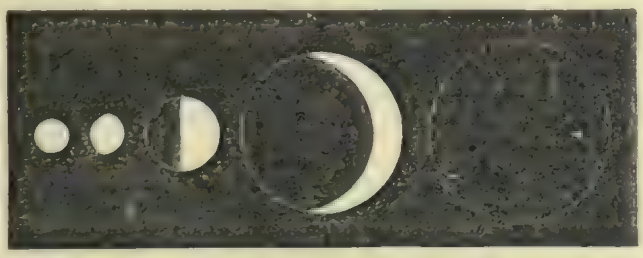


The magnitude of the illuminated part can readily be obtained for any epoch by the following simple construction:—The plane of projection being perpendicular to a line joining the earth and Venus, the boundary of the illuminated hemisphere will be projected into an ellipse more or less eccentric upon it, and the minor axis will be in the same proportion to the major, as the radius is to the cosine of inclination between the two planes. The inclination is the angle at the centre of Venus, formed by lines drawn to the sun and earth.

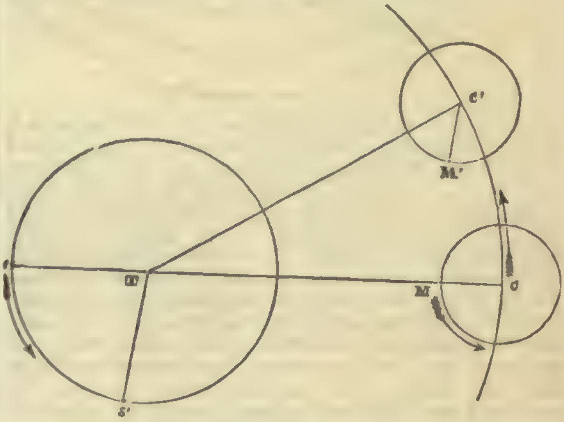
The greatest and least diameters of Venus are about 60″ and 10″, as seen from the earth; and it follows that if r be the distance between the sun and Venus, that the greatest and least distances will be $1 + r$, and $1 - r$ between Venus and the earth. The relative distances of Venus and the earth from the sun may therefore be found, as the extreme distances will be in proportion to the extreme diameters, or

$$1 + r : 1 - r :: 60 : 10, \text{ or } r = \frac{50}{70} = 0{\cdot}72.$$

The distance of Venus from the sun is therefore $\frac{72}{100}$ of that of the earth.

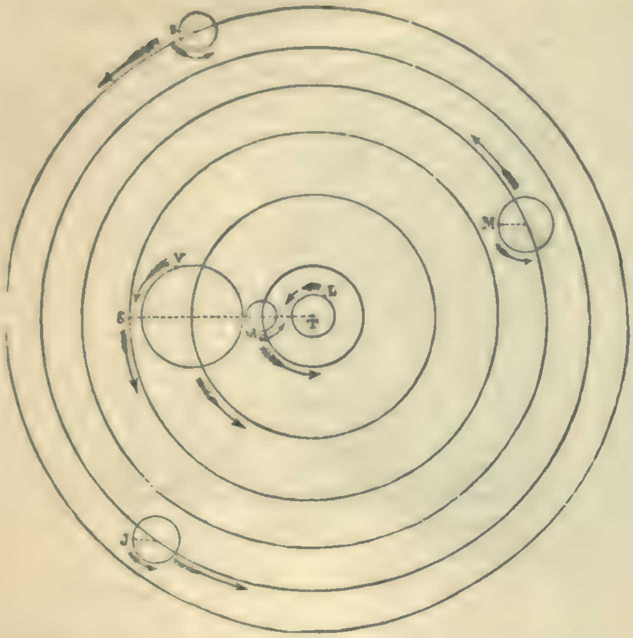
Whilst the planets Mercury and Venus can only be separated by a certain distance from the sun, and only perceived in the mornings and evenings, the other planets which are known at the present time can be seen at all parts of the sky, and pass the meridian at midnight when in opposition. The first are called the inferior, the latter the superior planets The apparent course of the latter in the sky is, however, equally irregular as the former; for the greater part of their revolution they are direct, and for a short time retrograde; their motion is sometimes slow and sometimes fast, and their latitude is equally variable. Mars returns to the same position in the heavens in 687 days, but preserves its direct motion 707 days; whilst its retrograde motion varies between 61 days and 81 days; but the direct motion, combined with the retrograde motion which follows, comprises about 780 days on the average. When in conjunction with the sun, its motion is always direct; but when in opposition, it becomes retrograde, and the arc of the latter may vary between 10° and 19½°. Jupiter, Saturn, Uranus, &c., are in a similar manner retrograde at opposition, and direct at conjunction. Jupiter's direct motion continues for 278 days, and the retrograde from 116½ to 122½ days, the arc of the latter being constantly at about 10°. In a similar manner, the period during which Saturn moves in the order of the signs is 239 days, and the duration of retrogradation may vary between 135½ and 138½ days, the arc described varying between 6° 40′ and 6° 55′. The manner in which these various motions were accounted for by the ancients was the same system of epicycle already described for Venus, but some slight modification was introduced. The planet M (Fig. 58) was supposed to describe an epicycle in such a manner that the radius C M, which joined it to the centre, was parallel to T S at all parts of its orbit, as C′ M′ to T S′, &c. If the different positions of Mars in reference to direct and retrograde motion be examined, it will be found to agree closely with this explanation.

Fig. 58.



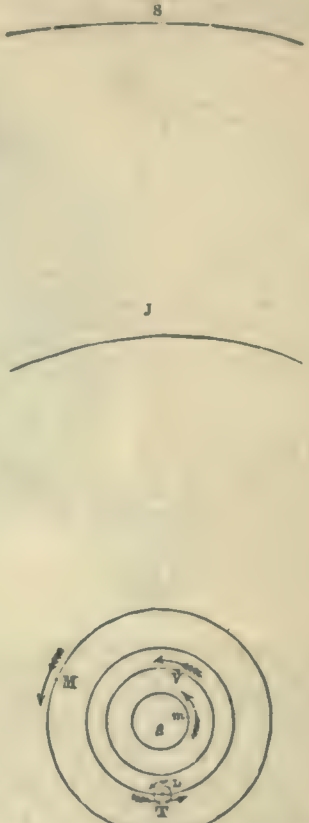
It was by this system of epicycle and deferent, that Ptolemy accounted for the apparent motions of the planets in their paths through the heavens; and he endeavoured to arrange the radii and motions of the epicycles in such a manner that they would agree with the observed appearances. As, however, new inequalities were brought to light, it was found to be impossible to explain them by those single epicycles; and, in most cases, a compound system of "wheel within wheel" had to be constructed, in order to obtain a more approximate similarity between the calculated and observed places. The more simple Ptolemaic system will be perceived from the following diagram (Fig. 59). The earth T is placed at the centre; next to which is the moon, L, which performs a revolution in 29½ days. Next to the moon is placed Mercury, *m*, whose period is 116 days; beyond which Venus, V, is situated, with a period of 584 days. The sun, S, next occurs in the order of distances; then Mars, Jupiter, and Saturn respectively, as their distances from the earth were judged to be greater or lesser, according to the length of time which elapsed between their successive returns to the same point of the heavens. It will be seen that the radii drawn from Mars, Jupiter, and Saturn, to the centres of their respective epicycles, always remain parallel to the line which joins the sun to the earth, and that the centres of the epicycles of Mercury and Venus are always in the same line with the earth and sun. Plato considered that the sun should be placed nearer to the earth than Mercury and Venus, as these two latter planets were never seen upon the disc of the sun; but it does not interfere with any of the foregoing explanations or appearances on which side it is supposed to be placed. At the present time, this could not remain arbitrary, as the phases and variable diameters of the planets would prove. It would have been much more natural for him to have made the planets Venus and Mercury revolve round the sun; but as it was not possible for him to do this in respect to the superior planets, it was likely that he would not adopt it on that account.

Fig 59.



Copernican System.—After the Ptolemaic system had been received among the learned for so many ages, who were educated in the belief of the heavens "with cycle and epicycle scribbled o'er," it was a difficult task which Copernicus had to contend with, when, with all those motions partly accounted for by the Ptolemaic system, he endeavoured to reconcile all, by far more simple machinery. How far the suppositions of former astronomers, however true they were found to be, essentially agreed with those subsequently enunciated by him, is of little consequence, as the idea of placing the sun at the centre of the system is but a small portion of the glory of his discoveries, which consisted in explaining all the apparent motions of the sun and planets, and the variety of seasons, on the most simple grounds. The Egyptians had conjectured that the planets Mercury and Venus might revolve about the sun; and others supposed that the earth was itself in motion around that body; but no further progress was made in this conjecture; and, although it might have arrested the attention of Copernicus, along with many other of the dreams and speculations, it could not afford him any insight to the system he developed.

Fig. 60.

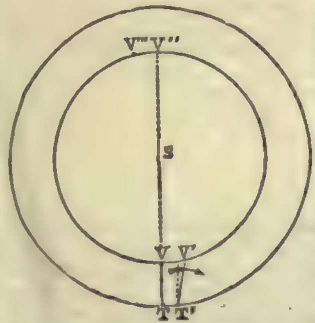


The system of Copernicus is represented in Fig. 60. The sun, S, is here the centre of the great orb, and the planets Mercury, Venus, the Earth, Mars, Jupiter, and Saturn, *m*, V, T, M, J, S, revolve about it in regular order, and all in the same direction. The moon was held, as in the Ptolemaic system, to have a direct motion around the earth, but was now made to accompany it in the same manner as a subsidiary planet; and, in order to explain the rising and setting of bodies, or the diurnal motion, the earth was supposed to have a motion on its axis in twenty-four hours. These, which have already been explained, all tend to confirm it as the true system of the heavens: the phases of Venus and Mercury, and many other proofs hereafter to be given, tended further to place it beyond doubt; while its simplicity and philosophical spirit led to its being generally acknowledged. The motion of the earth was, however, greatly opposed by many of the learned at that time; and, among others, Tycho Brahé endeavoured to form a system, in which all the apparent motions would be explained on the supposition of the immobility of the earth, which he considered was fully apparent from the absence of a sensible annual parallax of the fixed stars, as well as from what he judged to be the improbability, that an immense body, like the earth, would move at so great a rate in space.

The system framed by Tycho, which, at the present time, is preserved only as one of the curiosities of scientific history, is a combination of the Copernican and Ptolemaic systems. The earth is by it supposed to be stationary; the planets revolve about the sun; but the sun, accompanied by all these bodies, revolves around the earth, in exactly a similar manner to the moon. Whilst it explains the various motions of the sun, moon, and planets, it must, at the same time, be regarded as very unphilosophical, and as only fitted for the prejudices of the age.

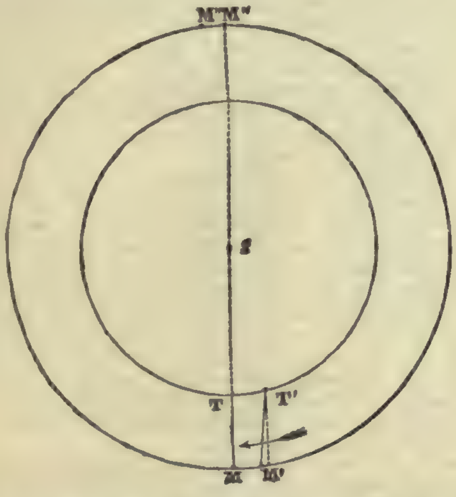
Stations and Retrogradations.—The various progressive and retrograde motions of the planets, explained by the cumbrous machinery of the Ptolemaic system, on the supposition of the earth being stationary, follow naturally from the circular motions of the planets themselves, combined with that of the earth, in the true system of the universe, and, indeed, led the illustrious Copernicus to his great discovery. The two inferior planets, Mercury and Venus, move round the sun in less time than the earth; and if S be the sun (Fig. 61), V, Venus at inferior conjunction, and T the earth, the planet will pass through an arc V V′ of its orbit, in the same time that the earth passes through the smaller arc T T′ of its orbit. The planet, therefore, has appeared to move quicker than the earth in the direction of the arrow, which is in a retrograde direction. If, however, Venus be found at superior conjunction with the sun, and it passes from V″ to V‴ in the same time that the earth moves from T to T′, it will appear to move in a contrary sense to the arrow, and, therefore, direct. Between these two points, the planet will, of course, be animated with different rates of motion, and, at certain times, will appear quite stationary in the heavens. If the earth were fixed at T, the planet would appear stationary at the point of greatest elongation. As it is, however, the planet and earth must be both moving at the same rate, and in the same direction, in order that the former may appear stationary. The duration of the retrograde movement of Venus is only three weeks before and after the time of inferior conjunction.

Fig. 61.



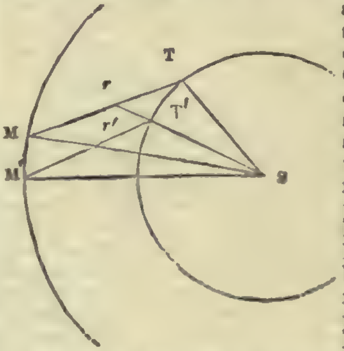
The superior planets bear the same relation to the earth as the latter does to Venus and Mercury; so that when the earth is stationary for any of those planets, the planets appear in the same manner to be stationary to the earth. The progressive and retrograde motions of the superior planets may, therefore, be explained in nearly the same manner. If M be Mars in opposition (Fig. 62), as the earth moves more rapidly in its orbit than the planet, it will pass from T to T′, whilst Mars only moves from M to M′; so that whilst it was first seen in the direction T M, it will afterwards appear in the direction T′ M; or, in other words, the planet will appear to have fallen back in the manner indicated by the arrow, or in retrograde direction. When the planet is in conjunction with the sun, or at M″, whilst it passes from M″ to M‴, the earth will have moved from T to T′ in the contrary direction, so that the planet will appear to move in a direct sense, or according to the order of the signs. Thus all the superior planets are retrograde at the time of opposition, because their motion is slower than that of the earth; and at the time of conjunction they are always direct, because moving in the contrary direction. Between those points the planet will appear as stationary at that part of its orbit, when the earth, passing from T to T′, will be so oblique in regard to M M′ that the lines T M and T′ M′ will be parallel; and as the distances of the stars are immense in comparison with any of the planets, the lines T M and T′ M′ will be directed to the same point of the heavens, and the planet will appear exactly in the same position in respect to any fixed point or star.

Fig. 62.



To Determine the Elongation of a Planet when Stationary is a difficult problem, when the inclinations and ellipticity of the orbit are taken into consideration; but as at the present time it is more a matter of curiosity than interest, the orbit may be considered as circular without much error, and situated in the same place as the ecliptic. Let S (Fig. 63) be the sun, T the earth, and M the position of Mars near its stationary point; then, when the earth passes from T to T′, the planet will move from M to M′, and the lines M′T, M′T′, may be considered as parallel, as before explained. Consequently M′ T′ S—M T S = M r S —M T S = T S T′; and in the same manner S M r — S M T′ = S r' T′— S M′ T′ = M S M′. Whence it follows that the angular variations at T and M are proportional to the angles T S T′ and M S M′; or as the angular velocities are inversely as the periodic times, then S $M^{\frac{3}{2}}$: S $T^{\frac{3}{2}}$; and putting a = S M, and S T = unity, the sines of the angles M and T will be in the ratio of their opposite sides, or as a ; 1, and the contemporary variations of the angles will be as their tangents; or,

Fig. 63.



$$\frac{\text{sin. T}}{\text{cos. S}} : \frac{\text{sin. M}}{\text{cos. M}} :: a^{\frac{3}{2}} : 1,$$

$$\text{whence } \frac{\text{sin. T}}{\sqrt{(1-\text{sin.}^2 \text{T})}} : \frac{\text{sin. M}}{\sqrt{(1-\text{sin.}^2 \text{M})}} :: a^{\frac{3}{2}} : 1$$

$$\text{And sin.}^2 \text{T} = \frac{a^3-a^2}{a^3-1} = \frac{a^2}{a^2+a+1},$$

$$\text{and sin. T} = \frac{a}{\sqrt{(a^2+a+1)}}$$

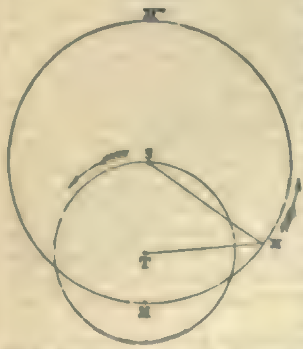
For an inferior planet the M and M′ may represent the place of the earth, and T and T′ the positions of Mercury and Venus. Thus if the mean distances of the earth and Venus be taken at 100,000 and 72,333, then sin. T = 0·48264, the sine of 28° 51′, or at this angle of elongation from the sun, the planet is stationary.

To determine the time when a planet is stationary, the time of conjunction or opposition must be known. If m and n are the daily motions of the earth and planet, then $m-n$, or $n-m$ is the daily variation at the angle T S M, as it is a superior or inferior planet; then,

$$\left.\begin{matrix} m-n \\ n-m \end{matrix}\right\} : \angle \text{TSM} :: 1 \text{ day} ; \frac{\angle \text{TSM}}{m-n}$$

Phases of the Superior Planets.—None of the superior planets show the same succession of phases as Mercury and Venus; and only one of them, Mars, is near enough to the earth to show any appearance of departure from a full disc, the illuminated hemisphere being turned nearly always towards the earth. The point of its orbit, at which Mars will appear most gibbous, will be at M (Fig. 64); at the points M′ and M″, when at opposition and conjunction, its illuminated hemisphere will be wholly turned towards the earth. The diminution of its disc from a complete circle is, however, very sensible; and a small table of its defective illumination is given in the *Nautical Almanac* for every month in the year. It is wholly insensible in Jupiter and Saturn; and to reduce the observation of the limb to the centre, it is only requisite to apply the semi-diameter.

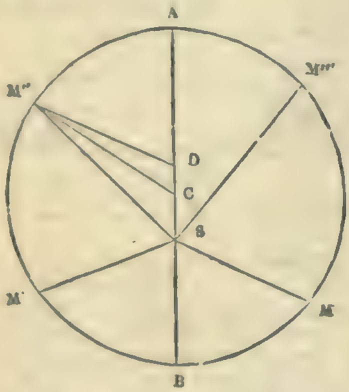
Fig. 64.



Kepler's Laws.—Copernicus, in explaining the apparent motions of the planets in the heavens, confined himself, it will be seen, to circular motion, and all the planets were supposed to revolve round the sun, as a centre in circular orbits, which he considered the most natural of any. It has already, however, been seen that the sun's motion in its orbit is not equable; nor will it be explained by supposing the earth to revolve in a circle, of which the sun is placed eccentrically to the orbit, and that it can only be accounted for by supposing that our planet moves in an ellipse, of which the sun is placed in one of the foci, whilst rejecting all the other cumbrous hypotheses of the Ptolemaic system. In order to explain the various inequalities caused by this elliptic motion, Copernicus was forced to retain the supposition of epicycle and eccentric. The observations of Tycho Brahé, in the hands of the immortal Kepler, however, threw off this last obstruction, and discovered not only the true figure of the orbits of the planets, but likewise other wonderful laws in relation to them.

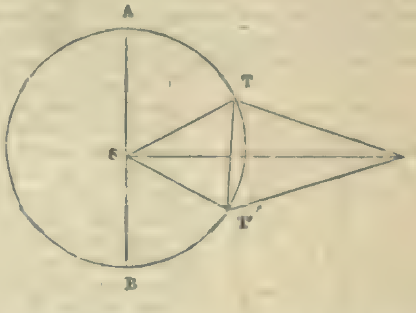
In examining the orbit of Mars, he endeavoured to determine the eccentricity in respect to the sun, supposing it to be a circle, in the following manner:—Supposing that D (Fig. 65) was the point round which the motion of the planet was uniform, C the centre of the circle, and S the position of the sun, M, M′, M″, M‴, being four places of Mars at opposition, he endeavoured to determine the angles A D M″, A S M″, in such a manner that the four points, M, M′, M″, M‴, were situated on the circumference of the circle with the centre C. By assuming the distance S D, and the two angles, A D M″, and A S M″, he calculated, trigonometrically, all the other parts of the figure, in order to determine if the four angles at S made up 360°, and the points, S, C, and D, on the same straight line. After seventy most laborious trials, he at length arrived at one which agreed so well with observation, that out of twelve oppositions, none of them differed more than 1′ 47″ in longitude; and he thought that Tycho's observations might be in error by that, or even a quantity of 2′. When compared with observations of the planet out of opposition, it, however, became apparent that this orbit would not answer, the errors of longitude sometimes amounting to 8′, which he was persuaded could not be due to the observation of Tycho. He was consequently led to doubt if the observations could be satisfied by any circular hypothesis, and further computation served to confirm his doubts.

Fig. 65.



Supposing S to be the sun (Fig. 66), M, Mars, and T and T′, two positions of the earth, when Mars returned to the same part of its orbit, whilst the earth was at T, he determined by observation the angle M T S, and when at T′, the angle M T′ S. The distances T S, T′ S being known, and the angle T S T′, the side T T′, and the angles S T T′ and S T′ T will be known, and consequently the angles M T T′ and M T′ T. The side M T may be found in the triangle M T T′, and finally the side M S in the triangle M T S, or the distance of Mars from the sun. By this method Kepler determined the distance M S, at perihelion and aphelion, the former of which he found to be 138500, and the latter 166780; the mean distance being 152640; that of the earth being supposed to be 100000. In the same manner Kepler determined three other distances of Mars, from observation at different parts of his orbit, which he found to be 166255; 163100; 147750. But by calculating these distances on the supposition that the mean distance was 152640, and the eccentricity 14140, the distances were found to be respectively 166605; 163883; 148539. Whence the errors were found to be 350, 783, and 789. The true distances of Mars from the sun were, therefore, shorter than those calculated; and as the line of apsides and the perihelion and aphelion distance were truly known, it followed that the orbit was of an oval form; and the ellipse being the simplest of all ovals, he found that this was the true curve. By examining Mars at many other parts of its orbit, he found that it agreed closely with this supposition. Thus the first law of Kepler was discovered by infinite labour and sagacity, viz., *that the planets revolve about the sun in elliptic orbits, the sun being situated in one of the foci.*

Fig. 66.



The second great law of Kepler was likewise discovered by him from observation, by comparing the velocity of the planets in their orbit with their distances from the sun, or rather the areas of the sectors, and the arcs included between the radii vectores bounding them. He found that when at their apsides, the velocity of their motion was inversely as their distances from the sun, or that the *planets describe equal areas in equal times* at those points; and he was of opinion that this was true at all parts of the orbit, although he could not prove such to be the case. This, however, has since been proved to be a necessary law, and to follow consequently from the doctrine of universal gravitation.

The third great law of Kepler connects the distances of the planets from the sun, with the time in which they make a complete revolution about that luminary. The further a planet is removed from the sun, the slower he found its motion on comparing it with the absolute motion of the earth. The distance of Saturn from the sun being nine and a-half times that of the earth; consequently if their rates of motion were alike, the period in which Saturn would perform a complete revolution would be nine and a-half years. It is apparent that the periodic times do not, however, increase according as the squares of the distances, as in that case the periodic time of Saturn would be upwards of ninety years, whilst in reality it is about thirty. After numerous and laborious trials, Kepler at length found out the remarkable analogy that *the squares of the numbers representing the periodic times were exactly proportional to the cubes of their mean distances from the sun.* Comparing the earth and Mars, for example, we find that $(365 \cdot 2564)^2 : (686 \cdot 9796)^2 :: 100000^3 : 152369^3$. All of those remarkable laws were afterwards found by Sir Isaac Newton to be necessary consequences of the laws of gravitation; and thus what was deduced by Kepler from observations on one particular planet, and at one particular point of its orbit, was verified, and found to be universally applicable to the whole solar system, and to form a connecting link between all its members.

From the third law of Kepler the mean distance of a planet from the sun can be readily calculated, and with much less difficulty and more accuracy than by direct observations. The periodic time may be found by observing the time of the planet's passage through the nodes, and by observing the intervals between the ascending and descending nodes, and the descending and ascending (which, if the orbit be an ellipse, will not be exactly alike); a value of the eccentricity may be obtained from the greatest difference, the true and mean anomalies, or the equation of the centre. To determine the mean distance—supposing t to be the periodic time of the earth, and r that of the planet, D being the mean distance of the earth, and $\triangle$ that of the planet, we have

$$t^2 : r^2 :: D^3 : \triangle^3, \text{ whence } \triangle = D \times \left(\frac{r}{t}\right)^{\frac{2}{3}}$$

The longitude of the planet in the nodes, or the longitude of the node, may be determined from two heliocentric latitudes and longitudes.

Telescopic Appearance of the Planets.—The planet Mercury appears under all the phases of the moon and Venus, but is seldom visible in our latitudes to the naked eye, as, when most favourable for that purpose, there is always a strong twilight, and it is situated too near the mists of the horizon. At its nearest approach to the earth, or at the time of inferior conjunction, its apparent diameter amounts to 12″, and at its superior conjunction this decreases to 4″; at its mean distance from the earth its apparent diameter is 6″·7. Its diameter is upwards of 3,000 English miles; but observers differ considerably as to its apparent diameter as measured by the micrometer. In such a small body as this, it is almost impossible to perceive anything beyond the mere form of the disc by means of the most perfect and powerful telescopes; and even these are sometimes rendered useless by the scintillation and bad definition of the planet. The only observer who has followed this planet with the requisite attention, is Schroeter, who, by means of powerful reflecting telescopes, was able to perceive that the crescent was not always regular, but that sometimes one horn was blunter than another. This, he naturally considered, was due to their irregularities on the surface of the planet—a mountain, or chain of mountains, situated in the southern hemisphere, intercepting the rays of the sun from proceeding onwards. Schroeter endeavoured to make use of this appearance in determining the time of rotation of the planet. He attentively observed the form of the disc, and the degree of bluntness of the southern horn at one particular time; and the changes which it underwent in a few hours were found to be plainly perceptible. When the planet reappeared on the following day, or any number of days afterwards, the time at which its disc presented the same form was again recorded, and so on for any length of time. Schroeter concluded, from these observations, that the time of rotation of the planet on its axis must be 24h. 5m.; and by taking the extreme times of observation, and dividing the interval by the number of revolutions, he concluded it must have one rotation on its axis in the space of 24h. His assistant, M. Harding, on one occasion, perceived a faint spot on the disc, and, by following it attentively, he arrived at the same conclusion as Schroeter. The latter attempted to arrive at a knowledge of the height of the mountains by measuring the deficient part of the horn; and his observations go to prove that some of those were upwards of twelve miles in altitude, which is three times that of any on the earth, and, compared with the actual size of the two planets, is out of all proportion. During the passage of Mercury over the sun's disc on November 9, 1802, Sir W. Herschel could not perceive any indications of an atmosphere, nor the least departure from the circular shape in its form. Even if it were as much compressed at the poles as the earth, the ellipticity of its outline would not, however, be visible in such a small body. Many observers have perceived a dusky ring of considerable extent surrounding the planet at those times, and others have noticed a bright spot on its disc on the same occasions; but this has been explained on optical grounds. During the passage, Mercury appeared as a very dark spot, and considerably more so than any of the spots which appeared on the sun at the time. The transits of Mercury over the sun's disc, which will occur during the remainder of the present century, are as follows:—

1868, November 4. 1891, May 9.
1870, May 6. 1894, November 10.
1881, November 7.

Those in 1881, November 7, and 1891, May 9, are invisible in the northern parts of Europe.

Venus.—The phases which Mercury undergoes are seen in a much more perceptible manner in those of Venus, from the great size and brilliancy of the planet at those times. The same appearance of the different sharpness of the horns has likewise been noticed; and from these circumstances Schroeter endeavoured to determine the period of rotation in the same manner as pursued by him in Mercury, and apparently with more chance of success. Not only was the southern horn noticed to be very blunt, but a detached point of light was perceived by him, which he concluded to be the summit of a mountain illumined by the setting rays of the sun. By numerous consecutive observations on this planet (continued for many years), Schroeter came to the conclusion that it performed a rotation on its axis in the space of 23h. 20m. 59·04s., or, in round numbers, 23h. 21m. Previous to this time, Cassini had perceived, in the clear sky of Italy, a small bright spot on the surface of the planet; by the observation of which, on several consecutive mornings, in the summer of the year 1667, he arrived at the conclusion that its period of rotation was 23h. 21m. or 22m. A far more extensive series of observations on several *dusky* spots was made during 1726-'27 by Bianchini, at Rome, with excellent telescopes. The period of rotation, as determined by this observer, from those numerous spots, was very different from those of Cassini and Schroeter, amounting to 24h. 8m. It had been suspected, by recent observers, that a mistake arose from the spots so closely resembling each other; and as they were only observed during the evenings, it was impossible to recognise them by their appearance alone. The late De Vico has reobserved all the effects perceived by Bianchini (from which it is certain that they were not of the fleeting, cloudy nature, suspected by Herschel and Schroeter); and from some thousands of micrometrical observations, made both during the day and evening, he concluded that it performs its rotation on its axis in 23h. 21m. 21 9s. The axis of rotation was supposed by Cassini, Schroeter, and Bianchini to be inclined as much as 70° to the pole of the ecliptic. The latter determination of De Vico, although it does not show an inclination so considerable as this would prove to be, shows one nearly twice as great as that of the earth—*viz.*, 53° 11′. Sir W. Herschel, on one or two occasions, perceived spots, but they were too faint and uncertain to give any idea of the time of rotation. He was never, however, able to perceive the bluntness of the southern horn observed by Schroeter; which is the more remarkable, as it has plainly been seen by most observers who have examined it; and Maedler has perceived the quick changes which they undergo. Herschel, however, confirmed other appearances detected by Schroeter—viz., the brightness of the outer or circular edge of the crescent, and the dimness of the elliptical boundary. Herschel considered that the atmosphere of Venus was like our own, refracting and reflecting light; and as we view the circular part more obliquely than the elliptical boundary, and consequently a greater thickness of the atmosphere comes into view, this explanation would be more in accordance with the appearances observed by Schroeter, where the outer bright portion gradually melted into the interior dusky region that was observed by Herschel himself—the outer bright part being distinctly separated from the inner, and appearing as a bright colour.

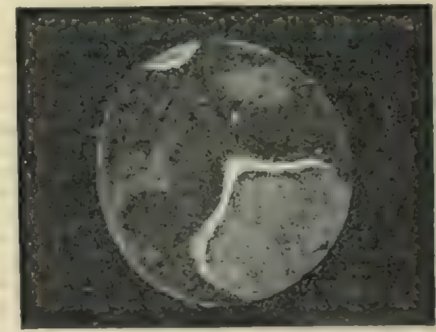
In observing Venus when near its inferior conjunction, Schroeter perceived, in the very slender crescent seen on such occasions, a very faint light stretching beyond the pointed horns, which, as seen in an ordinary telescope, would be the extreme points of the illuminated semicircle; and Herschel confirmed this curious fact. This twilight affords further proof of the atmosphere of Venus, which Schroeter supposed to be of about the same density as that of the earth, having concluded that the horizontal refraction was 30½′. In the inferior conjunction of 1849, Professor Maedler plainly perceived this faint extension of the horns; and he found, for the horizontal refractions, quantities varying from 39 to 48 minutes, but whose most probable value was 43′·7. It is consequently about one-sixth greater than that of the earth's atmosphere. From appearances noted during the transits of Venus across the sun's disc, it would appear probable that the atmosphere is very considerable. The two next transits of Venus will occur on December 8, 1874, and December 6, 1882.

The apparent diameter of Venus, at its mean distance, is 16″·9; but, at the time of inferior conjunction, this increases to 62″, and at the time of superior conjunction, decreases to 9½″. It resembles the earth, in volume and density, more than any other of the planets. Its diameter is 0·985 of that of the earth; its volume 0·957, and its density 0·923. A body which would weigh one pound on the earth, would weigh 0·91 on the surface of Venus. Light and heat would be nearly twice as great at Venus as on the earth. No compression at the poles has been perceived in Venus.

MARS.—This planet shines with a ruddy and dusky light, quite different from any of the other heavenly objects. When at favourable opposition, or when near its perihelion and opposition at the same time, it is a very bright object, and so different from its ordinary appearance, that it has been frequently mistaken for a new star. Its apparent diameter, at its mean distance, is 5″·8; but at the time of opposition this can increase to 23″, and at conjunction decrease to 3″·3. The true diameter of this planet is 0·519 of that of the earth, and consequently its volume is only 0·140 of that of this earth. Its density, compared with that of the earth, is 0.948. A body which would weigh one pound on the earth, would only weigh half a pound in Mars. The light and heat which it receives at its mean distance from the sun is 0·43 of the earth.

When examined with powerful telescopes, many dark spots are perceived on the surface of this planet, which then loses much of that red colour so apparent to the naked eye. These dusky portions, it has been found, are quite fixed and constant in their position, and they have thus been supposed to be the seas and continents of this planet (see Fig. 67). But not only have the land and water become visible on its surface, but likewise its climate; for we perceive, at its north and south poles, bright white patches of light, which are naturally held to be the snows of Mars collected in an immense mass. This conjecture is considerably strengthened by the fact, that when, by the position of the axis of Mars in respect to the sun, those luminous spots are turned towards that luminary, they diminish in size rapidly. In 1781, Sir W. Herschel noticed that the southern white spots were extremely brilliant and extended; this was after a winter of a year's duration on this part of the planet. In 1783 this same spot was very small, but the sun had continued for nearly eight months above the horizon of this part, and melted it away. The existence of an atmosphere to this planet is apparent from other considerations, as, at various times, dark, extraneous, cloudy patches have been noticed, which have obscured the planet and hid the spots on its surface. When the snow melts away, a dusky and densely-clouded atmosphere appears to hang over the planet at those parts.

Fig. 67.



The rotation of the planet has been determined by several observers; and from the fixed nature of the spots observed, and the good definition with which they appear under favourable circumstances, it has been found with considerable accuracy. Cassini, in 1666, determined it to be performed in 24h. 40m.; and, in 1704, Maraldi repeated the observation, and found the period of rotation as 23h. 39m. Herschel made many observations relative to the telescopic appearances of this planet. He determined the sidereal rotation as 24h. 39m. 21·7s., and the synodical at 24h. 38m. 20·3s. The equator of Mars he found was inclined at an angle of 28° 42′ to his orbit, and the node was directed to the constellation Sagittarius. The seasons on this planet would not, therefore, be much different from those on the earth; but, on account of his great eccentricity, their duration is very different.

The compression of Mars at the poles appears to be considerably greater than that of the earth, which, considering his small diameter, and that the rotation and density are nearly similar to those of the earth, is rather remarkable. It does not appear, however, to be so considerable, as determined by Sir W. Herschel, according to whom the ratio of the polar and equatorial axes was as 98 to 103, or as 15 to 16. Schroeter estimates them at 80 to 81. According to M. Arago, it is more than $\frac{1}{30}$. Harding has noticed that the equatorial sides of Mars sometimes appear very bright; and he thinks that the irradiation caused by this circumstance produces discrepancies in the measurement of the equatorial and polar diameters.

THE ASTEROIDS.—The present century opened with the discovery of four small planets—Vesta, Juno, Ceres, and Pallas, situate between Mars and Jupiter; called asteroids (the appearance of stars), because of their stellar aspect under telescopic examination. The order of their discovery, with the names of their discoverers, is as follows:—

Ceres . .	January 1, 1801, by M. Piazzi, of Palermo, in Sicily.
Pallas . .	March 28, 1802, by M. Olbers, of Bremen, in Saxony.
Juno . .	September 2, 1804, by M. Harding, of Lilienthal, in Hanover.
Vesta . .	March 29, 1807, by M. Olbers, of Bremen.

These bodies are sometimes styled planetoids, as more expressive of their character, and extra-zodiacal planets, because their orbits are not confined within the zodiac like those of other planets. They are exclusively telescopic objects, and require the very best instruments to be caught, with the exception of Vesta, which, under favourable circumstances, has been seen by the naked eye.

Vesta, before which, however, there are others in the order of succession in the system, is at the mean distance of 225,000,000 of miles from the sun, and performs a revolution in 1,325 days, somewhat more than three years and a-half.

This planet is much brighter than its compeers, and appears like a star of the fourth or fifth magnitude.

Juno is at the mean distance of 254,000,000 of miles, and accomplishes an orbital revolution in four years and a hundred and twenty-eight days.

Juno has a very eccentric orbit, varying in her distance from the sun to the extent of 130,000,000 of miles. This eccentricity has a remarkable effect upon her motion, for she goes through that half of her orbit which is nearest the sun in nearly half the time that she travels through the remainder. The planet has a reddish colour, and appears like a star of the eighth magnitude.

Ceres, following Leda, revolves round the sun in about four years and two-thirds, at the mean distance of 263,000,000 of miles.

The telescope reveals Ceres as a ruddy star of the eighth magnitude, under circumstances which leave the impression of an extensive atmosphere.

Pallas is at nearly the same mean distance from the sun as Ceres, and has nearly the same period of revolution.

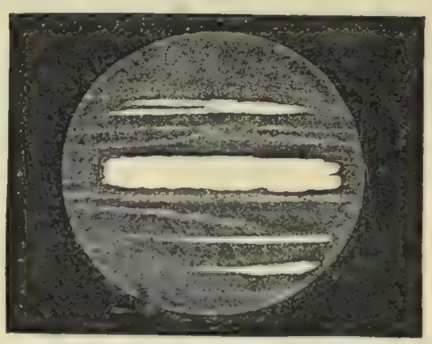
The discovery of the asteroids was not an accidental circumstance, but the result of a search conducted upon the presumption that the harmony of the solar system required the presence of a planetary body between Mars and Jupiter. It was observed, that the distance between the orbits of Mars and the earth is about double that between those of the earth and Venus, or 50,000,000 of miles; whereas, between the orbits of Mars and Jupiter there is the tremendous interval of 340,000,000 of miles, nearly two-and-a-half times the whole distance of the former from the sun. Astronomers, therefore, became thoroughly imbued with the notion that an undiscovered planet existed in the gap; and commencing an active search of the heavens, the asteroids were met with in the vacancy.

On the ground of these peculiarities, it has been surmised that these inferior bodies have diverged from a common node, and therefore originally formed a single large planet, which some mighty convulsion shattered. This bold hypothesis, first started by Olbers, has received a very general sanction. It obtains evidence from the powerful explosive forces in action in the interior of our own globe, to which its volcanic vents act as safety-valves; from the phenomena of meteoric showers, respecting which we have no supposition better than that they are *débris* which the earth encounters in its orbit, fusing upon contact with its atmosphere.

Of the telescopic appearance of this group of planets, now increased to above eighty in number, it would be difficult to say anything. A keen eye can detect, in a good telescope, the difference between one of these asteroids (when not less than the eighth or ninth magnitude) and a star of the same degree of brightness; but this perhaps is the extent of the power of the telescope. Their diameter is very doubtful. Some observers consider them as a few hundred miles in circumference, others as many thousands. The hazy appearance surrounding Ceres, which was noticed by Herschel and Schroeter, whence they surmised that the asteroids were partly of a cometary nature, has not been noticed by modern observers, and may be due to the imperfection of their reflecting telescopes.

JUPITER.—This is one of the finest planetary objects to which the telescope can be directed; and even with a small instrument, its disc, band, and satellites can be plainly seen; and at each opposition there is but little difference in the brightness. Whenever viewed with a telescope, the singular appearance which its disc presents, being always surrounded by two or more dark belts or bands, cannot fail to strike the beholder, and the changes to which they are subject are still more curious. The equatorial portions are generally the brightest, and it is at this part the bands are most distinctly visible. They are generally directed parallel to the equator; but this is not always the case. The polar portions are for the most part darker than any other, but it is only on rare occasions they are equally so; and indeed the whole cloudy covering of the planet is of such a shifting and unsteady character, that it may almost be said to vary from night to night. In addition to the dark bands, there are occasionally to be seen, on the disc of the planets, dark spots of irregular form, which are subject to the same changes as the bands, though they are frequently of long duration, and remain for months together at nearly the same place. A telescopic view of Jupiter, and the appearance of its surface under favourable circumstances, will be seen at Fig. 68.

Fig. 68.



By attending to the motions of those spots, it has been found that Jupiter, like the planets hitherto described, rotates upon its axis; but the length of its day is much shorter than that of the planets in the vicinity of the earth. It is rather difficult to tell the exact duration, for the spots themselves have got a motion on the disc; and Herschel found that the time of rotation appeared to be sometimes 9h. 55m. 40s., at other times 9h. 54m. 53s., from observations of the same spot; whilst, by a different spot, it was sometimes 9h. 51m. 45s., and at other times 9h. 50m. 48s. As the equator of the planet is but very slightly inclined to the plane of its orbit round the sun, it follows that there is but very little variation of the seasons; so that during its long year, the length of the day and night varies very slightly, either being at any latitude about five hours in length.

From the rapid motion which those spots undergo near the equator, Herschel thought it was not improbable that at these portions of the planet's disc there existed currents of air similar to the trade winds, the effect of which would likewise be to form the loose vapours on its surface into the parallel belts. From Herschel's observations on these accidental clouds—as he was of opinion the spots were—he considered that they were occasionally driven along at the rate of ninety-six leagues per hour, a velocity far exceeding that of our most violent hurricanes.

It might be thought, at first sight, that the dark bands represented in Fig. 68, were the clouds, the overcast portion of the planet's disc, and the brighter belts were parts of its surface. Herschel, however, considered that the contrary was the case, and in this he is followed by all modern observers. He supposed that the more brilliant portions were the zones, in which the atmosphere was charged with clouds, the darker parts those on which it was quite clear and serene. The latter allow the solar rays to pass through to the surface of the planet, where the reflection being less powerful than from the clouds, less light was consequently returned.

The disc of Jupiter is considerably flattened at the poles, and bulged out at the equator. This is immediately seen when the eye is directed through a telescope to the planet; and the extent to which it occurs will be seen by the diagram (Fig. 68). The belts appear always parallel to the greater axis.

The four satellites of Jupiter are constantly seen in the same direction, and almost in the same straight line; and the motions of the two inner ones round their primary are very rapid. They almost describe circles around the planet; the orbits of the third and fourth satellites are, however, slightly eccentric. The following table shows their mean distances from the centre of the planet, expressed in the equatorial diameter of Jupiter. The diagram (Fig. 69) represents the relative orbits of the four satellites in exact proportion.

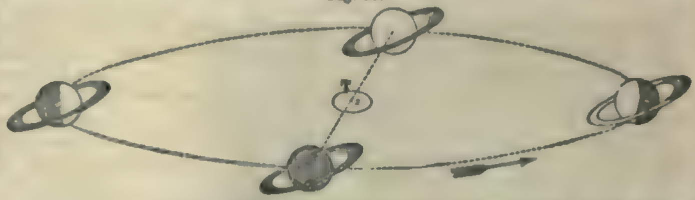
Fig. 69.

	Mean distance.	Period of revolution.
1st satellite . .	3·03 . .	1·77 days.
2nd „ . .	4·81 . .	3·55 „
3rd „ . .	7·68 . .	7·15 „
4th „ . .	13·50 . .	16·69 „

The laws of Kepler are as strictly fulfilled in the passage of the satellites round their primary, as in the case of the motions of the planets round the sun. They are subject to eclipses and occultations, and are sometimes seen projected on the limb in the form of small white spots. As the cone of the shadow is of considerable length, Jupiter being at a great distance from the sun, and the satellites comparatively near it, it follows that, at every revolution, the first three satellites are immersed in the shadow, and it is only the fourth which occasionally escapes. The use made of the eclipses of Jupiter's satellites, is represented by A, of the engraving at the end of Chapter IV., page 940. The centre globe being our earth, two lines are drawn from places on its surface, forming an angle, and meeting at Jupiter; an observer at each place marks the time at which the satellite enters the cone of the shadow. Assuming the time at the nearest line to be ten, and the farthest eight o'clock, the two hours = 30° show the one place to be distant 30° from the other. These observations of the eclipses give the readiest means of determining the longitude of any place at which they are observed. This accurate observation of the moment of disappearance depends partly on the excellence of the telescope used, and partly on the keenness of sight and experience of the observer. When the satellites pass between the sun and Jupiter, they produce solar eclipses; and the shadow of the satellite, in addition to the satellite itself, may be seen slowly traversing the disc of the planet, in a powerful instrument.

Saturn.—The most wonderfully constituted body of the solar system is Saturn. Surrounded by numerous rings, of different form and brilliancy, and eight satellites, with the varied bands which, as in the case of Jupiter, cross the ball of the planet, it forms the most curious of telescopic objects. The ring was first detected by Huygens, by means of his powerful telescopes, and he was likewise the first to perceive the brightest of the satellites. He explained the various appearances at different times by taking into account the obliquity of the ring, and the parallelism which it retains at all parts of its orbit; which is, indeed, similar in all respects to the change of seasons on the earth. This will easily be seen by the diagram (Fig. 70), where S is the sun, and T the earth, and the outer circle the extent of Saturn's orbit. It is plain, that to an observer at T, the upper side of the ring, and the northern pole of Saturn, will be visible, as at Fig. 71. At the opposite part of the orbit of Saturn, the *southern* pole of the planet and the *under* side of the ring is that which will be illuminated by the sun, and seen by an observer on the earth. As Saturn passes from the one to the other of these points, the ring will become gradually less open; and at the points between the two it will only be visible by the illuminated edge, as in Figs. 72 and 73; whilst at other times, the unillumined plane of the ring will be turned to an observer at T, and the outer edges of the ring will not be visible, as at Fig. 70. This disappearance of the ring will take place twice during every revolution of Saturn, and it may be compared to the position of the earth's axis at the times of the equinoxes in respect to the sun, both poles coming into sight, for the ring of Saturn surrounds the equator of the plane.

Fig. 70.



The ring of Saturn is seen, with an instrument of moderate power, to be divided into two parts; but when a stronger telescope is made use of, under favourable circumstances, the outer portion is found to be divided into two likewise; thus making three in all, as seen in the diagram, Fig. 71. Some observers have been able to detect other divisions in the bright ring when it is most open. The most remarkable appearance detected of late years is, however, the dusky ring, situated between the ball and the bright ring, and adjoining the latter. The existence of this curious appendage is now placed beyond doubt, by the testimony of different observers; and it appears to be of a misty, semi-transparent nature, as the ball of the planet can be seen through it. From the observations of the elder Herschel, it would follow that the globe of Saturn revolves on its axis once in 10h. 16m., and that the ring makes a rotation in its plane once in 10h. 32m. 15s. Both move in the direction of the other planetary bodies—viz., from west to east.

Fig. 71.

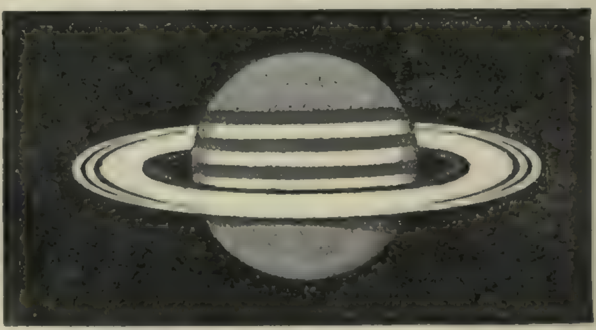


Fig. 72.

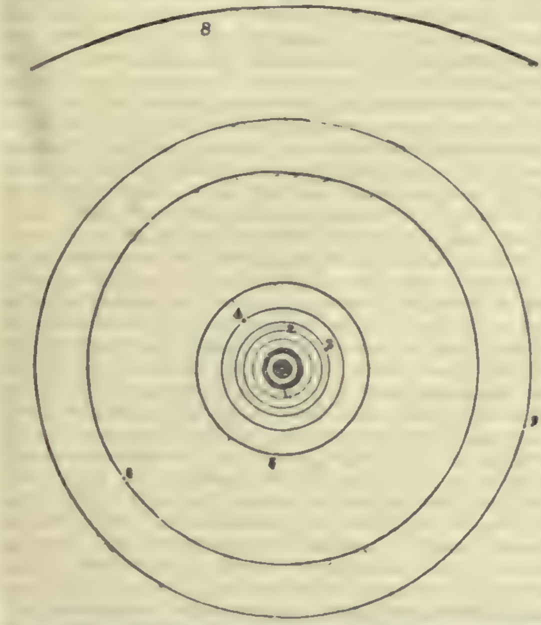
Fig. 73.

The system of satellites which surround Saturn and his ring will be seen from the accompanying diagram (Fig. 74). Of these the brightest is that discovered by Huygens, and resembles a star of the ninth magnitude.

Fig. 74.



It is the sixth in the order of distance, counting from the planet, and its orbit is the best determined of any of them. The third, fourth, fifth, and eighth, discovered by Dominique Cassini, are likewise comparatively bright; but the first and second, discovered by Herschel, and the seventh, discovered by M. Sassel in 1848, are the faintest of telescopic objects, and require both great light and high power to be seen at all. The orbit of the eighth satellite is considerably inclined to the equator of the planet; those of the other seven lie nearly in the same plane as the ring. The mean distances, expressed in equatorial radii of the planet, and the periods of their revolutions, are seen from the following table :—

	Mean distance.	Time of Revolutions.
1st Satellite	3·35	0·94
2nd „	4·30	1·37
3rd „	5·28	1·89
4th „	6·82	2·74
5th „	9·52	4·52
6th „	22·08	15·94
7th „	27·78	22·50
8th „	64·36	79·33

Uranus and Neptune.—Of the telescopic appearance of the two exterior planets, Uranus and Neptune, very little can be said. The former appears in the telescope as a star of the sixth magnitude, of a planetary aspect, and with the appearance of a well-defined disc. The latter is of the same faint blue colour, but the disc is more difficult to be perceived; but, if compared with a neighbouring star of the same magnitude, the difference in their definition is more apparent. Herschel considered that he was able to detect a slight ellipticity in the figure of Uranus, from which it appeared that its axis is very little inclined to the plane of the elliptic, and that consequently the sun is hid for many years from its poles.

The satellite system of Uranus (according to Herschel) is represented in Fig. 75; but only four of those satellites, two of which do not agree in their periods with that set down by Herschel, have been perceived by M. Sassel; and he seems inclined to believe that only that number exists. The second and fourth have frequently been seen, and their orbits are pretty well determined by the observations of Sir J. Herschel and M. Lamont, of Munich. The orbits of those satellites are very greatly inclined to the plane of the elliptic, the angle between the two being nearly 80°. The periods of revolutions and mean distances of the several satellites are seen from the following table :—

Fig. 75.

	Mean Distances.	Time of Revolutions.
1st Satellite	13·12	5·89
2nd „	17·02	8·71
3rd „	19·85	10·96
4th „	22·75	13·46
5th „	45·51	38·07
6th „	91·01	107·69

The only satellite to Neptune which has yet been perceived is that discovered by M. Sassel, and it is represented in Fig. 76, on the same scale as that of the satellite systems of Jupiter, Saturn, and Uranus. It will be seen that it differs but slightly from that of the moon to the earth (Fig. 77) in the dimensions of its orbit. The period of revolution is 5·87 days, and its orbit is inclined at an angle of 35° on the elliptic. It is excessively minute, and has hitherto been seen only by Messrs. Sassel and Bond.

Fig. 76.

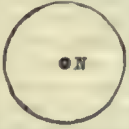


Fig. 77.

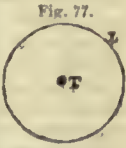

Having thus described the leading phenomena presented in the planetary system, we shall next proceed to consider the constellations, and the fixed stars generally.

CHAPTER VI.

STELLAR ASTRONOMY.

In no other subject to which the mind of man can be directed, is the grandeur so imposing or inexhaustible as in that relating to the distant regions of space known as the sidereal heavens. This is not merely made manifest by the help of gigantic telescopes, and other artificial appliances which the intellect of man has devised; even with the naked eye, we can perceive how multitudinous are the brilliant specks of light so lavishly scattered in every direction, and congregated in such numbers. In the constellations of Orion or Taurus, however, in the Hyades, and, above all, in the great southern Magellanic Clouds, or the wonderful zone of the Milky Way, the stars are so numerous that they cannot be separately seen by unassisted vision. But although the prospect is so magnificent, and apparently so boundless, even in the most simple and universal view, it becomes infinitely more so when the depths of the heavens are sounded by means of the telescope. When we consider, furthermore, that our sun is but one out of those myriads of objects, shining by their own light, and that each is performing in its sphere the same important functions to worlds receiving its radiated heat and light, which the sun performs for us, we become more and more deeply impressed with the boundless extent and variety of celestial objects.

Viewing the heavens with the unassisted eye, we perceive that the stars are of very different degrees of brightness; and, for the purposes of classification, astronomers have chosen to divide those visible to the naked eye into six degrees of lustre; the faintest, or those just seen by persons of ordinary eyesight, being termed stars of the sixth magnitude. This classification, however, gives but a rude approximation to the truth, as it would be difficult to find a number of stars of exactly the same degree of brilliancy, while it would be easy to count twenty or thirty stars of perceptibly different degrees of brightness. With the help of the telescope, ten additional degrees of magnitude—each ranging from the seventh to the sixteenth magnitude—have been described by astronomers. Stars of the seventh magnitude can be perceived by persons of keen eyesight; but those of the fifteenth and sixteenth magnitudes are only visible in the largest telescopes: even in the gigantic reflectors of Herschel, of twenty feet focal length and two feet aperture, they are very faint objects. The satellites of Uranus, and the faintest of Saturn's moons, are estimated to be of this degree of brightness. When the magnitudes of the fixed stars are expressed in this manner, it should be premised that their *apparent* magnitudes are understood by the expression, and not their intrinsic and absolute value. The relative intensity of the light of the stars is still a matter of considerable doubt; they have not yet been determined phonometrically with any exactitude. Sir W. Herschel endeavoured to compare the light of a star of the sixth magnitude with that emitted by Sirius, by covering the speculum of the telescope, when pointed at the latter object, with a disc having a circular opening; and the aperture was so diminished that Sirius appeared as a star of the sixth magnitude as seen with the full opening. When the magnitudes were thus rendered artificially equal, he found that Sirius, viewed with a circular aperture of one inch in diameter, was reduced to the same intensity of light as a star of the sixth magnitude when viewed with the full aperture of eighteen inches; and he concluded from this, that if the light of the latter be supposed equal to unity, that of Sirius would be eighteen times eighteen, or three hundred and twenty-four. As the light of Sirius is fully three times that of a star of the ordinary first-class magnitude, he considered that, in general, the light of a star of the first, in proportion to that of one of the sixth magnitude, was as a hundred to one. If, in the intermediate classes, the brightness is supposed to be inversely as the squares of the distances, we have—

1st magnitude . . the brightness = 100
2nd ,, ,, $\frac{100}{4}$ = 25
3rd ,, ,, $\frac{100}{8}$ = 12
4th ,, ,, $\frac{100}{16}$ = 6

And in the two remaining classes, he concluded, without reference to this law,

5th magnitude . . the brightness = 2
6th ,, ,, = 1

This determination of the relative intensities of the brightness of stars, rests, however, on too narrow a basis to be regarded as more than an approximation; and it is, perhaps, impossible to determine the brightness of one class of magnitudes in fractional parts of that of another. All that astronomical observers have hitherto accomplished on this subject, has been to arrange and catalogue them in the order of brightness, which, for the first six magnitudes, is best done with the naked eye. When they are estimated by means of the telescope, great discrepancies have occurred between different observers; and the fault of our celestial globes and charts has been, that a number of faint telescopic stars are inserted as among those visible to the naked eye; whilst others, equally bright, are completely omitted, their magnitudes being set down at the time their positions were first determined, and, perhaps, wrongly estimated from the state of the atmosphere, position of the moon, or other causes. Those visible to the naked eye in the northern hemisphere have been thoroughly revised by Argelander, who has subdivided the six classes formerly reckoned into sixteen, inserting two new divisions between each of the ancient classes; thus, for instance, between the fourth and fifth magnitudes he finds many stars a little fainter than the fourth, which he terms the 4·5 magnitude; and others a little brighter than the fifth (yet not so bright as those of the 4·5 class), which he denominates the 4·8 magnitude. Sir John Herschel, during his sojourn at the Cape, has instituted a further approximation to correctness in the relative brightness of stars, which will be of the utmost importance to future ages in arriving at a knowledge of the constancy of their brightness. This method of *sequences*, as he terms it, consists in choosing one of the brightest stars in any region of the heavens; secondly, one just inferior to it in lustre; thirdly, one immediately inferior to that of the supposititious *second* magnitude; and so on for twenty or thirty times, until a catalogue is formed for this particular region, with the stars ranged merely in regard to their brightness. On any subsequent opportunity this is repeated with a new set of stars, introducing, however, as many as possible of the former series. By this means, the relative intensity of all such stars as are visible to the naked eye, may be determined with the most rigorous accuracy. A valuable catalogue of such objects, and various proofs of the almost absolute certainty of the process, may be seen in Sir J. Herschel's *Result of Observations*, made at the Cape. The want of such a class of observations has led many astronomers to conjecture that great changes have taken place in the brightness of stars since the time of Bayer, at the commencement of the seventeenth century. Among others, Sir W. Herschel was of opinion, that at least one out of every thirty stars observed and mapped by Bayer, had diminished or increased in brightness in the two centuries which intervened between the end of the sixteenth and commencement of the nineteenth. It was supposed that Bayer's practice was to call the brightest star of *any* constellation by the first letter of the Greek alphabet, α; the next brightest, β; the third, γ; and so on. But Sir W. Herschel found that, instead of the stars in the constellation of Cygnus preserving this order, α, β, γ, δ, ϵ, &c., they now appeared according to the order α, γ, ϵ, β, and δ; in Aquila they had changed to the order α, γ, δ, β, ϵ; in Draco, to γ, β, δ, α; in Leo, to α, γ, β, δ, ϵ; and this change was apparent in numerous other instances. But it would now appear as if the magnitudes of the stars had been carelessly inserted by Bayer, no such change being due to the objects themselves.

Number of Stars.—In our estimation of the number of the fixed stars, it would appear that we are liable to an illusion; and that the generality of individuals suppose a much greater number to be visible than is found to be the case. The attention is probably directed to the richest portions of the heavens; and it may not unfrequently happen that the judgment is biased by what we have heard or read, rather than by what we see. In this case, it may naturally be supposed that other parts of the surface of the heavens are equally crowded with stars, though they are not so bright or apparent as the part which we really have in view; and it may thus be erroneously concluded that thousands of stars are visible at the same moment, which only exist in imagination. When we come to test this conclusion by absolute proof, it is found to be vastly out of proportion to these impressions. The *whole number* of stars visible to the naked eye in the central parts of Europe—viz., those included in the whole surface of the heavens north of the equator, and including a zone of 30° of south declination, comprising nearly eight-tenths of the whole sky—only amounts to 3,256; so that scarcely more than 2,000 stars can be visible to the naked eye, and above the horizon, at the same moment.

An attempt has been made to ascertain the number of stars of different magnitudes by supposing them to be situated at equal distances from one another, and that they are all of the same absolute magnitude, but appearing differently in consequence of their various distances. There being fourteen stars of the first magnitude, we are to suppose them arranged at equal distances upon a sphere: supposing the stars of the second magnitude to be twice the distance of those of the first, the surface over which they would be scattered would be four times that of the former; and if placed at the same distances from each other, it would take fifty-six stars to cover this area. The sphere of stars of the third magnitude would be nine times the area of that of the first, and it would consequently take one hundred and twenty-six stars to fill that surface; and in a similar manner there would be two hundred and twenty-four on the fourth, three hundred and fifty on the fifth, and so on. This law, however, does not correspond with the observed number of stars of different magnitudes, there being seventy stars of the second, and three hundred of the third—a much greater number than would exist on this supposition. Various other hypotheses have been formed to show the probable number of stars, of different magnitudes, visible on a given portion of the sky; but the data are too inconclusive and vague to secure any degree of accuracy in the result.

It would be difficult to determine the number of stars fainter than those of the sixth magnitude. The catalogue of Lalande (called the *Histoiré Céleste*, and published at the latter part of the last century) contains the places of about 50,000 stars visible from the north pole to 25° of south declination, and including those from the first to the ninth magnitude. The zone included between 15° of north, and 15° of south declination, contains, according to the more modern observations of the illustrious Bessel, 31,085 stars, viz.:—

664	bright stars from the 1st to the 6th magnitude.
2,500	of the 7th magnitude.
8,183	,, 8th ,,
19,738	,, 9th ,,

Stars fainter than those of the ninth magnitude increase in number in a wonderful degree; and Struve concludes that the number of stars visible in the twenty-feet telescope of Herschel, in the same zone of 30° in breadth observed by Bessel, amounts to the enormous number of 5,819,000, by far the greater number of which are situated at those parts where the Milky Way intersects the equator at six and eighteen hours of right ascension. Nor will this appear overrated, when we recollect that on one occasion Herschel perceived that nearly 120,000 stars passed through the field of view of his telescope (15′ in diameter) in a quarter of an hour. The stars observed by Herschel appear to have been situated in the following order in respect to their right ascension; and their density as they approach the Milky Way becomes immediately apparent.

From 1h. to 5h.	of right	ascension	391,700	stars.
,, 5h. ,, 9h.	,,	,,	1,984,200	,,
,, 9h. ,, 13h.	,,	,,	235,400	,,
,, 13h. ,, 17h.	,,	,,	387,000	,,
,, 17h. ,, 21h.	,,	,,	2,365,100	,,
,, 21h. ,, 1h.	,,	,,	455,600	,,
			5,819,000	

Thus, in respect to the distribution of stars of different magnitudes in the heavens, we perceive that the least crowded regions lie between nine and seventeen hours, and twenty-one, and five hours of right ascension. If we take the most brilliant stars, or those of the three first magnitudes only into account, we find them to be pretty evenly distributed over the surface of the heavens; but those of the fourth, fifth, and sixth magnitudes are congregated more densely as they approach the Milky Way. At every succeeding class this becomes more and more apparent, and the faintest stars are most thickly crowded in and near this zone. This would naturally lead us to imagine that there is some connection between the great galactic circle and the other portions of the heavens, and that they might form one great system.

The Milky Way extends completely round the heavens, and makes almost a great circle upon its surface. The breadth is very unequal: in some regions it is not more than 5°; in other parts it is two or three times that breadth. For one-third of its extent, viz., between Serpentarius and Antinous, it is divided into two branches; but for this distance of about 120°, the dark opening is of no great breadth. The resolvability of the Milky Way into distinct individual stars, which was proved immediately on the invention of the telescope, had been long previously conjectured by some of the ancient philosophers; whilst the absurd suppositions of others on its structure—if they were ever supposed worthy of examination—were dissipated by the same discovery. No other theory was started, however, to supply their place, or to explain this phenomenon, until about the middle of the eighteenth century, when Thomas Wright, of Durham, author of the *Clavis Cœlestis*, endeavoured, in his *Theory of the Universe*, to account for this appearance, by supposing that the stars were ranged in regular *strata*, and not dispersed fortuitously throughout space, as was previously supposed. By this arrangement, although the individual stars composing the stratum were at vast distances apart, yet, supposing our sun and its attendant satellites to be situated near the centre of this plane, we should witness such an appearance as the Milky Way presents. In the direction of the plane, the stars would be seen in such vast numbers, although the more distant ones would be so extremely small, that it would appear as a white and confused zone of light projected on the dark space surrounding us on every side. This idea received further development from the celebrated Immanuel Kant, who considered that it was rendered probable, from the arrangement of the three or four thousand stars visible to the naked eye, the greater number of which were contained in a zone within a short distance of the galactic circle. Lambert was likewise of opinion, that all the stars visible through the best telescopes lay in one vast stratum; but he considered that many of the clusters in the Milky Way were separate and individual systems, but nevertheless subsidiary members of one great system. Those immense clusters, each containing millions of stars, were connected and held together by the same power which predominates in inferior and more simple systems; and Lambert went so far as to imagine that the separate clusters performed revolutions round a great central body, in the same manner as our planet and satellite move round their primary.

The attention of Sir W. Herschel was particularly directed to the subject of the construction of the heavens; and his labours in this field must be regarded as among the most important of his works. In order to bring the theories started by his predecessors to a test, and to obtain an idea of the form and dimensions of the stellar universe, Herschel had recourse to a long and laborious method, which he properly termed "gauging the heavens." This was done by directing a powerful telescope (the twenty-foot reflector) to different parts of the sky, and counting the number of stars in each field of view. In order to insure greater accuracy, he counted the number of stars in ten contiguous fields, and took the average to express the comparative riches or poverty of the district. In some portions of the sky, only three or four stars of all magnitudes were seen *per* field for a considerable distance round; whilst at other times the field was crowded with many hundreds; and those latter portions were always found in or near the Milky Way. By combining the numerous "gauges" which he made, he endeavoured to determine the various depths (from the different degrees of obliquity in which the stars were viewed) of the Milky Way. Supposing the individuals composing it to be placed at pretty equal distances, he concluded the whole visible heavens to be of a lenticular form, and not a stratum of stars inclosed by plane surfaces. The proportion the thickness bears to the diameter of this *lens*, he considered was as one to five and a half; and he further concluded that the sun was removed but little from the centre of the group. Subsequently, when the motion of various double stars, consequent on their physical connection, was discovered by Herschel, his ideas were considerably modified; he now imagined that he perceived evidences of this physical connection in the great groups of the Milky Way, and that this "clustering power," as he termed it, tended to break it up into fragments.

Nor was this the only evidence of the motion of the stars, for many of them are endowed with an indubitable motion, as was apparent from their positions, compared with neighbouring stars; and, whether due to their own proper motion, or to that of the sun, it must be considered as an absolute proof of the instability of these bodies in space. Among the stars which are thus known to have considerable proper motion, we may mention μ Cassiopeiæ, which has a proper motion of 5″·82 annually, in right ascension, and 1″·55 in north polar distance. The star 61 Cygnus, whose distance has been determined with some exactness, is one of those which has a large proper motion; and it was in consequence of this circumstance that it was chosen by Bessel for the determination of the annual parallax. The proper motion, in right ascension, amounts to 5″·39, and in north polar distance, to 3″·30. In 40 Eridani, the proper motion, in right ascension, amounts to 2″·16, and in north polar distance, to 3″·45. The star 1830 of Groombridge's, which was considered to show the greatest amount of parallax, is one of those whose proper motion is most considerable, amounting to 5″·16 in right ascension, and 5″·70 in north polar distance. Other stars, in almost every constellation, have large proper motions; but the quantities are, as yet, somewhat doubtful, as it is only by the comparison of accurate modern observations with ancient authorities nearly as accurate, that these small quantities can be deduced; and it is but since the times of Bradley that the places of the objects can be depended upon.

Enough, however, has been effected to show the reality of their movement, and its direction. If this were due to the motion of the stars themselves, it might be supposed that they would move in all directions, north or south, east or west; and though this is found to be the case with some, yet, with far the greater number, the direction taken is much more regular. It has hence been conjectured that it is the sun itself which is in motion—the consequence of which would be, that those stars which are situated in that part of the sky which we approach, would appear to be separated more and more, as the angular distance would increase the nearer we approach to the objects. In that part of the celestial regions which we are leaving behind us, the stars would appear to be falling closer together, for the contrary reason. Although this supposition, explaining the proper motions of stars as being due to the simple effect of parallax, was made by both Mayer and Lambert, it was Sir W. Herschel who first attempted to show the direction of the solar motion, which he concluded was towards a point in the constellation of Hercules, whose position, in 1783, was at 257° of right ascension, and 65° of north polar distance. An attempt has since been made, by Argelander, to solve this problem; and that celebrated astronomer arrives nearly at the same result as Herschel, finding, from an examination of the proper motions of three hundred and ninety stars, that the part of the heavens towards which the sun is progressing, is probably situated at 260° 51′ of right ascension, and 58° 43′ of north polar distance.

Nature and Different Species of Stars.—It would, of course, be impossible to form any idea of the stars; but analogy would lead us to imagine that the heat and light which they emit, is in every respect similar to that of our own sun; and some photometrical experiments, which have been made on the latter object, seem to show that, if it were transported to the same distances as some of the stars whose distances are pretty well known, its apparent magnitude would not be so great as that of many which we see around us. From the distance and orbit of 61 Cygni, Bessel was able to arrive at a rough idea of the masses of those stars, which he found were not greatly under that of the sun; and if this were the case with a star of that magnitude, we may conclude that the brighter objects are considerably larger than our luminary. It is certain that reflected light could not reach us from such immense distances; and we must conclude that, like our own sun, they are self-luminous, although we know nothing of the agency at work to produce those extraordinary effects. It would be rash to imagine that, like it, they are all accompanied by a *cortége* of planets; for some of the latter bodies in the solar system have numerous satellites; our own earth but one; and others none whatever. But it would be equally rash to conclude that their heat and light expend themselves in the unprofitable and dark voids of the celestial spaces; and, in addition to the slight evidence which analogy affords, we have the further proofs of their being the centres of great systems from the remarkable phenomena of *double* and *changeable* stars, the latter of which, in a different point of view, may be regarded as evidence of their rotation on their axes, similar to that of our own sun.

Double Stars.—A few of those curious objects have been known ever since the invention of the telescope; and in a cursory examination of some of the brighter stars, as Castor, ζ Ursæ Minoris, α Herculis, γ Virginis, an observer could not help detecting the strange appearance of two stars close together, and almost blending their light, forming, apparently, but one star to the naked eye. In the middle of the seventeeth century further importance was attached to those curious objects, and several were closely examined, although without any result, for the purpose of determining their annual parallax, for which they offered peculiar advantages. It was then supposed that all these objects were fortuitously or optically double; one of the components—most probably the fainter—being situated at a much greater distance from us than the brighter, but both appearing in the same direction. It was for this purpose, likewise, that Sir W. Herschel commenced, in 1779, to apply his powerful telescopes and delicate micrometers to the task of recording their distances and positions in respect to one another. But in looking for one thing, as sometimes happens, another was found; and it became apparent that the components were not only at the same distance from the sun, but that the smaller body, in many instances, described an orbit round the larger star. It should not be forgotten, however, and it tends much to the credit of philosophical conjecture, that this remarkable law was previously surmised by the celebrated Lambert, who considered it possible that there were some groups in which the stars might make complete revolutions round a common centre of gravity in a comparatively short period of time. Mitchell conjectured the same law to apply to the more simple case of a double star; and, in 1784, he supposes that in a few years this question would be resolved by the stars whose positions and distances were ascertained by Herschel. The great discovery was first published by Herschel in 1803, who had then perceived a decided change in the positions and distances of several stars, as ξ Ursæ Majoris, Castor, ξ Bootis, 70 Ophiuchi, ξ Cancri, ξ Herculis, &c., &c. The labours of the elder Herschel were resumed in more modern times by his celebrated son, who, in conjunction with Sir J. South, reobserved all the stars in the northern hemisphere, and who has also observed independently, and measured all those discovered by him in the southern hemisphere. Struve, at Dorpat and St. Petersburg, also made the subject his constant care since the year 1814, and, with the powerful means at his command, has observed and reobserved their positions with the greatest possible accuracy; indeed, the publication of his great work, *Mensuræ Micrometricæ Stellarum Duplicium*, forms an era in this subject. This work contains observations of three thousand one hundred and twelve double stars, nearly three-fourths of which were discovered by himself.

The combinations of the components of double stars take every variety, both in regard to magnitude, distance, and, we might add, colour. The components of Castor are each of the third magnitude, and of the same ashy white colour, and close together, as are likewise those of γ Arietis in the same respects; whilst the stars Polaris, α in Herculis, γ in Delphini, are very different either in magnitude, distance, or colour. Out of the 3,000 stars detected by Struve, only a small portion have as yet been determined to be physically connected, or to form *binary systems*, as it has been termed; and the numbers whose orbits and periods have been even approximately determined, are fewer still. The time which has elapsed since the discovery, has been too inconsiderable to determine their true periods; some of which, as that of ε Lyræ, cannot be less than 2,000 years; and in others, as in 61 Cygni, or γ Leonis, the period is several hundred years. Among those whose orbits have been determined with more or less exactness, we may mention the following:—

Name of the Star.	Mean Distance of the Components	Eccentricity.	Period.	Direction of Motion.
			Years.	
ξ Herculis . .	1·25	0·448	36·4	Retrograde.
η Ursæ Minoris	2·44	0·431	61·6	Retrograde.
η Cor. Bor. .	1·20	0·404	67·3	Direct.
70 Ophiuchi .	4·97	0·444	92·3	Retrograde.
σ Coronæ . .	2·93	0·577	199·9	Direct.
γ Virginis . .	5·35	0·868	157·6	Retrograde.
Castor . . .	7·01	0·797	230·3	Retrograde.

M. Savary was the first who determined that the revolution of a star round its primary was performed in the same manner as that of a planet round the sun, and conformably to the laws of gravitation; and the same principles applied to other stars, have shown that the first two laws of Kepler, founded upon the motions of Mars, extend to the revolution of sun around sun. In determining the orbit, supposing it to be an ellipse, the same elements have to be deduced as in a planetary orbit, with the exception that the period of revolution and the semi-major axis are here two distinct elements, and that the latter is not expressed in linear measure, but in an arc of a great circle. From four observations of the angles of position and the distances, knowing the intervals and taking the Keplerian laws as the basis of calculation, the seven elements of period, semi-major axis, eccentricity, nodes, inclination, position of peri-astre, and epoch of the peri-astre, can be determined. In the first place, however, the *apparent* ellipse must be determined before the *real* one can be arrived at. The first is that which the star describes around its primary on the plane of the sky; but the *orbit* may be inclined at any angle to this plane; and it is only when the plane of the orbit is perpendicular to the line of sight, that the true and apparent ellipses are identical. The projection of the circular or elliptic orbit on the plane of the heavens, remains always an ellipse, but the projection of the focus and the major and minor axes will take different positions; and the proportions of the latter to one another, and consequently the eccentricity of the orbit, will be different. In consequence of this difference between the apparent and true orbits, we sometimes see the one star projected on, or occulted by, its companion. Such was the case with γ Virginis, which, from 1834 to 1836, appeared as a well-defined single star. The plane of the orbit of the companion of 44 Bootis, is almost perpendicular to the plane of the heavens; and between 1802 and 1819 an *almost central occultation* must have taken place. The companion of ξ Herculis has twice undergone an eclipse, in consequence of the great inclination of the orbit to the plane of vision—once in 1802, and again in 1831.

In addition to the double stars, triple and quadruple stars are sometimes met with; and if the fortuitous combination of the former is so little to be expected, that of the latter is much less probable. Among the more conspicuous of the triple stars, that of ξ Cancri holds the most prominent position; the three stars, all of which are nearly of the same magnitude, being physically connected. The close double star has made upwards of a revolution in a retrograde direction since 1782, and the more distant one has moved fifty degrees in the same time. In the list of quadruple stars, the most remarkable is that of ε and 5 Lyræ, which can be detected as *double*, by a keen eye, without the aid of any instrument; but each of which, when examined with a power of two hundred, appear as a double star, the four components being nearly of the same magnitude and colour. This system likewise seems to be physically connected. Among the multiple stars, that of θ Orionis, situated in the centre of the great nebula, is the most apparent, six stars being situated in a circle of twenty-three seconds in diameter.

The colours seen in the components of many double stars have been described by some as an optical illusion, on the ground that it is always the complementary colours which are thus perceived, as, in a similar manner, a white spot seen on a red ground will appear green. It is, however, impossible to view the components of α Herculis or γ Andromeda, without coming to the conclusion that they have a proper colour of their own, and that the blue and orange so vividly distinct is something more than the effect of contrast. In those stars which show high and brilliant colours, the larger star is always of a golden orange, the smaller greenish or bluish. In many, however, the components are of the same colour; but it seldom happens that the two colours are of a bluish or greenish tint; most frequently they are white and yellow.

TEMPORARY AND VARIABLE STARS.—Those stars which vary in brilliancy from time to time, and others which suddenly seem to start into existence and disappear as precipitately as they have become visible, must be regarded as the most curious objects in the heavens, for they prove manifestations of life and motion in the immeasurably distant regions of space; they form one of the subjects, too, in which even a lover of science who does not possess a telescope, can, by simple observation of the relative brightness of the various stars, recorded on favourable opportunities, confer considerable benefit on this branch of sidereal astronomy. A telescope, in this case, is of little value; the field of view is much too small to include the stars proper for comparison with the object whose light is suspected to be variable, and the photometer has hitherto been of very little service. The most accurate results which have been obtained as yet, are due to observations with the naked eye, compared with stars in its vicinity; by this means the interval between the faintest and brightest phases have been found with far more accuracy than would be imagined.

There are numerous instances of the appearances of temporary stars recorded in the Chinese annals; but the two most remarkable of those phenomena have occurred in comparatively modern times, and have been minutely described by the two great contemporaries, Tycho Brahé and Kepler. The first appeared in the year 1572, in the constellation of Cassiopeiæ. On the 11th of November of that year, when seen for the first time by Tycho, it surpassed in brilliancy both Sirius and Jupiter, the most lustrous objects in the heavens. In the following month it had diminished slightly in brightness, but was still equal to Jupiter. At the beginning of 1573, it was inferior to that planet in brightness; and by the end of March it was not brighter than the principal star in Taurus, although still a good first magnitude. It continued gradually to decrease until the end of the year, but remained visible to the naked eye until March, 1574. If its period of increase were equal to its period of decrease, it must have been visible to the naked eye for nearly three years, as it was not noticed until it had attained its maximum brightness. For a description of the second instance we are indebted to Kepler. The star was perceived suddenly in the constellation Serpentarius, on October 10th, 1604, and appears to have been nearly as brilliant as it was formerly, though not so favourably situated for observation. It remained visible to the naked eye (the telescope had not yet been invented) for upwards of a year. A star of the third magnitude also appeared suddenly in the constellation of Cygnus, in the year 1670, which soon afterwards disappeared; it again made its appearance, and again disappeared, and has not been since seen. It underwent several changes during the two years in which it was observed.

VARIABLE PERIODIC STARS.—The appearance of temporary stars is as rare as the phenomena observed are extraordinary. Of a similar nature, however, are the class of periodic variable stars, whose changes of lustre are equally as decided and curious as those of the objects just mentioned; being more known, however, they excite less attention. The most singular of those objects is that of *ο* Ceti, whose variability was first discovered by Holwarda in 1639, and which has a period of about eleven months. Although at its maximum brightness it reaches to the second magnitude, it does not appear to have been at all noticed by any observer previous to 1596; but this may be partly in consequence of the length of its period; for if the maximum intensity of light fall in the summer months, it may sometimes remain invisible for three or four years together. During the winter months this is not the case; but, as happened in February and December, 1847, two maxima may take place during the same year. There is another circumstance which has been noticed, and which may tend to explain the silence of ancient authors and observers. This is, that the star does not always reach the same brilliancy, sometimes approaching in brightness to stars of the first or second magnitudes at this period, whilst at other times it is not brighter than the fourth maximum. It has generally been supposed that it disappears entirely at the period of its minimum, even in the best telescopes; but this is not always the case, for at these times it has occasionally been observed to be not fainter than stars of the eleventh magnitude. What its variations of light may be when visible only in the telescope is not very well known, as it has not been closely observed at those times; but it is certain that, whilst visible to the naked eye, its fluctuations of brightness are very remarkable. It is visible to the naked eye, on an average, for about two months previous to the period of its maximum brightness; but the period of its diminution of brightness is generally longer than that of its increase; and it has been visible for three months after its maximum, the average duration being, however, only seventy days. It sometimes, but rarely, happens that the interval which elapses between its coming into sight and its maximum brightness, is greater than the time between its maximum and disappearance. Some attempt has been made to reduce the fluctuations which its light undergoes, and to establish a law; but the changes are too abrupt and irregular to be dealt with in this manner, or to be foretold with any accuracy.

Among the other stars of long period, which are visible to the naked eye for a length of time, and then entirely disappear from sight, is χ in the neck of Cygnus, which is almost as remarkable as the preceding. Its light varies between the fifth and eleventh magnitude. Its maximum brightness, like that of *ο* Ceti, is, however, very variable; sometimes it reaches to the fourth magnitude, and at other times its maximum is not more than the 6·7 magnitude, when it is quite invisible to the naked eye. The variability of the light of this star was discovered by Gottfried Kirch; but the period was first found by Maraldi. The interval between its successive *maxima* and *minima*, as well as its intensity of light, at those times, has since been discovered to be very irregular. On some occasions it has been visible to unassisted vision for a period of nearly three months; but the average duration, according to Argelander, is only fifty-two days, being twenty days of an increase, and thirty-two of a decrease. The longest period which has yet been recorded in the class of variable stars, occurs with the star 30 Hydræ, whose period has been determined, by Maraldi, at four hundred and ninety-four days; this period, however, is very irregular. At its maximum brightness it sometimes arrives at the fourth magnitude, and at other times only at the fifth, and thence it decreases in brilliancy until its entire disappearance. The star 19 Leonis is another with a very long period, the interval between its successive maxima being three hundred and eleven days. This period, however, is also somewhat irregular, and the changes in its brilliancy occasionally abrupt. At its maximum brilliancy, it is equal to stars of the fifth magnitude, and is invisible at its minimum. These are the only four stars hitherto discovered which are invisible to the naked eye at their *maxima*, and vanish out of sight at their *minima*, except to the most powerful telescopes. There are a few other stars discovered by Harding, Schwerd, and Hind, with periods which appear to be upwards of a year; but, even at their maxima, these stars are only visible in a telescope, and not the slightest trace of them can be perceived in the best instruments at the epoch of their minima.

In others of the variable stars, the period is much shorter; but the change of light is not so considerable. The most remarkable of those is the star β Persei, in which the interval between two successive maxima is only 2d. 20h. 48m. 58s., and is otherwise a very curious object, from the abrupt and variable changes of brilliancy which it exhibits. For the greater portion of its period it remains at nearly its maximum brightness, or of the two-and-a-half magnitude. In about four hours it suddenly decreases to the fourth magnitude, which is its minimum brightness; and in a like period of four hours it regains its former brightness. There are other but less remarkable changes in its light; it is one of the best determined of the variable class. The majority of the periodic stars shine with a reddish light, but this shows no sign of colour, being of a pure white. The star δ Cephei has a period of 5d. 8h. 37m., with a variation of brilliancy from the third to the fifth magnitude. This star exhibits a great regularity in its successive changes of brilliancy, which have been determined with considerable exactness; but the periods of increase and decrease are very dissimilar, as it takes 3d. 18h. to pass from its maximum to its minimum, and only 1d. 15h. to return from its minimum to its maximum, according to the careful observations of Argelander. During eight hours of its decrease, it scarcely, if at all, changes; and for a whole day its diminution of brightness is scarcely perceptible. Two other variable stars of short period—η Aquilæ and β Lyræ—are known at present. Both of those stars change from the three-and-a-half to the four-and-a-half magnitude; the former in 7·18 days, the latter in 12·8 days. The period of the latter star was first stated to be 6d. 9h. by Goodricke, who detected its variation, which he at first supposed to be from the third to the fifth magnitude. In this determination of the length of the period he was partly correct; for it is one of those stars in which there is a smaller variation of brilliancy within the larger period. After its minimum brilliancy, it passes in 3d. 5h. to its first maximum, and then in 3d. 3h. to its second minimum. In 3d. 2h. it again rises to its second maximum, and after this, in 3d. 12h., to its former minimum. The whole period, according to Argelander, is 12d. 21h. 46m. 40s., in which period it performs all the preceding changes. This celebrated astronomer is of opinion that the period is diminishing, and that it is now some hours shorter than when first discovered. Even from recent observations it is apparent that there is a decrease in the period.

Previous to the time of Sir W. Herschel, it was only stars of very long and very short periods which were known to be variable. The period of α Herculis, discovered by him, proved, however, that there was an intermediate class. This star is remarkable for its deep orange-red colour, which is very strikingly contrasted with its small dark blue companion. The period was considered by Herschel to be 63 days; but the change of lustre is very slight, being only from the third to the third and a-half magnitude. There is still some doubt respecting its period, some observers considering that it is as much as ninety-five days; but from seven years' observations, it would appear that a period of sixty-six days would agree better with the changes which it undergoes. The observer Heis, who has particularly attended to this species of phenomena, is of opinion that the variations of light are best satisfied by a period of 184·9 days with two maxima and two minima. Since the time of Herschel, various other stars of *medium* period have been added to that of α Herculis, nearly all of which are, like it, stars of considerable magnitude. Thus α Cassiopeiæ changes from the second to the third magnitude in 79d. 3h., according to Biot; but it is very difficult to determine the exact period, the change of brilliancy being very slight, and apparently irregular. This is equally the case with α Orionis, which, at its minimum, becomes slightly inferior to stars of the first magnitude; and, according to Argelander, the period of increase of light takes place in ninety-one days and a-half, whilst it continues to decrease in brilliancy during a hundred and four days and a-half. The period of α Hydræ is supposed by some to be performed in fifty-five days; but the change of brightness being minute, as in other instances, it is somewhat doubtful. Sir J. Herschel considers it to be performed in twenty-nine or thirty days. The star commonly designated as *l* in the constellation of *Sobieski's Shield*, is remarkable for the great variation of its magnitude, particularly at its minimum, when it varies between the sixth and ninth magnitudes. At its maximum it only varies between the fifth and sixth. Among those of shorter period may be counted that of β Pegasi, which varies between the second and second and a-half magnitude, but whose period is not more than forty days. At the present time, we thus know stars of almost every period from 2d. 20h. to 406 days. There are ten whose period varies between 1 and 100 days; two between 100 and 200; eight from 300 to 400; and two above 400. It is curious that there are none at present known whose period is between 200 and 300 days.

Herschel considered that, by introducing a medium period between those which were very long and very short, he proved the rotation of those objects on an axis, by which means such portions of their surfaces as were dark and obscure came into sight at stated times, and hence their apparent faintness. To the astronomers of the 16th and 17th centuries—by many of whom the rotation of the earth was doubted, and that of the other planets unknown—this method of accounting for it would have appeared strange. It was attempted, however, by Bouilland to explain the changes seen in ο Ceti on this principle: the larger portion of the surface of this star was, he considered, non-luminous, which rendered it invisible for the greater part of its period. Another supposition in respect to those changes was, that they were due to the interposition of opaque bodies, by which their light was more or less eclipsed at regular intervals. Maupertius considered that, among the many stars which were scattered through space, there were some whose figure was not regularly spherical, but greatly flattened at the polar regions, and that the variations of light were due to the thin edges of those being sometimes presented to view, and at other times the large surface of the flattened disc. There is yet no *experimentum crucis* known, by which it can be said whether either or any of these hypotheses are correct.

CLUSTERS AND NEBULÆ.—The most striking and magnificent objects which the sidereal heavens present to view, are the clusters and nebulæ, where, in a telescopic field of view of a few minutes in diameter, we may perceive a crowd of stars collected together, and forming a small patch of light, the individuals composing which must be some thousands in number. To those wherein the stars are plainly seen, have been given the name of *clusters;* but in others, which are unresolved, the terms *nebulæ* and *unresolved nebulosities* have been applied. The nebulæ and clusters which are at present known are of every degree of resolvability; and though some of those which are generally called nebulæ have been resolved by the most powerful instruments, yet there are others which have baffled all the attempts of opticians to separate them into individuals. They are of every conceivable shape and size, from the regular and minute form of the planetary nebula of a few seconds in diameter, to the amorphous and large surface of the great nebula in Orion. Numerous clusters of stars are visible to the naked eye, as the Pleiades, Hyades, the Presepe of Cancer, and that in the sword-handle of Perseus; and in the southern hemisphere we have the Magellanic Clouds, which cover a space of some degrees square.

The most magnificent of the clusters which have been resolved by the telescope, is that in the constellation of Hercules (Fig. 78), which can be detected on a clear night by the naked eye, and which, in the telescope, presents one of the finest instances of dense isolated clustering in the whole of the heavens. The stars are from the tenth to the fifteenth magnitudes, and are so densely congregated round the centre, that it presents the appearance of a blaze of light in that part. The stars are pretty evenly distributed in the interior, but are rather irregular at the edges, where they are formed into curvilinear branches. Sir J. Herschel is of opinion that there are many thousands of them, some of which are the faintest the telescope can show. This object is only seven or eight minutes in diameter, and, with the telescope which Sir J. Herschel employed, no appearance of a nucleus was perceptible; although, with a smaller one, such might be suspected.

Fig. 78.

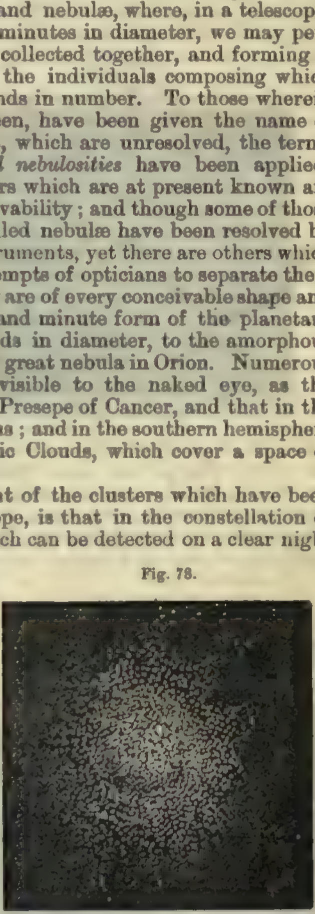

Fig. 79.

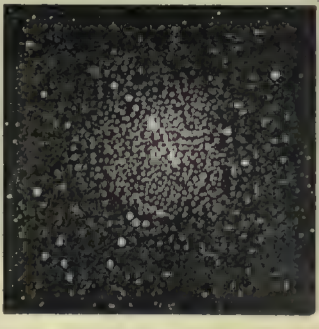

The fifth object in Messier's catalogue, is another very rich but compressed specimen of a globular cluster (right ascension 15h. 10m., north polar distance 87° 16′). In this case (Fig. 79) the density towards the centre is not gradual; the condensation commences suddenly, and the blaze of light into which it is formed, appears projected on a loose irregular ground of stars. The neighbourhood of this cluster is very poor in stars—a circumstance which Sir W. Herschel remarked in other cases, and which he conceived might be due to the stars being attracted to one point, and formed into one cluster. The cluster situated at 21h. 25m. right ascension, and 91° 34′ of north polar distance, appears like an unresolved nebula with instruments of even considerable power; and it is only when viewed with the great light of high magnifying powers, that faint traces of stars become apparent on its surface, and it takes a very fine sky and splendid instrument to show the grains of star-dust faintly visible (Fig. 80). *Finer* specimens of clusters, or rather nebulæ, *merely* resolved, are seen at Figs. 81 and 82. We may consider the latter of those as the extreme boundary of the clustering species; after which the nebulæ, properly so called, begin. As the reflecting telescope advances more and more to perfection, we may, however, expect that many objects will be won from the mysterious domain of nebulæ, and placed to the account of the more explicable clusters.

Fig. 80.

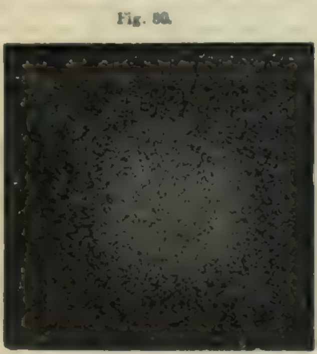

Fig. 81.

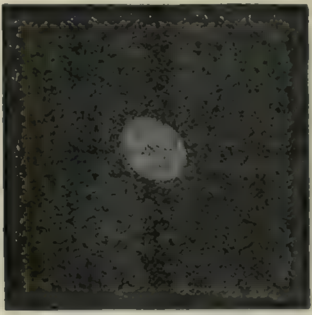

Fig 82.

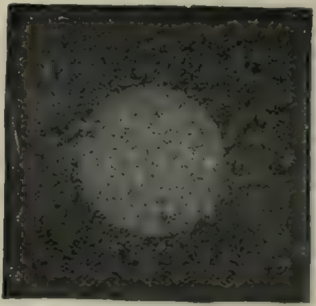
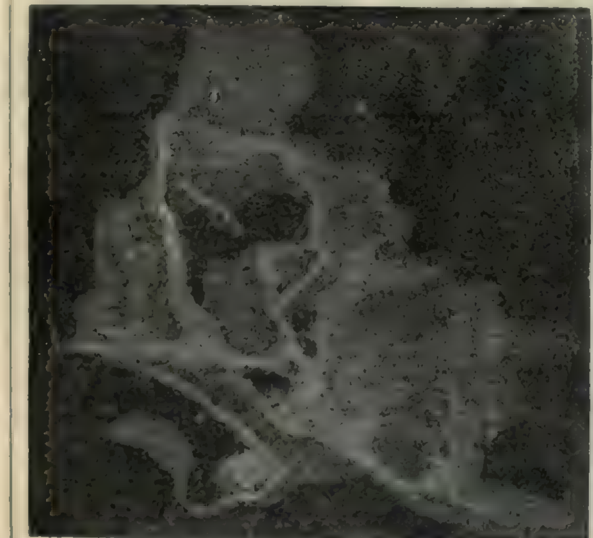


The large clusters have some approach to regularity, but this can scarcely be said of the more considerable nebulæ. The finest of those is, without doubt, that of Orion (Fig. 83), which, for its various inequalities of light and shade, its great extent, and the capricious irregularities in the form of the great promontories which jut out from the main body, constitute it one of the most noble and mysterious of those objects. When examined with the two-feet mirror of Sir John Herschel, and some powerful refracting telescopes, it shows some signs of resolvability, being likened to a curdling mass, or the breaking up of a mackerel sky. But with the great mirror of Lord Rosse, the resolution is complete, and it is broken up into distinct stars, which are scattered in irregular masses through its body. The great nebula of Andromeda (Fig. 84), is another very conspicuous object of the class, and may even be perceived with the naked eye on a fine dark night. It is a long, elliptical ray of light, rather broader towards the centre, and was compared, by its discoverer, Simon Marius, to the flame of a lamp shining through a piece of horn. With the improved optical means of more modern times, equally as with the imperfect telescope of Marius, no signs of resolvability have as yet appeared, though the surface has been noticed to be dotted over with innumerable stars, which are not, however, supposed to be directly connected with it, being merely casual groups interposed between it and the sun.

Fig. 83.



The majority of the nebulæ hitherto discovered—now upwards of 3,000 in number—are mostly of a regular form, being either circular or more or less elliptic, like that of Andromeda. But there are many others; and

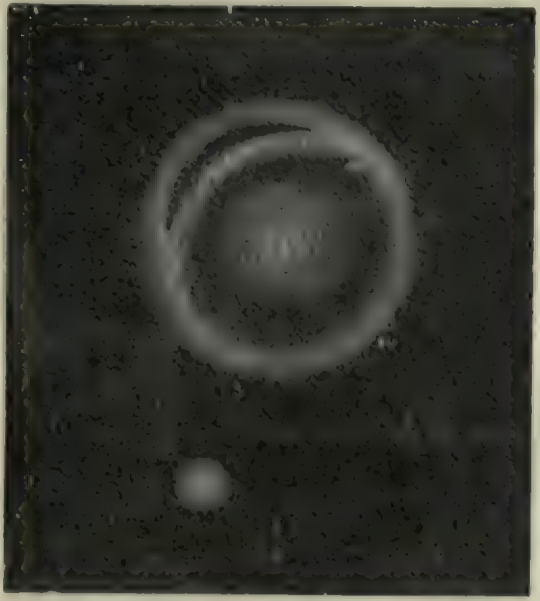
among those that are the largest and brightest, in which the nebulous matter is dispersed very capriciously, no regularity is perceptible. Among the latter, the one situated at 272° 42′ of right ascension, and 106° 15′ of north polar distance (Fig. 85), may be instanced, being of the shape of the large Greek omega, and having no symptoms of resolvability apparent. Among the more regular forms, are those termed *annular* nebulæ and *cometary* nebulæ. The fine object situated at 200° 40′ of right ascension, and 41° 56′ of north polar distance (Fig. 86), and which is large enough to be perceived as a faint patch of light in a small telescope, is among the finest instances of the former kind. In this, the surrounding ring appeared, in the two-foot mirror of Sir J. Herschel, to be divided into two branches; but in the great telescope of Lord Rosse, the whole takes the form of a spiral, and many curious details become visible. The smaller nebula below (here represented as quite detached), appears to be connected with the larger body by a projecting branch of the spiral. A fine specimen of the more simple and rare form of annular nebulæ, is that situated in the constellation of Lyra (Fig. 87), at 281° 49′ of right ascension, and 57° 11′ of north polar distance. It is not quite dark in the centre. The form of cometary nebulæ will be seen by Fig. 88, the pointed end being attached apparently to a star, which appears like a stellar nucleus. (See folio plates).

Fig. 86.



In the circular, or globular form of nebulæ, the degrees of condensation of the nebulous matter towards their centre is very different. In Fig. 89, right ascension 18° 45′, north polar distance 77° 59′, there is little or no condensation towards the middle. In Fig. 90, right ascension 202° 13′, north polar distance 107° 1′, the condensation is considerably more marked. In Fig. 91, right ascension 59° 43′, north polar distance 47° 57′, the central bright portion is of smaller extent than in the last instance, but better defined and much more lustrous. In Fig 92, right ascension 59° 39′, north polar distance 59° 40′, the central portion becomes almost stellar, appearing like a well-defined star surrounded by a halo. The different degrees of condensation recognisable in these objects, led Herschel to imagine that the nebulous matter, in the course of ages, underwent considerable changes, and that, having condensed gradually, the nebulæ finally ended by becoming stars. These changes were so slow that they had not yet been perceived; but it was visible, by comparing them together, that such probably was the case. In some cases, the central star or stars was distinctly visible. Such an object is perceived at right ascension 295° 5′, north polar distance 39° 54′ (Fig. 93), in which the nebula is evenly distributed round the star. At right ascension 271° 45′, north polar distance 109° 56′ (Fig. 94), an elliptic nebula is visible, with a small star situated in each of the foci of the ellipse; and at Fig. 95, right ascension 80° 3′, north polar distance 55° 54′, a triangle of stars is congregated at the centre of a small nebula. In those which were equally bright throughout the whole disc, Herschel conjectured that the star was not visible on account of its faintness, or from being surrounded by a dense nebulosity. Such an one is situated at right ascension 166° 12′, north polar distance 34° 4′ (Fig. 96).

Among the most curious forms of the nebulæ, those which are double take a prominent place. In those, both the components are sometimes of equal magnitude (Fig. 97), right ascension 174° 20′, north polar distance 55° 31′; and similar in every respect, or like those at Fig. 98, right ascension 140° 38′, north polar distance 67° 45′; and Fig. 99, right ascension 183° 18′, north polar distance 84° 35′, where they are of irregular size and condensation. In all these examples the components are joined together by the surrounding nebulosity; but in some cases the two nebulæ are quite distinct, as in Fig. 100, right ascension 342° 48′, north polar distance 103° 43′. In such cases, Herschel imagined he perceived symptoms of the gradual formation of a *double* star, the nebulous matter of which they are formed, condensing towards two centres of attraction. It will appear from this that the *nebulæ*, properly so called, according to Herschel's ideas, were far from being such important objects as the clusters, the latter being great agglomerations of stars, the nebulæ only the material of a single, or, at most, a double star. But it would be hazardous to say that any particular nebula was irresolvable. The gigantic telescope of Lord Rosse has shown that many such, hitherto deemed of this nature, consist of innumerable stars, very different from the single individual star which Herschel thought it was probable it would finally become.

The suppositions relative to this nebulous substance, which Herschel thought to be so plentifully scattered through space, and the changes which he surmised that it underwent in the course of time, led the celebrated astronomer Laplace to form a similar hypothesis on the formation of the solar system, and the progressive development of the bodies of which it is composed, from one single and primitive mass of nebulous matter. He supposed that the sun was originally included among the nebulæ, which extended as far as the most distant planet, and was endowed with a rotary motion round the centre; and that, in the course of ages, this gaseous substance became more condensed towards the centre, leaving the exterior portions in the form of immense rings, still preserving their revolving motion, precisely similar to the ring of Saturn as at present existing. From many different causes it was impossible for those rings to exist in that form, and they finally broke up into globular masses forming the different planets. By this means he explains the revolution and rotation of the planetary bodies in one direction, as well as of their satellites, formation of comets, &c. Even the zodiacal light was fully explained on this hypothesis. The nebulous matter, as he conjectured, was not quite condensed, but still surrounded the sun in a very diffused state, and by the rotation of that body on its axis, took a lenticular form, as was observed to be the case with many of the nebulæ already discovered. Thus the great nebula of Andromeda is of this elliptic form; and different degrees of ellipticity will be seen from the figures in the folio plate (Figs. 101, 102, and 103), which are some of those actually observed by Sir J. Herschel.

CHAPTER VII.

ON THE CONSTELLATIONS AND FIXED STARS

OUR present arrangement of the constellations into groups or clusters, representing figures of men and animals, dates from the most remote antiquity. Aratus, a Cilician of Eudoxus, B.C. 370, a contemporary of Plato, enumerates forty-five as being then in use, all of which still remain on our celestial globes. In the majority of instances, however, there is no similarity between these configurations, and the figures to which they are supposed to bear some resemblance. Of the fixed stars, in both hemispheres, nearly 5,000 are visible to the naked eye, the greater number of which have been catalogued by Argelander, in his standard work, the *Manometria Nova*. They are divided into classes of magnitude, the *first* consisting of stars pre-eminently bright, and which amount in our latitude to about 14; the second magnitude consisting of about 50; the third of 140; the fourth of about 320; the fifth of 809; and the sixth of 2,000 (roughly speaking). Objects of a magnitude greater in class, but apparently less in size than the sixth, are only seen by the help of telescopes, and are reckoned on to the thirteenth or fourteenth magnitude.

Bayer appears to have been the first astronomer who systematically arranged the stars of each constellation in the order of magnitude. In his catalogue, of which the epoch is 1603, he classed the brightest stars in each constellation according to the first letter of the Greek alphabet; the second by the second letter, and so on; afterwards using for smaller objects the *Roman letters*. Of the first magnitude in these latitudes, we have nine north of the equator, and five south, viz. :—

North.

Vega, or α Lyræ
Capella, or α Aurigæ
Arcturus, or α Bootis.
Aldebaran, or α Tauri.
Betelgeux, or α Orionis.
Regulus, or α Leonis.
Altair, or α Aquilæ.
Deneb, or α Cygni.
Procyon, or α Canis Minoris

South.

Sirius, or α Canis Majoris.
Rigêl, or β Orionis.
Spica, or α Virginis.
Antares, or α Scorpio.
Fomalhaut, or α Piscis Australis.

Bayer's arrangement has since been used by astronomers.

The most ancient catalogues we possess of the fixed stars are those of Ptolemy, Ulugh Beigh, Tycho, and Hevelius, all of which have been formed from observations by the naked eye. The catalogue of Ptolemy is based on the observations of Hipparchus, and amounts to upwards of 1,000, which are arranged in the order of longitude and latitude. That of Ulugh Beigh contains 1,019 stars for the epoch of 1437, observed at Samarcand in Persia, north latitude 39° 52′. The epoch of Tycho's catalogue is for the end of the sixteenth century, and contains 777 stars, reduced and edited by his pupil, Kepler. The catalogue of Hevelius contains 1,564 positions of stars for the epoch 1660. All the preceding works have been re-edited by Mr. Baily, to whom this branch of astronomy is much indebted, and are given in the thirteenth volume of the *Memoirs of the Royal Astronomical Society*.

Since the application of the telescope to astronomical observations, we have the catalogues of Halley and La Caille, observed in the southern hemisphere; and those of Flamsteed, Bradley, and Mayer, observed in the European observatories. The work of Flamsteed is the basis of that of Bradley, and they both, in common, contain nearly the same stars, but, in the latter case, observed with more improved instruments. The numbers in the catalogues of Flamsteed, Bradley, and Mayer, are respectively 3,400, 3,222, and 998 stars.

At the commencement of the present century we possessed the catalogues of Groombridge, Piazzi, and Lalande, of which the first consists of circumpolar stars numbering upwards of 4,000; the second of 7,646 stars; and the last of 50,000 stars.

In modern times we have the catalogues of Busham and Taylor, observed at New South Wales and Madras respectively; the Greenwich catalogues of Pond and Airey; and the continental catalogues of Remiker, Bessel, and Argelander. The British Association have also published a standard catalogue of 8,377 stars.

THE ZODIACAL CONSTELLATIONS are twelve in number, all of which occur in the list prepared by Aratus.

I. *Aries* has two very conspicuous stars in the head of the Ram, about 4° apart. They are the nautical star, α Arietis, called *Hamal* by the Arabs, of the second magnitude, and *Sheratan*, of the third.

II. *Taurus*, one of the finest of zodiacal Asterisms, is just rising in the east when Aries is 27° above the horizon. It includes Aldiebaran, a star of the first magnitude, forming with Hyades the letter Y in the face of the Bull; on the left shoulder is the well-known cluster of the Pleaides.

III. *Gemini* has two principal stars, Castor of the first, and Pollux of the second magnitudes, about 4½° apart, in the neighbourhood of Propus, a small star of the fifth magnitude. In this constellation Sir John Herschel found Uranus, and it served for many years to guide astronomers to that planet.

IV. *Cancer* has no very conspicuous star. Two of the fourth magnitude, the Aselli (the Asses) of the Romans, and Presepe (the Manger). A nebulous cluster, at the distance of 2°, distinguishes this constellation.

V. *Leo*, a brilliant constellation, has Regulus, of the first magnitude, in the breast of the Lion, and Denebola, of the second magnitude, in the tail, about 25° apart.

VI. *Virgo* has Spica Virginis, a star of the fourth magnitude, in the Wheat-ear, remarkable for its solitary splendour, having only one other star, of the fourth magnitude, near it. This star is called *Al-simak-al-a-zal* (the Defenceless) by the Arabs.

VII. *Libra* has four subordinate but bright stars, which form a quadrilateral figure. Two in the northern and two in the southern scale, 7° and 6° apart.

VIII. *Scorpio* is a beautiful collection of stars, among which Antares (in the heart) is of the first magnitude, and is distinguished by a remarkably red appearance.

IX. *Sagittarius* has five stars of the third and fourth magnitudes, which form a figure resembling a straight-handled dipper, familiarly called the milk-dipper, because situated in the Milky Way.

X. *Capricornus* has only stars of the third and fourth magnitudes. The sun was formerly in this constellation, when at mid-winter he attained his greatest southern declination; hence it was called the southern gate of the sun, as Cancer was the northern. Now, owing to the precession of the equinoxes, the sun does not reach the constellation till the middle of January.

XI. *Aquarius* is recognisable by four stars of the fourth magnitude, so placed as distinctly to form the letter Y, which is visible about the urn of the Water-bearer.

XII. *Pisces* is a loose assemblage of small stars, not readily traced, occupying a large triangular space in the heavens. This is the first constellation in the order of the zodiac, opening the astronomical year, and preceding our vernal equinox.

In naming and figuring these zodiacal groups, the ancients are supposed to have been guided by the rural occupations coincident with the sun's appearance in particular parts of the heavens, or by other analogous phenomena presented to them. Thus, the RAM, the BULL, and the TWINS (originally two goats), relate to

NEBULÆ.—(See page 957).

animals most useful to them during the spring months. The Crab, walking backwards, is typical of the retreat of the sun from the northern tropics. The fierce Lion represents the intensity of summer heat. The Virgin, holding an ear of corn, refers to a girl gleaning. The Balance indicates the equality of day and night at the equinox; while the Scorpion indicates disease as the incident of the season.

Northern Constellations.—The constellations of the northern hemisphere are thirty-five in number, of which twenty were enumerated by Aratus. Of these Ursa Major is the most conspicuous, consisting of three principal stars, forming a triangle in the tail, and four forming a quadrangle on the body of the Bear. Commencing at the tip of the tail we have Benetnasch, a star of the second magnitude; Mizar, 7° distant west; and Alioth, about 4½° further off; 5½° from Alioth, at the root of the tail, is Megrez; south of it Phad, forming the shorter side of a quadrangle. On the opposite side, 8° west of Phad, is Merak; and 5° north, towards the pole, is Dubhe, the brightest star of the constellation.

Dubhe and Merak are called the pointers, because a line drawn through them, and carried about 29° in the same direction, passes almost over Polaris (the pole star), which is close to the north polar point in the heavens.

Ursa Minor, while it is inferior to the preceding in point of size, is more important from its position indicating the north polar point, and its utility as a guide in finding the latitude of places. Like Ursa Major, it consists of seven stars; three of the third magnitude, and four of the fourth. Polaris is the important star of this group. It is between the second and third magnitudes. It is at the tip of the tail of Ursa Minor, and appears stationary, the rest of the constellations appearing to swing round it in the diurnal revolution of the sphere. All the stars appear to revolve round the pole of the ecliptic, owing to the real revolution of the pole of the earth round it; a revolution, however, which requires the long cycle of 26,000 years, or thereabouts, for its performance.

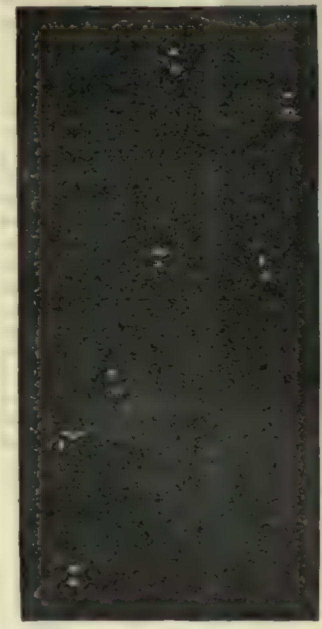
Bootes appears among the stellar groups to be driving on Ursa Major; hence it has sometimes been called the Bear Driver. Bootes has Arcturus, a star of the first magnitude, long supposed by the ancients to be the nearest star to the earth.

Southern Constellations.—The constellations of the southern hemisphere are forty-six in number; the most important being Orion, which constitutes the richest part of the visible heavens; and when on the meridian (which occurs about 10 p.m., January 1), presents the most magnificent view the starry heavens offer. Orion is visible, in its turn, to all the habitable world, the equinoctial passing through the centre of it. Four principal stars, in the form of a long square or parallelogram, form its outline. Betelgeux, of the first magnitude, is 7½° of Bellatrix of the second; Saiph of the third magnitude, and Rigel of the first, 8½° west of Saiph, and 15° of Bellatrix. Canis Major, on the south-east of Orion, contains one star of the first magnitude, four of the second, and two of the third; the former, Sirius, glowing in our winter hemisphere with a lustre unequalled by any other star in the firmament. Canis Minor, east of Orion, and north of Canis Major, has two brilliant stars—Procyon, of the first magnitude, and Gomelza, of the second, about 4° to the south-east. A knowledge of these constellations will enable us to find our path in the heavens.

When a few particular stars have been recognised, they will serve as starting-points; and by alignments, or imaginary lines, drawn from them, other stars and groups of stars will be found, and thus a general knowledge of celestial objects acquired. For this purpose, one of the most conspicuous objects is the constellation of Ursa Major, which never sets in our latitudes.

The seven stars (shown in Fig. 104) are nearly all of the same magnitude; a line drawn through β and α, and produced to a distance equal to that from α to η, will point out Polaris, an object of the 2·3 magnitude. This star will be easily distinguished, since it is not surrounded by any others of the same magnitude. The alignment to find the Pole Star is as follows:—A line drawn from δ Ursæ Majoris, or from ε Ursæ Majoris through Polaris, and produced the same distance as that from δ Ursæ Majoris to Polaris, will reach the centre of Cassiopeia. This remarkable group of stars, which, in these latitudes, is circumpolar, is always on the opposite side of Polaris to Ursa Major. When Ursa Major is near the zenith, Cassiopeia is near the horizon, and when Ursa Major is on the eastern side, Cassiopeia is on the western side of Polaris.

Fig. 104.



The right lines, which direct α and β Ursæ Majoris to Polaris, when produced in the same direction, will point out the square of Pegasus, formed of four stars of the second magnitude, the two upper of this group being respectively α Pegasi and α Andromedæ. A line drawn from the two latter will pass through β and γ Andromedæ, and finally to α Persei, a star of the second magnitude nearer the pole. It will be remarked that α Persei may also be found by drawing a line from δ, α, Ursæ Majoris through Polaris.

On the opposite sides of α Persei are situated γ and δ Persei, stars of the fourth and third magnitudes respectively; a line drawn from α, δ Ursæ Majoris will meet (after passing through α Persei) Algol, or β Persei, a star remarkable for its variability. Producing the arcs γ and δ Persei, we find α Arietis. Below these, the conspicuous cluster of stars, the Pleiades, are situated. If we join Polaris and α Arietes, and produce it beyond the latter, we shall meet with the constellation Orion, which is well known by its remarkable brilliancy and form. Of this group of stars, δ, ε, and ζ are called the belt; the remaining four stars of this group form an irregular quadrilateral, α and γ being the upper, and β and δ being the lower sides. α and β Orionis are of the first magnitude, and all the others are of the second magnitude.

The most remarkable object in the heavens, Sirius, or α Canis Majoris, is pointed out by producing the belt of Orion on the eastern side. By producing it on the western side, we meet with Aldebaran, or α Tauri, a star of the first magnitude. But this star may also be found by producing the line which connects α Ursæ Majoris and α Arietis (Fig. 105).

The diagonal of the square [α, β, γ, δ, Ursæ Majoris], or δ, β, being produced sufficiently, will pass through the bright stars of the constellation Gemini, α and β, or Castor and Pollux. A short distance in the same line, between Castor and Sirius, we find Procyon, or α Canis Minoris. This may also be found by prolonging the line passing through Polaris and

Fig. 105.

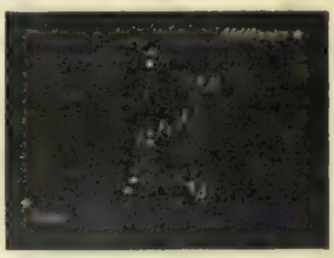


Fig. 106.

Pollux. The diagonal α and γ of the same square, produced on the side of γ above the pole, will point out α, or Spica Virginis, which forms an equilateral triangle with Arcturus and β Leonis.

The line connecting α and β Ursæ Majoris, which points so accurately to the Pole Star, when produced, will pass through the constellation Leo. This constellation consists of four principal stars, in the form of a trapezium. The most brilliant is of the first magnitude; all the others are of the second magnitude. ζ and η Ursæ Majoris, being connected in a line, will meet with a remarkable star of the first magnitude, Arcturus, or α Bootis.

At the side of Arcturus, and in the direction of the stars β, δ, ϵ, ζ of Ursæ Majoris, we find the constellation of Corona Borealis, composed of many stars, arranged in a semicircle, and of which the most brilliant is of the second magnitude.

Vega, or α Lyræ, is a conspicuous object, passing the meridian of Greenwich 13° south of the zenith. It forms a great triangle with Arcturus and Polaris, of which it occupies the summit of the right angle. At the side of α Lyræ are two stars of the third magnitude, β and γ, and three of the fourth magnitude, δ, ϵ, ζ. The four stars, β, γ, δ, ζ, form a parellogram, easily distinguished.

Between Lyræ and Pegasus the constellation Cygnus is found, composed of five principal stars, in the form of a cross. The line which joins Cygnus to Gemini is cut in two equal parts by Polaris. The same line, produced beyond Cygnus, passes through Altair, or α Aquilæ, a star of the first magnitude. α Aquilæ, is situated between γ and β Aquilæ, of about the third and fourth magnitudes respectively.

The folio plates afford a general view of the northern and southern constellations, with their most remarkable stars.

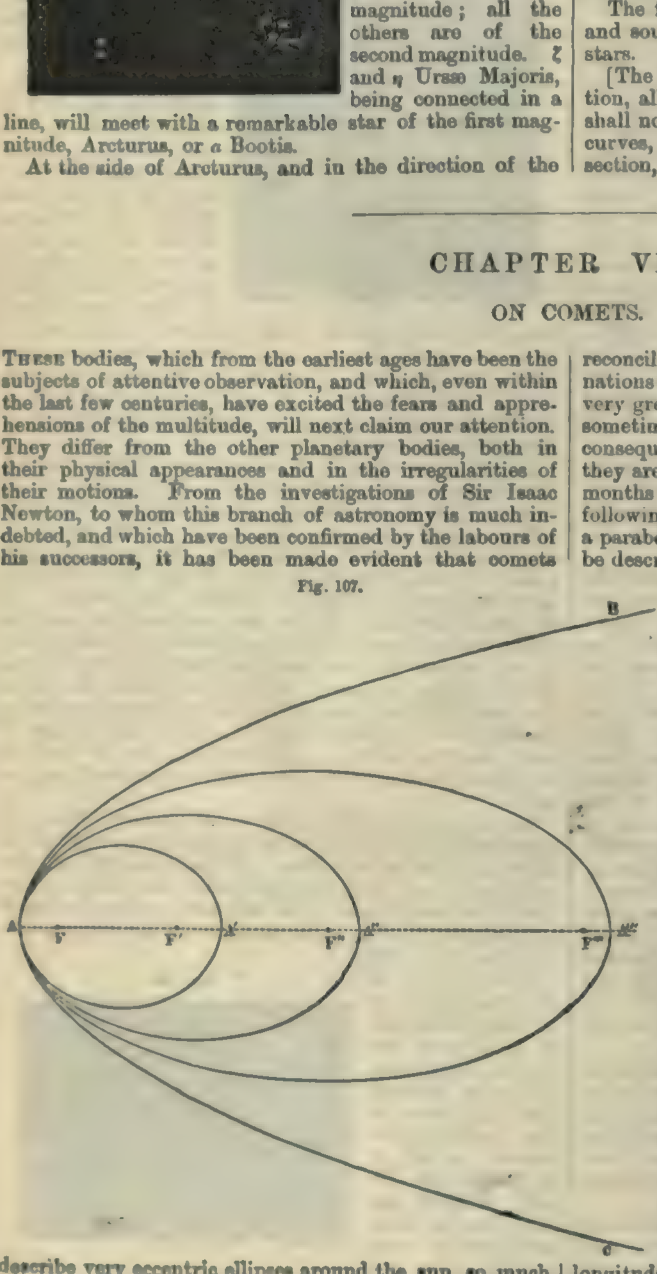
[The heavenly bodies, to which we have directed attention, all revolve in orbits of an elliptic character. We shall now pass to others moving in essentially different curves, which have been described in the Mathematical section, p. 608, *et seq.*]

CHAPTER VIII.

ON COMETS.

These bodies, which from the earliest ages have been the subjects of attentive observation, and which, even within the last few centuries, have excited the fears and apprehensions of the multitude, will next claim our attention. They differ from the other planetary bodies, both in their physical appearances and in the irregularities of their motions. From the investigations of Sir Isaac Newton, to whom this branch of astronomy is much indebted, and which have been confirmed by the labours of his successors, it has been made evident that comets describe very eccentric ellipses around the sun, so much so that, in the majority of cases, a parabola will perfectly reconcile their observed path in the heavens. The inclinations of their orbits to the ecliptic are also frequently very great, and the directions of their orbital motions are sometimes direct, and in other instances retrograde. In consequence of the great eccentricities of their orbits, they are seldom visible at the utmost more than a few months about the time of the perihelion passage. The following diagram (Fig. 107) will show, in a clear manner, a parabolic orbit. If with the two foci, F F′, an ellipse be described in the usual manner, we shall find that the major axis of this ellipse will be A A′, and that we shall obtain a curve differing little from an arch, and presented in a sense perpendicular to the axis A A′, or with a very slight degree of ellipticity. A second ellipse, with the foci F F″, will exhibit a greater degree of ellipticity, and will enclose the preceding one. A third ellipse, with the foci F F‴, will (still leaving A for the summit of the ellipse) show a still greater degree of ellipticity, and so on. By describing ellipses successively, we shall find the circumference of the curve more and more removed from the direction of the major axis A A″, till finally, we shall arrive at a point beyond which there is no variation. The curve B A C, thus described, is called a parabola. The point A is called the summit of this parabola, and the point F its focus. A parabola is then formed of two parts, A B and A C, exactly alike to one another, and extending infinitely on each side of the major axis, A F F′ F″. We can easily perceive that, as the comet recedes from the sun into space, it will be necessarily lost to our view. For the determination of the elements of the orbit of a comet, three complete observations are necessary as a first approximation, which can be afterwards brought to greater accuracy by means of the other additional observations during the time of its visibility. In a parabola the following elements are required:—1st, the longitude of the perihelion; 2nd, the longitude of the node; 3rd, the inclination of the orbit to the plane of the ecliptic; 4th, the time of perihelion

Fig. 107.



passage; and 5th, the perihelion distance. The observations will also give the direction of motion. Dr. Halley alone, acting according to the method of Sir Isaac Newton, calculated twenty-four orbits, by a comparison of which he was led to infer the periodic nature of the body which bears his name; and its certainty has been confirmed by the well-observed and authentic observations of successive returns.

Fig. 108.

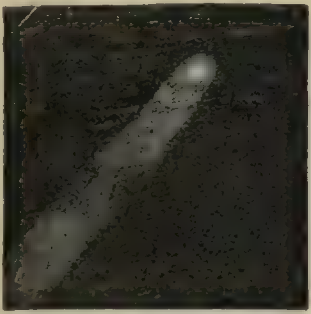


Fig. 109.

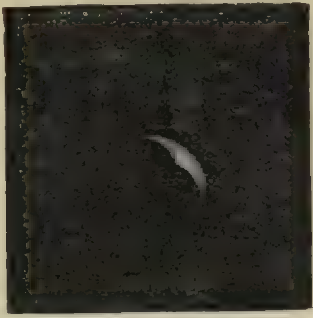

Fig. 110.

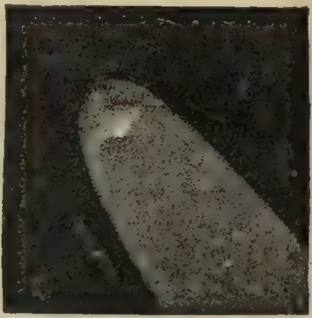

Modern astronomers have, with great zeal, applied the methods of Olbers and Gauss for this purpose, not only to those comets which have appeared in their own times, but also to others, whose paths in the heavens have been recorded by the ancient Chinese and European annalists. M. Langier has thus calculated, with a strong degree of probability, that the comets of 451 and 760, mentioned by the Chinese annalists, were returns of Halley's comet. Mr. Hind has also been led, by calculation, to consider the comets of 218 and 295 as appearances of the same body. But no certainty can be attached to any elements of this comet till the year 1378, the observations of which have been discussed by M. Langier, and of which the resulting elements are given with the others in the following table :—

		Long. of Perih.	Long. of Node.	Inclination.	Long. Perih. Dist.
1378, Nov.	8·764...	299° 31'...	47° 17'...	17° 56' ...	9·7560 R.
1456, June,	8·917...	301° 0'...	48° 30'...	17° 56' ...	9·7675 R.
1531, Aug.	24·888...	301° 39'...	49° 25'...	17° 56' ...	9·7538 R.
1607, Oct.	26·716...	301° 38'...	48° 40'...	17° 12' ...	9 7694 R.
1682, Sept.	14·795...	301° 56'...	51° 11'...	17° 44' ...	9·7656 R.
1759, March,	12·552...	303° 10'...	53° 50'...	17° 37' ...	9·7668 R.
1835, Nov.	15·939...	304° 32'...	55° 10'...	17° 45' ...	9·7683 R.

Fig. 111.

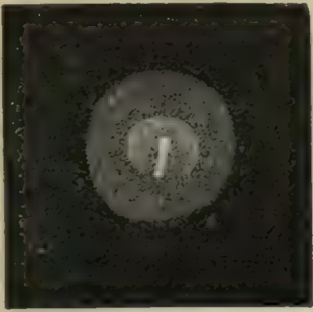

Fig. 112.

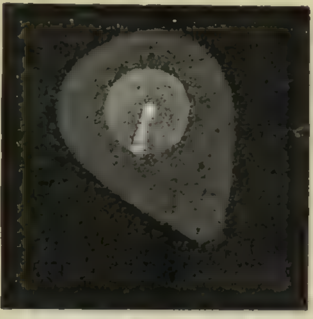

Fig. 113.

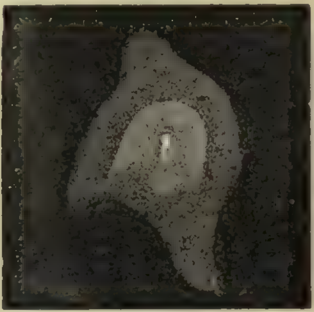


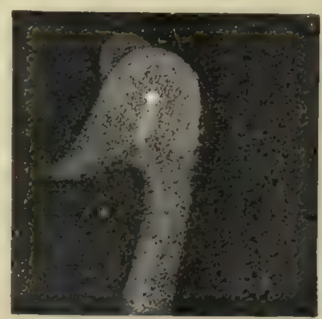
The striking similarity of the elements of the comets of 1531, 1607, and 1682, immediately presented itself to the mind of Dr. Halley, who was also led to infer that, by the influence of the planet Jupiter, the period of its next return would be considerably retarded. This prediction was found to be accurate by the laborious calculations of Clairaut, who, after minutely computing the disturbing effect of Jupiter and Saturn, found that its next return would be delayed by 618 days, as he concluded that the comet would arrive at its perihelion on April 13th, 1759.

The actual return, from the best elements, took place on March 12th, 1759, and the comet was seen for the first time at Dresden, by Pazlitch, on Christmas Day, 1758. This body being thus ranked in the planetary system, the investigation of the period of its next arrival at the perihelion was made the subject of a prize in several European academies. The investigations of Damoiseau and Pentécoulant, on this question, gave only the difference of one week in the predicted time of the arrival at the perihelion—an agreement very accordant, when the great intricacy of the problem is considered. The predicted return was stated to be on November 13th, 1835; and although the comet was attentively looked for during several months previously, it was not seen till August, when it was discovered at the Collegio Romano, of Rome. From the best elements, the return to perihelion took place on November 16th, the predicted time being only three days in error.

With regard to the physical appearances of these bodies, it is generally admitted, at present, that comets possess a very small degree of density.

The above diagram (Fig. 108) will show the appearance of Halley's comet, as observed by Sir J. Herschel, at the Cape of of Good Hope, on October 28, 1835. The bright spot situated in the head of the comet, is called the *nucleus*, and the luminous appendage which accompanies and surrounds this nucleus, is called the *tail*. On October 29, Sir J. Herschel observed the comet with a twenty-foot telescope, and noted its appearance, as in Fig. 109. A little later, on the same evening, the appearance was in Fig. 110. On January 25, 1836, it had an appearance as in Fig. 111; in the intermediate time the comet was not visible, in consequence of its proximity to the solar rays. On January 26, 27, and 28, 1836, it presented the appearances indicated in the Figures 112, 113, 114.

Fig. 114.



As to the light which these bodies possess, the late M. Arago inferred, from his experiments, that they shine by reflected light. But, although his experiments on the comet of 1819, and that of Halley in 1835, showed that they shone by reflected light, which he satisfactorily confirmed by experiments with a polariscope on the light of stars of the same magnitude in their neighbourhood, he was rather doubtful whether they had not a proper light of their own, since, without losing their property of reflection, some independent light might at the same time reach the earth.

So long ago as the year 837 of our era, the circumstance was remarked by the Chinese annalists; and again noticed by Appian, in the 16th century, that the tails of comets were generally directed from the sun. The appearance of these accompaniments are variable, both in regard to magnitude and brilliancy. Of the comet of 1689, the contemporary historians state that its tail occupied an extent of 90°, and presented an appearance similar to a Turkish sabre. The tail of the comet of 1769, was observed to be 97° in length. The comet of 1744 had as many as six tails, each 4° in breadth, and 30° to 44° in length. In our own days, the appearance of the comet of 1861 cannot be forgotten. At London, in July, its length, by observation, was found to be from 60° to 80°. The comet of 1618 had also a tail 104° in length.

In addition to Halley's comet, others of nearly similar period present themselves to our notice, and this remarkable group consists of the following:—

1st. The comet of 1812, which was discovered by Pons in that year, and only visible with the aid of a telescope. Encke, from all the observations, calculated its period to be 70·7 years.

2nd. The comet of 1815, discovered by Olbers, the period of which has been calculated by Bessel to be 74·05 years. According to the investigations of Bessel, the period of the next return will be retarded by two years, in consequence of planetary perturbations, or it would appear in 1891.

3rd. The comet discovered by De Vico in Rome, in 1846, Feb. 20, and observed till April. The calculations of De Vico and Peira, show that its orbit is decidedly elliptical, and that its period is upwards of 70 years. The only comet in the list of calculated orbits, similar to this body, is that of 1707.

4th. The next comet, nearly identical in period, is that discovered by Brorsen on July 20, in Triangularus, and observed at several places for the space of one month. Elliptic elements, compiled by D'Arrest, give its period as 75 years.

Another comet of long period, but the elements of which are not so well worthy of confidence, is that discovered by Flamsteed in 1663. Elliptical elements of this body, which are, however, too uncertain to be much relied on, assign to it a period of 187·5 years.

Several other elliptical orbits have been calculated, which will appear in a table at a subsequent page.

The most remarkable periodical comet (which there is a great reason to believe to be such, from the strong identity of the elements) is that discovered by Fabricius, in 1556, and which is considered to be a second appearance of the fine comet of 1264. Necessarily rude as the observations of this period were, Pingré and Dunthorne have calculated its elements from its recorded path, which agree in every particular with the comet of 1556. This subject has recently occupied the attention of M. Baume, who infers, from his investigations, that the comet will be retarded in its return to the perihelion by a period of some years. The last appearance, in 1556, was magnificent in the extreme. The tail was more than 100° in length; and, according to the Chinese accounts, it presented a curvature similar to a sabre. It remained visible till the 2nd of October of that year. There was a strong probability in the inference that this body would have returned to its perihelion, in the period from 1858 to 1860; but, as the elements are based on such uncertain data, we must not be astonished at the error which its absence has proved to exist.

After thus mentioning two comets, whose periods are the longest on record, and the first of which has been made evident by many successive returns, we shall now proceed to others, whose revolutions around the sun are of shorter duration. The first, and most celebrated, is that of Encke. This body was discovered by Pons, at Marseilles, on November 26, 1818; but the credit of being the first calculator of its elliptic elements is due to Encke, from which circumstance it bears his name. The similarity of the approximate parabolic elements to those comets observed in 1786, 1795, and 1805, immediately presented itself to the mind of Encke, who likewise found that a parabolic orbit would not satisfy the observations of 1818, 1819. Its period is approximately three years and a quarter. Since 1819, no return to the perihelion has passed without observation; and for this, in a great measure, astronomy is indebted to the laborious calculations of Professor Encke, who furnished the ephemerides of its predicted places. On June 2, 1822, the comet was seen by Rümker, for the first time, at the Observatory of Paramatta, in New South Wales, which had then been recently founded by General Busham. Although it was only observed there for a short space of time, the observations were found of considerable value in determining its next return in 1825. True to prediction, the comet was discovered by Valz, on July 13, within a short range of the calculated place. At this period the comet was well observed at Naples, and other European observatories. On its next arrival at its perihelion, 1828, it was first seen at Dorpat, by Struve, on October 13, and was observed in European observatories till December 25.

Although very unfavourably situated for observation in the northern hemisphere, in 1832, the comet was observed by Harding, at Göttingen, on August 21. Professor Henderson also observed it at the Cape of Good Hope; but the observations of this return were so few and scattered, that Professor Encke, in his investigations for its return in 1835, made no use of any of them. In 1835, the comet was observed, on July 26, by Boguslanzki, and previously by Kiel, at Milan, on July 22.

In 1838, it was again seen by Boguslanzki, on August 14, as a very faint, shapeless object, which afterwards increased in brightness till November. Professor Encke, in combining all the preceding returns at this period, found it necessary to alter the received mass of the planet Mercury, and also to allow for the effect of a resisting ethereal medium, pervading all space, and which had an appreciable resistance to the cometary motions. With these two important discoveries, Professor Encke published an ephemeris for its reappearance in 1842, on the 8th of February of which year it was observed by Dr. Galle.

Although the return of 1845 was very unfavourable, the comet was seen at Rome, and in America; but the observations were so few, that no use has been made of them in any investigation.

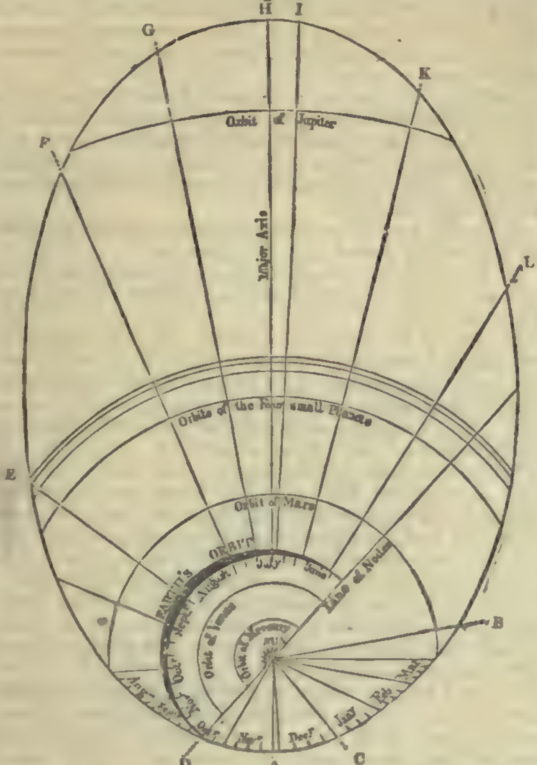
In 1848, it was observed for a period of three months, extending from August to November. The comet was very faint at first, but towards November its brightness increased considerably.

In 1852, the perihelion passage took place on March 14, and the comet was visible on the 2nd of January.

In 1855, the return of the comet was not favourable for observation in the northern hemisphere, but it was seen at the Cape of Good Hope, by Maclear. It was seen in November, 1861, by Valz, at Marseilles.

GAMBART'S COMET.—This body was discovered by Biela, on the 27th of February, 1826; but, as in the preceding case, it bears the name of Gambart, who first computed its orbit, and noticed its similarity with the comets of 1772 and 1805. Elliptical elements calculated by him and other astronomers, assigned to it a period of 2,460 days. In the interval of time from 1772 to 1826 it had performed six revolutions. The return to the perihelion, in 1832, was observed generally at all the European observatories. It was first seen at Rome, on August 25th, as a faint object, the light of which, however, increased afterwards. Professor Henderson likewise observed it at the Cape of Good Hope. On a calculation of the elements of its orbit—which are represented, with the relative position of the earth, in the following engraving—in order to ascertain the precise period of its return, it was, of course, necessary to study the perturbing influence of the planets; and when their places were ascertained and compared with its course, it was supposed that it would cross the earth's orbit about a month before our planet was at the point of intersection. This announcement excited much curiosity and some alarm. It will be evident, however, from a consideration of its orbit, that it never came within sixty millions of miles. It was a small, insignificant comet, looking like a collection of nebulous matter, and having neither tail, nor any appearance of a solid nucleus. In the engraving, A is its perihelion and H its aphelion, B its position, January 1st, 1840; C, on January 1st, 1833; D, its December node; E, its position January 1st, 1839; F, January 1st, 1838; G, January 1st, 1837; I, January 1st 1836; K, January 1st, 1835; L, January 1st, 1834. It will be seen from this diagram the point where the earth's orbit and that of the comet intersect is very near the descending node. The time at which the comet reached its perihelion in 1832 was the middle of November; it crossed the earth's orbit on the 29th of October, but the earth did not reach the same point until the 30th of November. At its return, in 1839, the comet was not seen from any part of the globe. In 1845, however, by means of an ephemeris calculated by Professor Santini, the comet was discovered by De Vico, at Rome, on November 26th. In a very short time afterwards a most singular circumstance took place; the comet appeared to have been divided into two portions. This appearance was first seen by Professor Wichmann, about the middle of December, and generally confirmed by other observers. The two nuclei were also observed till the 22nd of March, 1846.

Fig. 115.



On its return to the perihelion, in 1852, the comet was again seen by Professor Secchi at Rome, and at the Cambridge Observatory in England. At this time, although the predicted ephemeris was in error, both nuclei were again observed, but they had separated considerably. The comet at this return was exceedingly faint, and was only visible on nine different occasions. This and the comet of Encke are comprised within the limits of the solar system, and do not extend beyond the orbit of Saturn.

Faye's Comet.—The next known periodical comet, whose orbit is comprised within that of the planet Neptune, is that discovered by M. Faye, at the Paris Observatory, on the 22nd of November, 1843. At its first appearance it had a brilliant nucleus and tail. Faye and others (Gauss included) discovered that its orbit was elliptical, and that its period was 7·2 years. At first it was imagined by Argelander and Professor Henderson to be the lost comet of 1770, or that of Levell; but Leverrier has since proved that this could not be the case. Its orbit at aphelion and perihelion approaches near to Mars and Jupiter, and must have experienced considerable perturbations from the latter.

M. Leverrier calculated an ephemeris for its return in 1850, and, by means of this, the comet was observed on November 28th, of extreme faintness, at the Cambridge Observatory in England. With the exception of two other observations obtained in the Cambridge Observatory (U.S), by Mr. Bond, it was not seen at any other observatory. Mr. Bond described it as a very faint object in the twenty-three feet refractor.

The last four periodic comets are known as such by the frequent observations of their returns to the perihelion. But others exist, whose ellipticity is equally decided, although their returns have not been observed. Of these, the first is the comet of De Vico, comprised, as in the other case, within the planetary system, and discovered by him at Rome, in 1844. Its period was found to be 1980 days; but although its orbit has been ably investigated by Dr. Brünnow, it has not been seen either in 1850 or in 1855.

Brorsen's Comet.—This comet was discovered at Kiel, in Denmark, by Brorsen, on the 26th of February, 1846, and found to be elliptic, its period being upwards of five years and six months; Drs. Brünnow and Petersen consider that it was identical with the comets of 1532 and 1661. Dr. Halley, likewise, inferred the similarity of these comets; but, although expected, it was not visible in 1790. It appears probable that the influence of the planet Jupiter has a great effect on the elements of this body. Mr. Hind is of opinion that it experienced considerable perturbations from this planet in 1842.

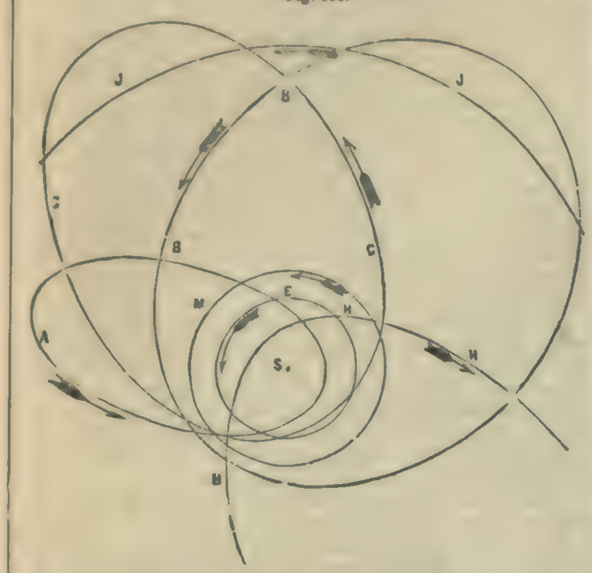
D'Arrest's Comet.—This comet, whose period is six years and five months, was discovered by D'Arrest in 1851, June 27th. It suffers great perturbation from the planet Jupiter in its path, and the time of its next return is not yet fixed.

Another remarkable comet of this class is that discovered by Messier in 1770, the orbit of which had been calculated by Levell, indicating a period of about five or six years. The planetary perturbations have, however, altered the path of this comet so considerably that it has never been since observed.

Fig. 116 shows the relative orbits of four periodic comets, and the comet of Halley. It must be remarked, however, that the orbits are not in the same plane, and that the cometary inclinations are sometimes very considerable. In Fig. 116, A is an orbit of comets of short period; B B, the comet of seven and a half years; C C, Gambart's comet; E, the orbit of the earth; H H, Halley's comet; J J, the orbit of Jupiter; M, the orbit of Mars; S, the position of the sun.

Nature of Comets.—Some attempts have been made to define with precision the difference between a star and a comet, and determine by what characteristics a newly discovered star is to be distinguished from one of these wanderers of the firmament. The planets always move in the same direction; the plane of their orbits being slightly inclined one to the other, and the eccentricity of these orbits are trifling. Comets on the contrary, for the most part, describe orbits so much elongated that they seem to move in a sort of parabola; and, in the case of the few with whose movements we are best acquainted, the eccentricity of their orbits distinguishes them in a remarkable degree from the planets. Each newly discovered object that is observed in an ellipse, only slightly eccentric, has been classed among the planets; while those which do not satisfy these conditions are regarded as comets. The comets we have described, while differing in many respects, seem to agree in the great degree of eccentricity of their orbits, and would seem to satisfy the inquirer that they cannot have the same origin.

Fig. 116.



Comets generally present the appearance of a brilliant nucleus, surrounded with a nebulosity which extends on one side more or less distant from the centre. This nebulous matter is so transparent, that stars, even of small magnitude, can be observed through the tail, and even through its thicker parts. The nebulosity of a comet, therefore, may be regarded simply as an extremely light vapour, which accompanies the central nucleus. The rapid changes which have been occasionally observed in the form of comets would seem to confirm this impression. For example, Halley's comet was observed with much care by Herschel at the Cape of Good Hope at the end of 1835, and we have already noted the changes he registered; but the most striking instance of change on record occurred in January, 1846, when Gambart's comet was observed to be separated into two parts, each having formed an independent nucleus, with the usual nebulous accompaniment. When the comet again appeared in 1852, the two objects also appeared, but at an increased distance.

Notes on Comets.—371 b.c. According to Diodorus of Sicily, about the end of the year 371, a comet appeared of prodigious magnitude, which was accompanied at the same time by inundations and an earthquake. Its apparent motion was from west to east, but its real motion was probably retrograde. From all recorded circumstances, it appears when observed to have been near its perihelion, and the inclination of its orbit to have been very great.

Seneca relates that the comet was divided into two portions near the end of its appearance. Stuyck is of opinion that the comet was identical with that of 1664, but there are no grounds for this supposition.

344 b.c. At this period, Diodorus relates that Fabius and Sulpicius, being consuls, on the occasion of Timoleus of Corinth undertaking an expedition to Sicily, a burning torch appeared in the heavens the whole night, and preceded the train of Timoleus, even till its arrival in Sicily. We may then infer that it had a considerable north declination, and that it appeared in the western heavens.

203 b.c. M. Cornelius Cethegus and P. Sempronius Iuditanus being consuls a comet was seen at Sethia, extending from east to west. The Chinese annals confirm this by its appearance, about the month of August, near Arcturus.

172 b.c. P. De Maille relates that a great comet appeared in China, at the end of the summer of this year, which had a tail.

156 b.c. In China, near the end of October, and visible for a period of twenty-one days, a comet in the west, which traversed the constellations of Aquarius, Equuleus, and Pegasus.

156 b.c. In this year, Seneca relates that, after the death of Demetrius, king of Syria, a comet appeared as large as the sun. At first its appearance was red and fiery, emitting sufficient light to dissipate the darkness of night. Gradually, however, its magnitude diminished, till it finally vanished.

136 b.c. In this year three comets were seen, which all may belong probably to the same body.

I. S. M. Emilius and C. Hostelius Mancinus being consuls, a burning torch was seen in the heavens at Prenéste.

II. Under the reign of Attalus, king of Pergamus, who reigned from 138 or 137 to 132 b.c., a comet was seen, which is supposed to be that of 136 b.c., and which, small at first, gradually increased till it reached the equator. Its tail equalled in length the parts of the heavens whose extent is the "Milky Way."

III. At the birth of Mithridates, who lived from this year to about 65 b.c., a comet, whose brightness was greater than that of the sun, lasted for about seventy days; the heavens appeared on fire, and the comet appeared to occupy one-fourth part of the sky; but it is doubtful whether this occurred in this year or 134 b.c.

133 b.c. In this year at Anisterne, the sun was seen during the night, and this lasted for some time; but it is likely that these appearances were due to the meteors which we so frequently observe.

48 b.c. Lucian mentions that in this year a terrible comet appeared; the darkness of the night was illuminated by it. In 49 b.c., or probably 48, a comet was seen in China whose paths were extended from β Cassiopeiæ through ι Cassiopeiæ, till it was lost finally among those stars which never set.

43 b.c. In the latter part of September of this year, during the feasts in honour of Venus, a comet was seen which was of great brightness, and was visible in all parts of the earth. It was visible about 5 p.m., when the brightness of the sun permitted it to be observed. It is very probable that it was in the sign Leo, with a north latitude of 35° to 40°, and that it was identical with the comet of 1680. In China, in this year also, a comet was seen in the months of May or June, which was in the constellation Orion; but, if this be the same comet as the preceding, it will not agree with the elements of the comet of 1680.

Since the Christian Era.—14. According to Dio Cassius, S. Pompeius Magnus, and S. Apuleius being consuls, many comets of the colour of blood were seen to shine.

39. In the Chinese annals mention is made of a comet in this year, which was visible from the 13th of March to the 30th of April, or for forty-nine days. Its path was from the Pleiades, through Pegasus, and finally to the head of Andromeda.

60. In China a comet was seen in the constellation of Capricornus, whose tail was eight degrees in length; its appearance lasted for fifty days, and it was last observed in the south of the head of the constellation Scorpio.

76. Pliny relates of a comet being observed this year, which was described by Titus Cæsar as having occurred in his fifth consulate. In China it was observed from the 7th of September, and was visible for forty days. Its tail was 3° in length, and the path of the comet was from the head of the constellation Hercules to 3° of the east of β Capricorn.

117. In the 9th of January of this year a comet was seen towards the west. On January 14th it was seen near β Libræ and α Equulei; it afterwards passed to the constellation Musca.

141. According to the Chinese annals, on March 27th

of this year, a comet, whose tail was 6° or 7° in length, was seen near α and β Pegasi. On the following 16th of April it was near ξ Andromeda. On the evening of the 22nd of April it had passed over the Pleiades, or about 11° of right ascension. On the 23rd of April, it was seen in the feet and legs of Gemini, and finally disappeared in Leo.

240. Seen in China, on the 10th of November, a comet with a tail 30° in length in Scorpio; it passed through Capricornus, and on the 5th of December entered into Libra. Its latitude was 2° south on the 10th of November, but at the beginning of December it was not an entire degree. On December 19th the comet was south of the ecliptic, and was in the constellations of Aquarius and Cetus.

252. In this year two comets were seen in China. The first was seen in the wing of Pegasus on January 10th. It was to the west, and appeared seventy days.

On the 25th of March, a comet was visible in the constellation Musca; it was seen for twenty days, and the length of its tail was 50° or 60°.

336. In China, on the 16th of February, in the evening, a comet was seen in the southern arm and the girdle of Andromeda, and in the northern part of the constellation Pisces. It is probable that this is the comet which is mentioned as having been seen at the death of the Emperor Constantine, who, however, died on May 22nd, in the following year.

363. At the end of August of this year, according to the Chinese annals, a comet was seen near the stars, α, ξ, κ, λ, ι, υ Virginis. Its brightness was so great that it was visible in full day.

389. In this year a brilliant comet was visible, in the month of August, in the morning, which Mascellin, Philosotorgus, and Nicephorus mention. It equalled Venus in brightness, and was erroneously placed near this planet. Payne has calculated that the planet Venus was at this time in inferior conjunction, and that it did not become visible in the morning till November; but he thinks that it was very likely that it was near Jupiter. Jupiter was, at this time, in August, to the west of the sun, and would rise a short time after midnight. The comet lasted for forty days, and finally disappeared in the constellation of Ursa Major.

390. In this year a comet appeared similar to a hanging column, which lasted for thirty days. There appears to be no doubt that this was a different body from that of the preceding year.

400. The historians of this year, Socrates and Sozerames, make mention of a terrible comet which occurred, and was seen in this year. Its form was that of a sword. It was also observed in China on the 19th of March, near the northern part of Pisces, and the girdle and southern arm of Andromeda; its tail was 30° in length. It successively passed through the constellations of Cassiopeiæ, and to the square of the Great Bear, where it was near χ Ursa Majoris, then to α Hercules, and finally between γ and β Virginis. But this does not appear probable, for it would have been more so, if, instead of the head of Hercules, it had been written the tail of the Lion.

418. During an eclipse of the sun of this year, on the 19th of July, a comet was seen which had a conical form, and was visible for a period of four months. This is confirmed by an actual calculation of this eclipse, which occurred at this time. It was also seen in China, and its path was as follows:—At its first appearance, it was near the star δ Cygni, from which it went to the square of the Great Bear; it afterwards proceeded to that part of the heavens which always remains above the horizon, to the constellations Bootes, Virgo, Leo, and Corona. Stuyck was of opinion, at first, that this comet was identical with that of 1596, but afterwards renounced this idea.

467. Perseus and John being consuls, a great prodigy was seen for some days in the heavens. It was observed for forty days, but in some places it was only seen for ten days.

504. In this year a star or comet of great brilliancy was seen, but the Saxon annalist describes it in exaggerated terms.

530 or 531. The Chinese annals make mention of the first, which appeared in the month of October, 530. Its course was from Arcturus to λ Ursæ Majoris. This would agree with the motion of the comet of 1680, which period Halley had assigned to it; and we may, therefore, infer its probability. The second, which appears to be a different body, was seen at Constantinople in 531. All the Byzantine authors speak of the last, which is described as having been a large and terrific body, and was visible with them for twenty days. Its rays extended to the zenith, and it was compared to a lamp.

539. This comet, which was visible for forty days, occurred in the 13th year of Justinian. Its head was in the east, and its tail extended to the west. Its appearance is described as being equal in magnitude to a great man, which afterwards increased. It was subsequently observed in China, in the constellation Sagittarius, near μ, τ, φ, σ, τ, and ζ. Its tail was 10° long. On the 1st of January, 540, the comet was within 3° of Venus; but this appears improbable.

565. On the 4th of August of this year, a comet was visible in China, and remained so for 100 days. It was seen in ε, f, θ, φ, o, and h of the Great Bear. Its tail was not a whole degree in length. It then approached γ Aquarii, and ε and θ Pegasi, at which time its tail was 10° long. Its last appearance was in Equuleus.

566. In this year a comet was seen which, according to one chronicler, lasted for a whole year; but, according to another, which is more probable, only remained for sixty-six days. It is described as throwing out a long flame, and appeared in the Arctic circle.

568 (first comet). On the 10th of July of this year, a comet was seen in China in the feet and thighs of Gemini.

568 (second comet). Another comet was observed by the Chinese this year, on the 3rd of September, in the face and heart of Scorpio, and proceeded eventually to the east. On the 8th of September, it had a tail of 40°, near the northern star of Delphinus. It then passed through the constellations near β Aquarii and α Equulei, and α Aquarii, and ε and θ Pegasi, and entered into the constellation of the Eye of Pegasus. On the 8th of October it was in the head of Aries. It was observed altogether for sixty-nine days.

582. At Easter day, which occurred on the 29th of March, a great comet is mentioned by many historians as having been seen at Soissons.

607. In China, two comets are mentioned as having been seen, which some astronomers consider identical. The first appeared on the 4th of April, in the west. It passed through the constellations, the Northern Fish, the girdle and the southern arm of Andromeda, the head of Aries, α and ζ Virginis, and the feet of the Virgin, where it disappeared.

The second was seen on the 21st of October, in the same constellations. It passed over the northern part of Leo, of Virgo, and of others stars more to the north. The comet did not attain the constellation α, β, γ, δ, ε, ζ, η, θ, κ, Orionis.

615. In July a comet was seen in China, in the Great Bear. Its tail was 50° or 60° in length. During the night its head or nucleus had, as it were, a motion of libration.

676. In the beginning of this year a comet was discovered in China, whose tail was 5° in length, to the south of the constellations α and ζ Virginis, and the feet of the Virgo.

729. Bede and other chroniclers mention a comet as having appeared in the month of January of this year, which was near the sun for 14 days. But some mention two having been seen, which is improbable. It is likely that it had a right ascension little different from the sun, with a northern declination, which would account for its setting after the sun, and rising before it.

837. Father de Maille, according to Pingré, relates that on the 22nd of March, in China, a comet was seen near α Aquarii, ε and θ Pegasi. The tail of the comet was 7° long.

On March 29th, it was seen in β Aquarii and α Equulei. On April 6th, it had a tail 10° long, and its motion was towards the west. On April 10th, the tail was 50° long, and separated into two portions. On April 6th, its tail was undivided, and its length was 60°. On April 14th, the length of the tail was 80°, at which time the comet was in the constellation Hydra. After this time the length of the tail decreased considerably, and on April 28th, it was seen for the last time, with a tail only 3° long. Pingré, after having carefully investigated all the preceding observations, deduces an orbit which appears in a table at the end of this section: there are reasons for inferring that it was probably an apparition of Halley's comet, which, from some errors in the published accounts, will not agree with the observations. There also appears to be a doubt as to the year of this appearance—the Latin accounts agreeing consistently in placing it in 838, whilst the Chinese give 837. Were two comets seen, or is there an error in the Chinese account? The account of an anonymous Latin historian differs, both in date and position. It is nearly as follows:—It was first seen in Virgo, and, pursuing a retrograde course, it traversed successively Leo, Cancer, and Gemini, all in the space of twenty-five days, and finally disappeared in Taurus, under the feet of Auriga. Pingré's orbit, which is based on the Chinese observations, will not agree with the latter path; and we may infer, with some reason, that the year was 838, and the comet of which the Latin historian speaks was that of Halley.

855. In this year, an ancient chronicler mentions two stars being seen in the month of August, on ten successive occasions. They were possibly comets, the larger being always visible, but the smaller not so freqently. A comet was also seen in France during 20 days.

875. On June 6th, an extraordinary blazing comet was seen, with a fine tail. It appeared first in Aries, and was visible during the whole month of June. This comet was supposed, at the period, to be the announcement of the death of the Emperor Louis II.

891. In China, on May 12th, a fine comet was seen in Ursa Major, with a tail 100° in length. This comet is also mentioned in the Saxon annals. Pingré was of opinion that this comet was identical with that of 1532 and 1661.

895. A fine comet, whose tail was 100° long, was visible in China, on June 25th. It was first seen near ι and κ of the Great Bear, and in the course of its appearance it passed over Corona, part of Hercules, and Serpentarius. The length of the tail increased to 200°, which, however, Pingré asserts is difficult to believe.

905. In this year, the European and Chinese annals mention the appearance of a great comet in the months of May and June.

912. In this year the Latin authors relate that a comet appeared in the month of March, for fourteen days, in the north-west. A Greek author mentions its duration as being forty days.

931. A comet was visible in Cancer, in the months of May, June, and July of this year.

939. On the 19th of July of this year a long eclipse of the sun was seen; and in Italy, during eight successive nights, a comet of great splendour was beheld.

942. A comet was seen in October of this year, for upwards of twenty days, in the western heavens. Its motion was towards the east. Its head was faint, but the tail projected and resembled smoke.

975. In the autumn of this year a comet is mentioned by the Latin and Chinese historians. In China it was seen on August 3rd in Hydra; its tail was 40° in length. The comet during the time of its appearance, which was for eighty-three days, passed through the constellation Cancer to the space between γ Pegasi and α Andromedæ. Pingré remarks that there is a considerable similarity in the above path to that of 1556, which is supposed, with great probability, to be identical with that of 1264. Taking its perihelion passage a few days before the end of 975, July, Pingré finds that it might have been seen about the 11th of July, which Father Ganbil states to be the case in China. On August 3rd it would have been in conjunction with the sun, but its northerly latitude being considerable, it would rise some time before it, and might leave, as mentioned, a tail 40° long. Its course would then be retrograde, apparently through the constellations of Cancer, Gemini, Taurus, and Aries, in which latter sign it would probably be visible about the month of October. There is sufficient accordance in the above, to give this opinion of Pingré's considerable weight.

989. An appearance of Halley's comet is supposed to have occurred in the autumn of this year. On August 5th it was seen in the constellation of Gemini, and, pursuing a retrograde direction, it passed through the constellations of Leo and Cancer. Buckhardt has computed an orbit from the rough account of the Chinese annalist, which appears in our table.

1000. A comet of extraordinary brilliancy was seen this year for nine days; but there appears to be some doubt as to the exact period.

1066. In the April of this year the Chinese and European annalists mention that a comet of great brilliancy was seen. It was supposed to be the forerunner of the conquest of England by William duke of Normandy. The orbit has been computed by Pingré, from the Chinese annalists, and there appears a strong probability of its identity with that of 1677.

1097. Although the comet of this year was only seen for a very short time (in Europe only fifteen days), it is remarkable as projecting two rays or tails, which were directed to the east and south-east respectively. In China, on October 6th and 9th, its tail was noted as being respectively 30° and 50° in length. On October 6th it was seen in China near α and μ Libræ. On October 16th it was seen near the head of Hercules. It ceased to be visible in China on October 25th.

1106. A great and fine comet was seen in Palestine on February 7th, and in China on February 10th. It was seen on February 7th in Pisces. Its tail was similar in colour to the whiteness of snow. Its appearance lasted for fifty days. In China, on February 10th, its tail was 60° in length, and extended from Gemini to Orion. During its apparition, it traversed the path from the end of Pisces to the end of Taurus. There is some similarity supposed to exist between this comet and that of 1686.

1222. In the months of August and September, a comet of extraordinary magnitude, very red, and accompanied with a great tail, was seen. In China it was observed on September 10th, beneath the feet of the Virgin, Arcturus, and Berenice. It disappeared on October 8th.

1231. A comet was seen in China, on February 6th, in Cygnus; its magnitude was equal to Saturn. From the recorded path, Pingré has calculated an orbit, which appears in our table.

1264. A great and celebrated comet, of which all the historians make mention. It is supposed to be identical with the comets of 975 and 1556. It was visible for some months—at least three, probably four. Its disappearance occurred the same day as the death of Pope Urban IV., or on October 3. Pingré and Dunthorne have calculated its orbit.

1265. An historian mentions that, at the commencement of autumn of this year, a comet was seen with a long tail, which commenced to shine after midnight.

1266. In the month of August of this year a comet was visible in France. It was also seen at Constantinople, near the sign of Taurus; there appears some doubt, however, with respect to this last account. It is questionable whether the comets of 1265 and 1266 be not identical.

1299. On January 24th of this year a comet was seen near Columba. It was visible for sixty-three days. Pingré has deduced its orbit from all the observations.

1301. A great comet, which is mentioned by the Latin historians as having occurred at the time of the autumnal equinox. It was also seen in China for forty-six days, commencing with September 16th. The elements deduced by Pingré are very uncertain, but Mr.

Hind is of opinion that this is identical with the comet of Halley.

1337. At the summer solstice a comet is noted as having occurred about the time of the death of Frederic, king of Sicily. It was also seen in China. The European historians give its duration for three or four months.

1337. A second comet was seen in this year, but it was not observed in China. The European historians mention it as having lasted two months.

1351. In the month of December a comet was seen in Cancer in the east. The account, however, is obscure, and gives its position with uncertainty. From the Chinese positions of November 24th, 26th, 29th, and 30th, Burkhardt has determined the time of the perihelion passage in November, as 26 days 12 hours.

1362. On March 5th a comet was seen in China, near the constellation of α Aquarii and ε and θ Pegasi. It disappeared on the 7th of April. It was visible in Europe during Lent as a very great and brilliant star.

1362. On June 29th this comet was seen in China for forty days. Its first appearance was in Capricornus, and it had an extensive tail.

1366. On August 26th a comet was seen in China, in Ursa Major. On August 27th it was visible in the tail of Scorpio. On August 29th it was near ε and μ Aquarii. On August 30th it was near β Aquarii and α Equulei.

1378. On the 22nd of September of this year, a comet was seen in China to pass over the stars in the western foot of Antinous. It was also seen in Europe. On September 29th it was near the constellation Ursa Major, between Aries and Taurus. (This is certainly an error—the Great Bear is not near these constellations). It was visible for five days, and its motion was in an opposite direction to the apparent diurnal motion. This is an appearance of Halley's comet.

1385. On October 23rd a comet was seen in the constellations of Leo and Virgo, to the south of the constellation Ursa Major. On the morning of October 30th, it was seen near χ Hydræ. It afterwards passed to the south of the constellations φ, μ, λ, υ, and κ Hydræ. The tail was 10° long.

1402. A very large and very brilliant comet, which commenced to appear on the first day of Lent, on the 8th day of February, and which remained to the beginning of March.

1433. At Bologna a remarkable and brilliant comet was seen, which appeared from evening to morning. It lasted more than a month, or rather less than three months. Some dated its first appearance on October 12th.

1456. A return of the celebrated comet of Halley. It is represented by all the historians as being grand, terrible, and of extraordinary magnitude, with a tail equivalent in extent to 66°. But the extent of this appendage was fleeting and uncertain, varying to only 7°. The period of its durability was about one month.

1457. In the month of June of this year a comet was seen in Pisces. Its body was small. Its tail, at first very long, was equal to 15° of a great circle. The colour of the comet was of the appearance of lead.

1468. The second comet of this year, which appeared in September, October, and November. It was first seen in Leo, near the tail of Leo. Its colour was blue, with some mixture of paleness. It was a very small body.

1472. In the month of December, 1471, a fine comet was discovered in China. At Japan it was observed on the 9th of January, 1472, where it is described as being very great, its tail being equal in length to a street. In Europe it appears to have been first seen about Christmas—at first small, but afterwards very large. The greater number of historians represent it as very fine, but as altogether fearful.

1490. At the commencement of this year a great comet, with a very white and very long tail, was seen. It was visible at Bologna about the middle of February. Its head was small, and its tail long, but of little brightness. Pingré makes the year of this appearance to be 1491; but another was seen in China in January, 1491, in Cygnus, which cannot be reconciled with the European observations.

1506. In the month of August of this year a comet was visible with a long and bright tail, which extended between the stars of Ursa Major. It was observed in China and Japan, and appeared for a period of eighteen or twenty days.

1531. On July 31st, the comet of Halley again made its appearance in Europe. In China and Japan it was seen on the 13th of July. Apian, astronomer at Ingoldstadt, observed it from August 13th to August 23rd; from which observations, however rude and imperfect, Halley has computed elements. Apian also observed that the tail was always directed from the sun. It appears, from the Chinese observations, that the tail was 7° in extent, and that the comet was visible for thirty-four days.

1532. A comet was visible this year, which is supposed to be identical with that of 1661. The orbit has been deduced from Apian's observations, which, as in the preceding case, are not worthy of much confidence. Its head appeared constantly in the morning before the sun, and was three times larger than Jupiter. Its duration was about seventy days. According to the Chinese accounts, it was visible altogether for 115 days, and its tail varied from 1° to 10° in extent.

1533. A comet appeared this year about the middle of June. It was seen in the summer solstice in Taurus, with a very long tail. Its appearance is generally dated at the end of June, and it was seen to the first days of September.

1556. This is the celebrated comet whose return is so anxiously expected. It began to appear about the end of February, at which time it equalled in magnitude one-half of the full moon. Its tail, however, was short and variable. It was not more, at the greatest, than 4° in length, and its flickering nature resembled much a flame agitated by the wind. The comet disappeared altogether on the 23rd of April, near the chain of Cassiopeia, after having been seen for many days; its brightness being effaced by the rays of the sun, which it was very near. It created great terror in the mind of Charles V.

1558. This comet appeared on July 14th, in Leo. It disappeared on August 24th and 25th, apparently behind the clouds. It was at first not brilliant, but its brightness increased in the latter part of its appearance.

1569. In the November of this year a comet was seen in Serpentarius, and in the signs of Sagittarius and Capricornus. Its motion, in longitude, equalled the extent of these two signs. The comet was discovered in November, and its tail was directed towards the east.

1577. A great comet, which was discovered at Peru on November 1st. It was seen in Europe by Tycho on November 13th, at Uraniburg, in the island of Huen;* on this day he estimated the diameter of the head to be 7′, and the length of its tail 22°; the head was white, but less bright than the fixed stars. It was observed to January 26th of the following year.

1580. This comet was discovered at Tubingen, by Mestlim, on October 2nd. Tycho discovered it on the 10th of the same month, and his observations have been used by Pingré in calculating the orbit. Tycho notes that the diameter of the head was 8′, its light faint, its colour livid, and its tail difficult to be distinguished. Dr. Halley's orbit was based on the uncertain observations of Mestlim. Tycho observed the comet to December 12th.

1582. The second comet of this year, which was seen for only fifteen days at the longest. Tycho discovered the comet, and observed it at Uraniburg, from May 12th to May 18th. On May 17th, the magnitude of the head was scarcely equal to stars of the fourth magnitude. Its tail was more than 3° long, and very faint. Pingré computed two orbits from Tycho's observations, which are both necessarily uncertain.

1585. This comet was discovered by the Landgrave of

---

* Uraniburg was a castle built by Tycho Brahé. Its name signifies "The Castle of the Heavens." It is now in ruins.—Ed.

Hesse, and Rothmaun, his astronomer, on October 18th, and afterwards observed by Tycho to November 22nd. At its first appearance it equalled Jupiter in magnitude, but of less brightness. This comet had neither coma nor tail.

1590. This comet was discovered on March 5th by Tycho, and observed to March 16. It is noted as being of a medium magnitude; but it had a great tail, which extended to the zenith. On the day of its discovery, the comet appeared as a star of the second magnitude, and shortly afterwards, on the same night, of the first magnitude. Its brightness, however, was not so great as stars of this description.

1593. This comet, which escaped entirely Tycho's scrutiny and observations, was discovered by his pupil, De Ripen, at Zerbst, in Anhault. On August 4th, it was noted as being of a livid and reddish colour; its head equalled in magnitude stars of the third class, with a tail 4½° in length. On August 9th, it was equal in brightness to stars of the fourth magnitude, and a very slight vestige of a tail could be perceived.

1596. This comet appears to have been discovered on July 11th, and observed to the 12th of August. Its colour was feeble and pale, with a tail small, fleeting, and undefined. Valz considered that this comet was identical with that of 1845.

1607. The third apparition of Halley's comet, as ascertained by the elements, which, however, are not considered so accurate as could be wished. It was observed by Kepler in Prague, by Longemontanus in Copenhagen, and Malmoe in Scania (a province of Sweden). Bessel's orbit is deduced from the observations of the English astronomer Harriott.

1618. The first comet of this year was discovered at Caschau, in Hungary, on August 25th, and observed by Kepler from September 1st to September 25th.

1618. The second comet of this year was discovered at Silesia, on November 10th, and at Rome on the same day. At Ispahan, in Persia, the Spanish ambassador saw this comet for the space of fifteen or sixteen days, commencing with November 10th, two hours before the rising of the sun. The length of its tail equalled in extent one-sixth part of the zodiac. On November 18th, the Jesuits at the Roman College noted the extent of the tail to be 40°.

1647. Seen in Prussia on September 29th, soon after the setting of the sun. This comet was small, and remained visible for a very short time.

1652. This comet, which was of a pale and livid colour, almost equalled the moon in magnitude, according to Hevelius and De Caniers. It was observed by many astronomers, but, with the exception of those by Hevelius at Dantzic, the observations are very rough. Dr. Halley has computed his orbit from the observations of Hevelius.

1661. This comet, which was considered at first to be a return of the comet of 1532, was discovered by Hevelius from February 3rd to March 10th. On these observations Dr. Halley has calculated its orbit; but no body, which bears any similarity to these elements, was observed in 1789 or 1790.

1664. This comet appears to have been discovered on November 17th, in Spain. It was observed by Huygens on December 2nd, and by Hevelius on December 14th. The observations were continued by Hevelius to February 18th of 1666. At its first appearance it was noted as large as a star of the first magnitude, but not so bright. The length of the tail was from 5° or 6° to 10°.

1665. This comet was seen at Aix on March 27th. From the observations of Hevelius, from April 6th to April 20th, Dr. Halley has calculated its orbit.

1668. This comet, of which the tail appears to have been only seen at Bologna, was observed principally in the southern hemisphere. There appears to be some similarity of elements with the comet of 1843.

1672. This comet was observed by Hevelius at Dantzic on March 2nd, and seen by him till April 21st. On these data Dr. Halley has computed his orbit. The comet was small, having a tail only 1° or 1½° in length.

1676. Father Fontenoy, of the Society of the Jesuits, observed a comet at Nantes on the 14th of February. It was visible to March 9th, and was equal to stars of the third magnitude. This comet had no tail.

1677. This comet was discovered at Dantzic, on April 27th, by Hevelius. It was observed to the 8th of May, and it is on these observations Dr. Halley has calculated his orbit. The magnitude of this body was equal to Jupiter, and it had a tail about 2° in length.

1678. La Hire discovered this comet on September 11th, and observed it to October 7th. The orbit, however, deduced by Dawes is very rough, principally in consequence of the uncertainty of the observations.

1680. This great and celebrated comet was discovered by a person whose name is unknown, at Coburg in Saxony, on November 4th. It was, independently, discovered by Godfrey Kirch, on the 14th of November, while about to observe the Moon and Mars. Flamsteed, at Greenwich, saw the comet on the 20th of December, and observed it to the 15th of February, 1681. The length of the tail on December 16th was 70°. Several elliptic orbits have been calculated for this comet.

1682. Halley's comet. It was first observed at Paris by Picard and La Hire, on August 26th, and last observed by Flamsteed on September 19th. Its head was 2′ in diameter, and the length of the tail varied from 12° to 15°.

1683. Hevelius observed this comet at Dantzic, from the 30th of July to the 4th of September. Clausen's elliptic elements, from Flamsteed's observations, give its period as 190 years. Its nucleus was equal to a star of the fourth magnitude, with a tail varying from 2° to 4°.

1684. This comet was discovered by Bianchini, at Rome. It was observed from July 1st to July 17th; on which observations Halley has calculated its orbit.

1686. In the August of this year a comet was visible at Para, in Brazil, during the whole month. Its head equalled stars of the first magnitude, and its tail was 18° in length.

1689. This comet was discovered at Pekin on the 11th of December. It was not seen at all in Europe. On December 11th, the part visible of the tail was from 10° to 12°. In the southern hemisphere it was regularly observed, and its tail, at the greatest, was 60° long.

1695. This comet was almost obscured by the atmosphere or coma by which it was surrounded, so that the nucleus was scarcely distinguishable. It was seen in the southern hemisphere, in the Brazils, by Father Jacob, a French Jesuit, on October 28th. The length of the tail was then 18°.

1698. The orbit of this comet is very uncertain, in consequence of the roughness of the observations. Cassini discovered it at Paris, in the beginning of September, in the constellation Cassiopeia. La Hire observed it to Septembr 28th. This comet was only seen at Paris, and was not larger than a star of the third magnitude.

1699. Discovered at Pekin, by Father de Fontenoy, on February 17th, and observed to February 26th. It was seen at Paris from February 20th to March 2nd.

1701. This comet was discovered at Pau, by Father Palla, from October 28th to November 1st. It was a small body without tail, and diminished sensibly in magnitude.

1702. This comet, which was the second discovered this year, was observed from April 20th to May 5th, at Paris, Rome, and Berlin. The orbit is uncertain, in consequence of the roughness of the observations. This comet was compared to a nebulous star on April 20th.

1706. Observed at Paris by Cassini and Maraldi, from March 18th to April 16th. This comet was also similar in appearance to a nebulous star.

1707. This comet appears to have been discovered at Bologna on November 25th, and observed to January 23rd of the following year. Of all known comets, this body has the greatest inclination. Viewed with a telescope, it appeared to be nebulous, and of the second magnitude.

1718. This comet was observed at Berlin by Kirch, from January 18th to February 5th. It appeared to be equal to a star of the fourth or fifth magnitude, with a nebulous diameter of 5′ or 7′.

1723. Discovered at Bombay on October 12th, and observed at Lisbon and other European stations to the middle of December. It appeared of about the third magnitude, with a very faint tail, not more than 1° in length.

1729. This comet, which is remarkable in the length of its visibility, and the greatness of its distance from the sun and earth, was discovered at Nîmes, by P. Sarabat, on July 31st. It was a small nebulous body, scarcely visible to the naked eye.

1737. The observations of this comet were made at Paris, Rome, Bologna, Oxford, Lisbon, and also in Jamaica and Madras.

1739. This comet was observed at Bologna, from May 28th to August 18th.

1742. First comet. Seen at the Cape of Good Hope on February 5th. It was also seen in Europe in March, and was visible to the naked eye. The length of the tail was 5° to 8°.

1743. First comet. This comet was observed at Bologna, Paris, Vienna, and Berlin. In Berlin, it appears to have been discovered, on February 10th, by M. Grischon. It was a small body.

1743. Second comet. Observed at Haarlem from the 18th of August to the 13th of September. This comet was small, but was seen, notwithstanding, with the naked eye.

1744. This comet appears to have been discovered at Haarlem on December 9th, 1743, and was seen to March, 1744, at several observatories. It was one of the finest bodies which had occurred since the comet of 1680. In February, M. Cassini noticed that the head was divided into two portions. The tail was also divided shortly after into two branches.

1747. Discovered at Lausanne, by Cheseaux, on the 13th of August, 1746, and observed there to September 22nd. His observations were then interrupted by illness; but it was last seen on the 23rd of November, near a star in Capricornus.

1748. The first comet of this year was discovered at Paris about the latter end of April. It was also observed in South America, and in Pekin in China, as well as the Royal Observatory, Greenwich. It appears to have been a fine object, easily seen with the naked eye, and having a tail 20° long. This comet was observed at Paris, by Maraldi, to the 30th of June.

1748. The second comet of this year was seen at the same time as the first, but in a different part of the heavens. Its nucleus was brighter than the preceding, but there was no appearance of tail. The orbit depends on three approximate observations made at Haarlem, and is consequently very uncertain.

1757. Observed at Greenwich from September 13th to October 18th. The orbit of this comet is very approximate.

1758. Discovered in the island of Bourbon on the 26th of May, and seen in London on June 18th. Messier first observed the comet on August 15th, and continued his observations to the 2nd of November. It appears to have been a diffused body, equal in diameter to Jupiter.

1759. Halley's comet, first seen on Christmas day, 1758, by Pazlitch, near Dresden, and on the 28th by Dr. Hoffmann. This return is very celebrated in the history of astronomy, as being the first predicted appearance of a comet. Dr. Halley roughly estimated that the time of arriving at its perihelion would be at least one year longer than the interval between the two preceding returns. Clairaut, by a laborious calculation of the planetary perturbations, fixed its return on the 13th of April, the true time having been determined by Rosenberger, from a minute discussion of all the observations, to have taken place on March 12th. From the beginning of 1759 to the middle of February, the comet was regularly observed, till it became plunged in the solar rays about the latter period. On its reappearance, at the end of March, it was again observed to the 17th of April, till its declination became too great to permit its observation at European stations. It was observed, however, from the 20th of April to the middle of May in southern stations. La Nux, at the Isle of Bourbon, found the length of its tail on March 21st to be 8°; on the 28th of March, 25°; on May 1st, 33° to 34°; and on the 5th of May, 47°. It afterwards diminished, till, on the 14th of May, it was not more than 19°. It afterwards reappeared above the European horizon, and was observed in France and Portugal to the 3rd of June.

1759. The second comet of this year is reckoned in the order of its time of perihelion passage. It was discovered on the 25th of January, 1760, in the constellation Leo, by the celebrated astronomer Messier, and regularly observed to the 16th of March.

1759. The third comet of this year (reckoning, as before, in the order of perihelion passage) was discovered on the 1st January, 1760, by all the astronomers of the French Academy, and observed till the 8th of February. Its motion was exceedingly rapid, being, on the day of its discovery, 2° 25′ of a great circle in two hours, or at the rate of 29° daily. The diameter of the nebulosity was found to vary from 20″ to 30″. Its tail was about 4° in length.

1762. This comet was discovered by Klinkenberg on the 17th of May, and observed by Messier and Maraldi to the 2nd of July. Its appearance at the time of its discovery was similar to a star of the fourth or fifth magnitude, with a slight tail. The nucleus was readily visible to the naked eye, but in a telescope was bright and ill-defined.

1763. Discovered by Messier on September 28th, and observed to the 25th of November. Its appearance was that of a nebulous star. On the 4th of October, its diameter was 7′ or 8′. The orbit of this comet gave Pingré considerable trouble. That of Burckhardt is founded on unpublished observations.

1764. This comet was also discovered by Messier, and observed by him from January 3rd to February 11th. It was a bright nebulous object, visible to the naked eye, with a tail 2½° in length.

1766. Discovered by Messier on the 8th of March, when looking for the supposed satellite of Venus, which had created great sensation about this period. It appeared as a small nebulosity, with a luminous centre.

1766. Second comet. This comet appears to have been discovered by Helfenzriella, of Dillengen, in Suabia, on the 1st of April. On April 9th, it presented a tail from 3° to 4°, its nucleus being similar to a star of the fourth magnitude. Pingré supposed that it would be visible after the perihelion passage, which proved to be the case; but not, however, in European latitudes. La Nux observed it in the Isle of Bourbon, from April 29th to May 13th.

1769. This remarkable comet was discovered by Messier, on the 8th of August, and observed by nearly all the astronomers. La Nux observed it at the Isle of Bourbon, from August 26th to September 26th. On September 11th, he found its tail by measurement 97° long. Pingré, the same day, measured its length to be 90°. On August 28th, Dr. Maskelyne noticed its tail as 7°; Messier as 15°; La Nux and Pingré as 19° to 20°. On September 9th, Dr. Maskelyne estimated its length 43°; Messier as 55°; La Nux upwards of 60°; and Pingré as 75°. This comet was also observed after its perihelion passage, from October 24th to the 1st of December.

1770. First comet. Messier discovered this comet on the 14th of June, and observed it regularly to the 2nd of October. This comet is celebrated for the trouble it has successively given astronomers in the attempts to investigate its orbit. Leverrier has recently determined its period to 5·6 years nearly, but it has never been observed since the time of its discovery.

1770. Second comet. This comet appeared in 1771, on the 10th of January of which year it was seen at Paris by Messier, and at Milan by Boscovich. It appears, however, to have been discovered by La Nux, at the Isle of Bourbon, on January 9th.

1771. Messier discovered this comet on the 1st of April, and observed it to June 19th. It was also observed by Dr. Maskelyne, at Greenwich, from April 14th to May 30th. Its appearance was similar in brightness to a star of the third magnitude, with a train varying in length from 1° to 3°. The orbit is supposed, with some probability, to be hyperbolic.

1772. BIELA'S COMET.—This body, of which there is no doubt as to its identity with the comet of Gambart, or Biéla, was discovered by Montague, at Limoges, on the 8th of March. Messier observed it on three occasions, on March 27th, March 30th, and April 3rd.

1773. Discovered by Messier on the 12th of October, and observed to the 14th of April, 1774. It was with difficulty seen by the naked eye.

1774. Montague discovered this comet on the 11th of August, at Limoges. This was a small body, not visible to the naked eye.

1779. The small comet of this year was discovered by Bode, on January 6th, at Berlin; and independently by Messier, on January 18th, who observed it on the 17th of May.

7780. First comet. This comet was discovered by Messier, on October 26th.

1780. Second comet. This was discovered by Montague, at Limoges, on October 18th. It was also seen by Olbers, on the same day.

1781. First comet. This small comet, which was not visible to the naked eye, was discovered by Méchain on the 28th of June. It had no tail. The diameter of the nebulosity did not exceed 3′ or 4′.

1781. Second comet, discovered by Méchain on the 9th of October, and observed to December 25th. On November 9th it was visible to the naked eye, the nebulosity being 4′ or 5′ in diameter, and its tail 3° or 4° in length.

1783. Discovered by Pigott at York, on November 19th, as a small faint body, with difficulty bearing any illumination of the telescope. There is little doubt as to the ellipticity of its orbit, the period varying from five years and ten years, in Burckhardt's two orbits.

1784. La Nux first observed this comet on the 15th of December, 1783, at the Isle of Bourbon. At Paris, in the month of January, 1784, it was visible to the naked eye, with a tail from 2° to 3° in length.

1785. First comet discovered by Messier and Méchain on the 7th of January. It was invisible to the naked eye.

1785. Second comet discovered by Méchain on the 11th of March, and observed to the 7th of April. On April 4th, the nucleus was visible to the naked eye, with a tail 5° in length.

1786. First comet. This is a well-ascertained appearance of Encke's comet, which was discovered by Méchain on January 17th, and only observed on two occasions.

1786. Second comet. This body was discovered at Slough, on the 1st of August.

1787. This comet was discovered by Méchain on the 10th of April. It was a small luminous body, only visible in a telescope.

1788. First comet. This comet, which at its first appearance was not visible to the unaided vision, was discovered by Messier on November 25th. Its brightness increased so much that it was visible to the naked eye on November 30th. It appeared with a train 2° or 3° in length. The last observation was on December 29th, when the comet had diminished considerably in brightness.

1788. Second Comet. This was discovered by Miss Caroline Herschel on December 21st. It was a small telescopic body, presenting, at its first appearance, a nebulosity of five or six minutes in diameter.

1790. First comet. Discovered by Miss Herschel on January 7th. This was also a nebulous body, only visible by the help of a telescope, and of a diameter equal to about five or six minutes of arc.

1790. Second comet. Discovered by Méchain on January 9th. It appears to have been nearly similar to the preceding, and visible at the same time.

1790. Third comet. This was discovered by Miss Herschel on the 18th of April. It was observed by Messier from the 1st of May to the 29th of June. Its brightness on the 17th of May was so great that it was visible to the naked eye; the length of the tail varied from 2° to 4°.

1792. First comet. Discovered by Miss Herschel on the 15th of December, 1791. It was a faint nebulous body.

1792. Second comet. Discovered by the Rev. E. Gregory on the evening of January 8th, 1793. It was a dull nebulous body, with a faint appearance of tail.

1795. First comet. Discovered by Messier or Méchain on the 27th of September.

1795. Second comet. Discovered by Peray on September 24th. Miss Herschel detected it on the 7th of October. Burckhardt estimated its period to be twelve years, which, from a revision of the elements by D'Arrest, is improbable. The latter astronomer makes its period to be 422 years.

1795. Encke's comet. Discovered by Miss Herschel on November 7th, and observed by Dr. Maskelyne, and other astronomers, to the end of the month. It was a round, ill-defined body, without a nucleus.

1796. This comet was discovered by Olbers on March 31st. It was a very faint body, and would bear no illumination of the field.

1797. This comet was discovered by Bouvard on August 14th. It was a nebulous body from 3′ to 5′ in diameter.

1798. First comet. Discovered by Messier on April 12th.

1798. Second comet. Discovered by Bouvard on December 6th. It was a faint body, with a slight increase of light in the centre.

1799. First comet. This body was discovered by Méchain on August 7th, and visible to October. It was very faint when first seen; but at the end of August it was visible to the naked eye, with a tail about 1° in length.

1799. Second comet. Discovered by Méchain on December 26th; it was visible to the naked eye as a star of the fourth or fifth magnitude. It had a tail from 1° to 3° in length.

1801. Discovered by Reissig, jun., of Cassel, on June 30th, and observed by Messier to July 23rd. It was a small body.

1802. Discovered by Pons, at Marseilles, on August 26th; it was not visible to the naked eye.

1804. This comet, which had neither nucleus nor tail, was discovered by Pons on March 7th. It was seen the last time on the 1st of April.

1805. (1) Encke's comet. It was visible to the naked eye, and much resembled the nebula in Andromeda. It was discovered by Thulis, of Marseilles, on October 19th. One observer mentions its tail as being 3° in length.

1805. (2) Biéla's comet. Discovered by Pons, on November 10th, as a very faint body, the nebulosity scarcely bearing the slightest illumination of the field.

1806. Discovered by Pons on the 10th of November. The coma was from 5′ to 7′ in diameter.

1807. Discovered by Pons on September 20th; but it appears to have been first seen eight days previously by an Augustine monk in Italy. This was the finest comet that had appeared since 1769. On the 30th of September, the nucleus was equal to a star of the first magnitude. Olbers, on November 7th, noted the division of the tail into two branches.

1808. (2) Discovered by Pons, in Camelopardus, on March 25th, and observed to the 2nd of April.

1810. Discovered by Pons, on the 22nd of August, and observed to October 8th. It was a faint and small round nebulous body.

1811. The great comet of this year, which was first discovered by Flangergues on March 25th, and visible to the end of October.

The great comet of this year, so remarkable in several particulars, was discovered by Flangergues at Vivières, on the 26th of March, and observed to August 17th, 1812. From the laborious investigations of Argelander. its orbit was found to be elliptical, the period being 3065 years. This comet, in addition to its magnitude and the remarkable duration of its visibility, presented, on September 7th, a tail bent off in two branches; but these branches did not proceed from the comet itself, but were hung together at a slight distance from it, and separated from it by a dark interval, so that they enclosed the comet as a parabola does its focus. At this period its tail was 5° in length. On September 20th, Bode found the length of the tail to be 10°. On October 11th, the tail was about 13° long; the diameter of the nebulosity being 1′ 20″. Its maximum length appears to have occurred in the first week of October, when the tail was found to be 25° long, and about 6° broad. Sir W. Herschel paid considerable attention to the physical appearance of this comet, and the reader is referred to the *Philosophical Transactions*, 1812, for his remarks, which are too extensive to be given here.

1811. The second comet of this year was discovered by Pons on November 16th, and observed to the end of January, 1812. It had a well-defined nucleus, with a faint surrounding coma.

1812. This comet was discovered by Pons on July 20th, and observed to the end of September. At first it was only visible in a telescope; but in September it increased in brightness, and had a tail 2° in length. Professor Encke found its orbit elliptical, the period being 70·7 years.

1813. First comet. This comet was discovered on the 4th of February, by the preceding observer; and its appearance was that of a small confused nebula.

1813. Second comet. This comet, the eighteenth discovered by Pons, was first seen on March 28th. It appears to have been visible to the naked eye on April 24th and 25th, as a small round nebulosity without tail.

1815. This comet was telescopic, and was discovered by Olbers on March 6th. It is remarkable as being one whose elliptical orbit is decided; the periods of revolution, by several computers, varying from 72 years to 77 years.

1818. First comet. Discovered by Pons, in Cetus, on the 23rd of February. It was very faint, and has recently been supposed to have been an appearance of the comet of Bièla.

1818. Second comet. Discovered by Pons, on December 26th, 1817. It was a faint telescopic body.

1818. Third comet. Discovered by Pons, on November 28th, as a small, round, and well-defined body. Bessel, independently, discovered a comet on December 22nd, which proved to be the same body.

1819. The first comet of this year was remarkable in affording to Encke the discovery of its periodic nature, and the identity of it with the comets of 1786, 1795, and 1805. It was discovered by Pons, on November 26th, 1818, as a small, ill-defined nebulosity. The history of this body has been given in the preceding part of this chapter. (See p. 962).

1819. Second comet. This was discovered by Professor Tralles, at Berlin, on July 1st. It appeared with a well-defined planetary nucleus, and a tail from 7° to 8° in length.

1819. Third comet. Discovered by Pons, on July 12th. Encke computed its orbit, which he found to be elliptical, with a period of 2052 days.

1819. Fourth comet. Discovered by Pons, on December 4th; and previously at Marseilles, by Blanpain, on November 28th. Encke found its orbit elliptical, and its period 4·8 years. Clausen was of opinion that it was identical with the comet of 1743.

From the year 1821 we can do little more than record the various comets which have appeared in our hemisphere, with their dates, and names of their discoverers:—1821. Discovered by Pons on January 28th. Santini saw it with the naked eye on February 19th, and estimated its tail to be 2½° long. It was observed to May 3rd.—1822 (1). Gambart discovered this comet on May 12th.—1822 (2). Encke's comet. Discovered at Paramatta by Rümker on June 2nd.—1822 (3). Discovered by Pons on May 31st, but not observed much in Europe in consequence of its southerly declination.—1822 (4). Discovered by Pons on July 13th. On August 21st it was visible to the naked eye, and had a tail 1½° long.—1823. Discovered by Pons on December 29th. Santini found it on January 3rd. De Zach, on January 23rd, noticed that in addition to the usual tail, directed from the sun, it had another in a contrary direction, varying from 4° to 7° in length.—1824 (1). Discovered by Rümker on July 15th.—1824 (2). Discovered by Scheithaner, at Chemitz, on July 23rd.—1825 (1). Discovered by Gambart on May 19th, in Cassiopeia. This comet has some resemblance in its elements with the third comet of 1790.—1825 (2). This small comet was discovered by Pons on the 9th of August.—1825 (3). Encke's comet. Discovered by Valz on July 13th.—1825 (4). Discovered by Pons on July 15th. It was visible to the naked eye, and in October presented a remarkable appearance in the heavens.—1826 (1). Gambart's or Bièla's comet. Discovered by Bièla on February 27th.—1826 (2). Discovered by Pons on November 6th, 1825.—1826 (3). Discovered by Flangergues on March 29th.—1826 (4). Discovered by Pons on August 7th, and observed to October.—1826 (5). Discovered by Pons on October 22nd. It was visible to the naked eye in December, with a beautiful train.—1827 (1). Discovered by Pons on December 26th, 1826.—1827 (2). Discovered by Pons on June 20th.—1827 (3). Discovered by Pons on August 2nd.—1829. Encke's comet. Discovered by Struve in 1828, October 13th.—1830 (1). Discovered by Professor D'Abbadie in the Mauritius on March 16th. It was also seen on March 17th, during a voyage from Calcutta to Boston, as a bright object, with a tail 8° in extent.—1830 (2). Discovered by Herapath on January 7th, 1831. It exhibited a tail 2½° long; the diameter of the nucleus was 3′ or 4′.

1832 (1). Encke's comet. Discovered by Mossotti, on June 1, at Buenos Ayres, and at the Royal Observatory, Cape of Good Hope, on the next day. It was only seen once in Europe, by Professor Harding, on August 21st.—1832 (2). Discovered by Gambart, on July 19th.—1832 (3). Gambart's or Bièla's comet. Discovered at Rome, on August 25th.—1833. Discovered at Paramatta, by Dunlop, in September.—1834. Discovered by Gambart, on March 8th, in Sagittarius.—1835 (1). Discovered by Boguslanski, on April 20th.—1835 (2). Encke's comet. Discovered by Boguslanski, on July 30th.—1835 (3). Halley's comet. Discovered by Dumonchel, at Rome, on August 6th. (See the history of this comet, at the commencement of the chapter.)—1838. Encke's comet. Discovered by Boguslanski, on August 14th.—1840 (1). Discovered by Galle on December 3rd, 1839.—1840 (2). Discovered by Galle on January 25th. It was very faint, without any appearance of tail.—1840 (3). Discovered by Galle, on March 6th. It had a tail several degrees in length.—1840 (4). Discovered by Bremieker, on October 26th.

1842. Encke's comet. Discovered on March 9th, by Valz.—1842 (2). Discovered by Langier on October 28th. It was very faint, and without tail.—1843. The great comet of this year is within the recollection of many readers of this work. It was seen in South America, on Febuary 27th, and observed afterwards in Europe to the middle of April. This was the finest body since the great comet of 1811.—1843 (2). Discovered by Mauvais, on May 2nd.—1843 (3). Discovered by Faye, on November 22nd. Its orbit is elliptical, and it was again observed at the Cambridge Observatory in 1850.—1844 (1). Discovered by De Vico, on August 22nd.—1844 (2). Discovered by Mauvais, on July 7th. It had a small brilliant nucleus of 3′ in diameter.—1844 (3). Detected by Captain Wilmot, at the Cape of Good Hope, on December 19th.—1845 (1). Discovered by D'Arrest, on December 28th, 1844.—1845 (2). Discovered by De Vico, on February 25th.—1845 (3). Discovered by Coller, on June 2nd. It was a beautiful object, visible to the naked eye, with a tail 2½° in length.—1845 (4). Encke's comet. Discovered by

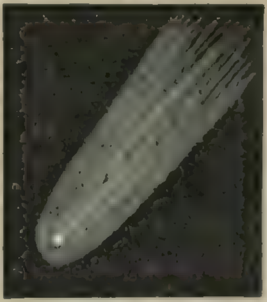
De Vico, at Rome, on July 10th.—1846 (1). Discovered by De Vico, on January 24th.—1846 (2). Gambart's or Biela's comet. Discovered by De Vico, on November 26th, 1845. At this appearance, the singular phenomenon of a double comet was seen.—1846 (3). Discovered by Brorsen, on February 26th. Its elements have some resemblance to the comets of 1532 and 1661.—1846 (4). Discovered by De Vico, on February 20th. There is no doubt as to the elliptical orbit of this comet, the period being 73 years.—1846 (5). Discovered by Hind and De Vico, on July 29th.—1846 (6). Discovered by Peters, on June 26th.—1846 (7). Discovered by Brorsen, on April 30th.—1846 (8). Discovered by De Vico, on December 23rd.—1847 (1). Discovered by Hind, on February 6th. —1847 (2). Discovered by Coller, on May 7th.—1847 (3). Discovered by Schweizer, on August 31st.—1847 (4). Discovered by Mauvais, on July 4th.—1847 (5). Discovered by Brorsen, on July 20th.—1847 (6). Discovered by Miss Mitchell, on October 1st.—1848 (1). Discovered by Petersen, on August 7th.—1848 (2). Encke's comet. Discovered by Hind, on September 13th.—1849 (1). Discovered by Petersen, on October 26th, 1848.—1849 (2). Discovered by Gonjon, on April 15th.—1849 (3). Discovered by Schweizer, on April 11th.—1849 (4). Discovered by Mr. Jenkins, on November 28th, at sea.—1850 (1). Discovered by Petersen, on May 1st.—1850 (2). Discovered by Bond, on August 29th.

1851 (1). Faye's comet. Discovered at the Cambridge Observatory, on November 28th 1850.—1851 (2). Discovered by D'Arrest, on June 28th.—1851 (3). Discovered by Brorsen, on August 1st.—1851 (4). Discovered by Brorsen, on October 22nd.

[Omitting various minor cometary appearances, we may give a short description of two remarkable comets, which appeared in 1858 and 1861.

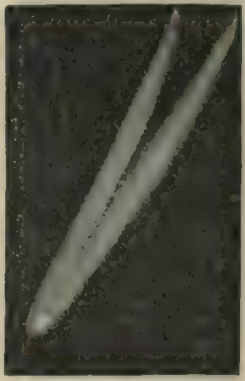
On June 2nd, 1858, M. Donati discovered the comet which has since borne his name. Until August 23rd, it did not present any marked appearance to observers in this kingdom, but was a round, bright object, like a nebulous patch of light, with a condensed centre, and without a tail. It was not visible to the naked eye till September, when it suddenly presented a most magnificent appearance. On October 5th, it passed near Arcturus, its tail being very brilliant, and of a length of full 40°, through which bright stars could be easily distinguished. The appearance of the tail continually varied. We observed it about the beginning of October, at Campbelton, in Argylshire, where the clearness of the air was extremely favourable, and, on one evening, a curious contrast was presented to it by the display of a brilliant aurora borealis, which it however exceeded in brightness. Its periodic time has been calculated to be 2,100 years. It was, at first, supposed to be the return of the comet of 1556, but its elements showed such an opinion to be erroneous. The annexed cut will give an idea of its general appearance at the commencement of October, as seen and sketched at the time.

Fig. 117.



In the latter portion of June, 1861, every one was startled by the sudden appearance of a comet, at dusk, on Sunday evening, June 30th. The writer observed it, before sunset, as a kind of nebulous patch, mistaking it for a star hid by haze. But, about eleven o'clock, all clouds having cleared away from the south-eastern sky, a magnificent comet, with a bright nucleus, and a tail of nearly 60° in length, presented itself. Its image was distinctly reflected from the sea (Ramsgate pier being the point of our observation). The tail had a quivering motion, very much resembling that of the streamers of the aurora borealis, and was divided near the head into two parts.

Fig. 118.



The annexed cut gives an idea of its appearance. (See, also, folio plate, page 957).

It was calculated, on June 25th, by Professor Challis, of Cambridge, that the comet was distant 82 millions of miles from the sun. And that its tail had a length of 10 millions of miles. Its brightness rapidly diminished as it receded from the sun; and, on August 24th, its distance from that body was about 140 millions of miles, increasing, in a week, to 152 millions, by which time it had arrived in the northern part of the constellation Bootes. Its tail had almost disappeared by this date, and in a few days powerful telescopes failed to discover it.

The most remarkable fact respecting this comet was its sudden appearance. It had not been seen by any of the observatories in Europe, till it so suddenly burst on the eye, of a size which was its maximum. For three days, however, previously to its discovery, the weather had been very cloudy, and the sky almost entirely overcast.] —EDITOR.

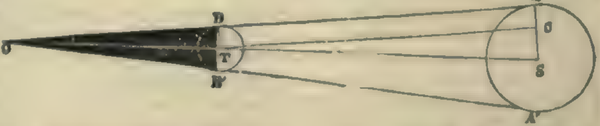
CHAPTER IX.

ECLIPSES AND OCCULTATIONS.

THE striking phenomena attending eclipses of the sun and moon, in which, apparently, the course of nature is interrupted, and for a time the discs of the sun and full moon lose their wonted lustre, and their light is almost extinguished in the mid-heavens, have ever been a source of curiosity, and occasionally of terror, to mankind. Whilst they have furnished many examples of credulity which have been taken advantage of by superior minds, they have sometimes served a nobler purpose; and the biography of astronomers is filled with instances in which the accidental occurrence of a solar or lunar eclipse, has been the cause of their first directing attention to the science that has been subsequently enriched by their investigations. *Eclipses* may be defined as a short interruption in the passage of light to the earth, which is either *real*, as in the case of the interposition of an opaque body between the earth and sun; or *apparent*, as takes place when the earth itself passes between the sun and the object previously illumined. The first are termed solar eclipses, and take place at the time of the new moon; the latter are lunar eclipses, and occur at the time of full moon, or when the earth is interposed between the sun and her satellite; the earth being a body of such dimensions that its shadow is sufficient to reach to the moon.

LUNAR ECLIPSES.—Taking the latter case, or that of a lunar eclipse, we readily see by Fig. 119 the form of the shadow cast by the earth. The sun, S, scatters its rays in all directions, and such as are directed towards the earth, T, will be interrupted in their onward passage by

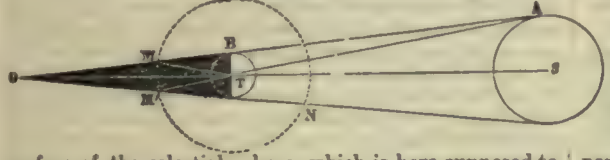
Fig. 119.



the interposition of this body; and we perceive that if the rays of light, A B, A′ B′, preserve their straight path they cannot penetrate within the portion B O B′, or between the summit of the cone A O A′ and the earth, and that this is the form and dimensions of the shadow cast by the globe T. In order that the moon may be eclipsed, it must be placed between the earth T and the summit of the cone O; and the distance of those two points is easily determined in the following manner:—Draw the line T C parallel to O A, and in the two similar triangles, O T B and T S C, we have the proportion S C : T S : : T B : O T. The radius of the earth, T B, being taken for unity, the line S C will be equal to the radius of the solar sphere, diminished by the former quantity, or to 111 radii of the earth. As the mean distance, T S, of the earth and sun are equal to 24,000 radii of the earth, we conclude that the distance O T is equal to about 216 terrestrial radii; or, more exactly, that the length of the axis of the shadow is 216·531 radii of the earth. At the time when the sun is in perigee this will decrease to 212·896 radii of the earth, and at the time of apogee will be 220·238 radii. As the distance of the moon from the earth never exceeds 64 terrestrial radii, and the least length of the shadow is 212 terrestrial radii, it is obvious that the moon must be obscured when the earth is situated between it and the sun. The breadth of the shadow of the earth at the distance of 108 terrestrial radii will be equal to half the diameter of the earth, and considerably greater at the distance of only 60 radii; but the exact dimensions of the latter point may be obtained as follows:—

Dimensions of the Shadow.—Let M N (Fig. 120) be the surface of the celestial sphere, which is here supposed to pass through the centre of the moon; this surface will cut the cone of the earth's shadow at M M′, and the angle M T M′ is the apparent angle of the shadow which it is required to determine. The half of this angle, or M T O, is equal to the angle B M T, diminished by the angle M O T; but the former is the parallax of the moon (since M T is the distance of the moon from the earth), and the latter is equal to the angle A T S (the semi-diameter of the sun) diminished by the angle B A T (the parallax of the sun). In order, therefore, to obtain the apparent semi-diameter of the shadow at the distance of the centre of the moon, we must add the parallax of the sun to that of the moon, and subtract the apparent semi-diameter of the sun.

Fig. 120.



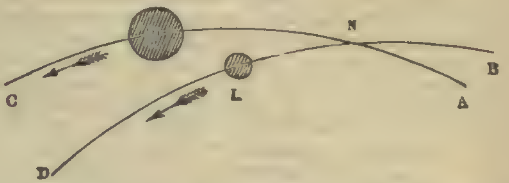
As the moon moves over a space about equal to its diameter in an hour, it follows that it may be entirely within the shadow for two hours. The greatest value of the dimensions of the earth's shadow at the moon, may be readily obtained by taking the greatest parallax of the moon, and the least of the sun; and as the former is 61′ 29″ at its maximum, and the sun's least semi-diameter and corresponding parallax, respectively, are 15′ 46″ and 8″·6, it would follow that the greatest semi-diameter of the earth's shadow at the distance of the moon is 45′ 52″.

The apparent semi-diameters of the shadow for other distances of the sun and moon may be readily calculated, and are here annexed:—

		′	″
Sun in perigee . .	Moon in apogee . .	37	42
	,, at mean distance	41	31
	,, in perigee . .	45	20
Sun at mean distance	Moon in apogee . .	37	58
	,, at mean distance	41	48
	,, in perigee . .	45	37
Sun in apogee . .	Moon in apogee . .	38	14
	,, at mean distance	42	3
	,, in perigee . .	45	52

Respective Positions of Moon and Shadow.—Let A C (Fig. 121) be the great circle of the ecliptic, and B D the orbit of the moon, N will be the nodes of this orbit. The shadow O moves along the first circle with a velocity equal to that of the sun, and the moon passes along the second circle with a velocity about thirteen times greater. In order that the moon may meet the shadow, it must happen that the centre of the shadow is sufficiently near the nodes N at the moment of opposition. By taking into consideration the above facts—that the apparent diameters of the moon and the earth's shadow vary from one epoch to another—and remarking that the distance of the centre of the shadow from the node N is precisely equal to the distance of the centre of the sun from the opposite node of the moon, we find that if the distance of the centre of the sun from the node at the time of full moon be greater than 12° 3′, there *cannot* be an eclipse; and if the distance be less than 9° 31′, there *must* certainly be an eclipse. Between these two extremes the case is doubtful; but a more exact calculation will show whether an eclipse really does occur.

Fig. 121.



PARTIAL ECLIPSES OF THE MOON.—When the moon is wholly obscured, as we see it can be, the eclipse is termed total; but when only a portion of the lunar disc enters into the shadow, the eclipse is partial. In the latter case, the outline of the earth's shadow projected upon the disc of the full moon, clearly shows its round and globular figure, although the diameter of the conical shadow is large in proportion to that of the moon. The accompanying diagram (Fig. 122) gives an idea of the relative proportions of the shadow of the earth and the disc of the moon at those times, and of the curvature of the circumference of the shadow *a b c*. But the definition of the earth's shadow is far from being so sharp as is here represented, and, like that of the shadow of any other opaque body, is edged with a cloudy and imperfectly-defined penumbra, the dimensions of which may be estimated by the following considerations:—Let the lines A O′ B′ C′ and A′ O′ B C be drawn (Fig. 123), another cone, A O′ A′, having its summit O′ between the sun and the earth, is formed, and enveloping the sun and the earth in its opposite parts A O′ A′, B O′ B′. It is clearly seen that all the part situated within the space C B B′ C′, and without the real shadow B O B′, would only receive a portion of the rays of the sun coming from the part of the hemisphere turned towards it, the other part being hid by the earth; and that the portion of the sun which is visible is greater according as this is nearer to the exterior surface of the space C B B′ C′, and, on the contrary, smaller as it is nearer to the real shadow of the earth, or B O B′.

Fig. 122.

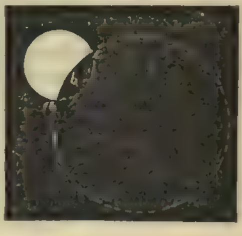


Fig. 123.

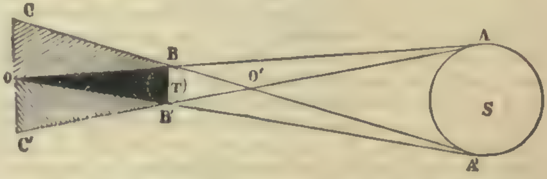

The consequence would be, that as the moon passed into the part C B B′ C′ before meeting with the real shadow, it would insensibly lose a portion of its light, and its lustre would become gradually less intense as it approached the real shadow. As, however, the breadth of the penumbra is equal to the angle O B C = A B A′, or the diameter of the sun as seen from the earth; and as the apparent diameters of the moon and sun are nearly equal, it follows that the whole disc of the moon may be within the penumbra C B O. When *any part* of the disc of the moon is obscured by the real shadow, it follows that the *whole* of its surface is more or less hidden by the penumbra. The insensible melting away of the real shadow into the penumbra is noticed at every lunar eclipse, but it is impossible to tell precisely where the penumbra ends, and the shadow begins.

EFFECT OF THE ATMOSPHERE OF THE EARTH.—Hitherto we have supposed the rays proceeding from the sun to pass in straight lines until they meet the lunar disc, but this is not the case; for those which pass through the earth's atmosphere are subject to refraction, and change their direction in the manner already explained in the case of a star. This will be more apparent when we consider the direction of the ray S A (Fig. 124), which traverses the atmosphere of the earth, and passes beyond it. The direction which it takes previous to entering the atmosphere of the earth makes an angle of 33′ with its direction when it arrives at that point; and after passing through it, it is still further deflected from its original course, and by the same amount as before. The consequence of this will be, that it is altogether deflected more than a degree, and that the solar rays will meet before arriving at the point O (Fig. 125); and, instead of the rays A B and A′ B′ taking a straight direction, they will be deflected to the point D (Fig. 125), which is considerably nearer the earth than the point O. Thus it will be only the inner cone B D B′, which is the real cone of the shadow; the remaining parts of the *mathematical* cone B O B′ will be traversed by the solar rays, which are bent from their primitive direction by the action of the terrestrial atmosphere. The distance of the point D from the centre of the earth can be calculated as in the former case, and it has been found that its average is forty-two terrestrial radii; and we conclude from this, that as the moon's mean distance is equal to sixty-four radii of the earth, it can never be inclosed within the real shadow of the earth B D B′; but at the time of total eclipse it falls within that part of the shadow where the rays, refracted by the atmosphere, penetrate. This is the cause that when the moon is wholly eclipsed, it still shines with a reddish light, being illumined by the faint rays refracted by the earth's atmosphere. This, however, is not the sole effect of the atmosphere, for the apparent diameter of the earth's shadow has been found by observation to be *greater* than might be expected from the preceding investigation; and it has been accounted for, by supposing that the solar rays do not really touch the surface of the earth, but that the lower strata of the air absorbs those which approach its margin; and if such be the case, the diameter of the globe of the earth and its shadow would accordingly be greater.

Fig. 124.

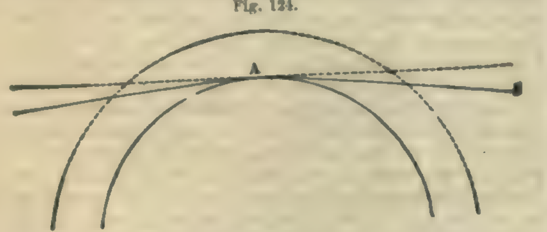

Fig. 125.

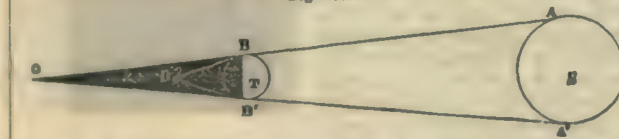
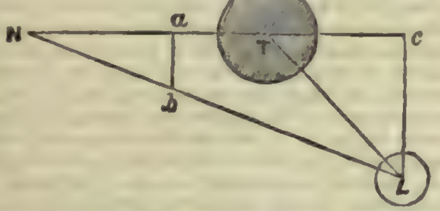


The *condition* of the atmosphere through which the rays of the sun pass, produces considerable changes in the appearance of the lunar disc at the times of total eclipse. In ordinary cases, as before mentioned, the colour of the moon is of a red or coppery tint, similar to that frequently assumed by the setting sun, and produced by the same causes—viz., an absorption of the blue rays of light when passing through great depths of the atmosphere. If that portion of the atmosphere be charged in addition with cloud and dense vapours, the whole of the elementary rays will be stopped in their passage to the lunar surface; and several instances are on record in which the disc of the moon was completely invisible at the time of total eclipse. In the eclipses of 1601 and of June 1620, this was the case, although the air was sufficiently clear to allow the light of stars of the fifth magnitude to be distinguishable; and, in a similar manner, the moon could not be perceived (even with the aid of a telescope) during the eclipse of April, 1642, although the sky was equally as clear as in the former case. When, however, the sky is clear at those portions of the earth's surface through which the solar rays pass, the red rays are transmitted in great number, and the lustre of the lunar surface is but slightly dimmed in consequence. Such was the case with the eclipse of the moon which happened in March, 1848, when the lunar disc was almost as apparent as on ordinary dull nights, and when many persons who were observing it could scarcely be persuaded that it was really eclipsed. The dark spots and bright places were as well seen on its surface as if viewed through thin cloud or vapour; and one observer, who had witnessed lunar eclipses for more than sixty years, never remembered one in which the illumination was so strong—appearing like the glowing heat of fire from the furnace, and tinged with a deep red. Sometimes the moon becomes invisible during the progress of its immersion in the shadow, as was the case with that observed by Wargentin, in 1761, when the moon was very bright for ten minutes after its total immersion; but for an hour afterwards became so completely invisible that not the slightest trace of it could be detected, either with the naked eye or telescope, although the sky was clear, and stars, in the immediate vicinity of the moon, appeared bright and distinct. In other cases, the region of the atmosphere, through which the rays have passed, has been clear at some parts, and obscured at others: and the consequence has been, that whilst the lunar disc appeared clear and bright in some portions, it was very dark at others. Kepler states that, during the total eclipse of August, 1598, one half of the moon appeared so bright that it seemed doubtful if it was eclipsed at all, whilst the other was seen with the utmost difficulty. A similar variegated appearance was presented by the lunar disc in October, 1837. Sir W. Herschel perceived many bright spots on the occasion of a total eclipse, and was induced to believe that they were volcanoes in action. Such an appearance, however, it will plainly be seen, may be supposed due to the various reflective qualities of the surface of the moon, and that the bright spots noticed by Herschel were only the bright mountainous districts illuminated by the red light of the sun. (See Note, p. 984).

PREDICTION, DURATION, AND MAGNITUDE OF A LUNAR ECLIPSE.—If the moon did not depart from the plane of the ecliptic, there would be a lunar eclipse at each full moon, and a solar one at new moon; but as it is sometimes above and sometimes below this plane, an eclipse can only take place when the moon approaches the nodes of its orbit. It was known to the ancients that at certain intervals the new and full moon returned again on the same day of the month; and they had observed that at the end of eighteen years, eleven days, or a period of 223 lunations, there was a return of the same eclipses, and were thus enabled to foretel them with considerable, but not with perfect accuracy; for the exact recurrence, if it took place, would depend upon the return of the sun's place, the moon's place, the position of the moon's apogee, and that of the ascending node of the moon to exactly the same situation. This exact return cannot happen, but is sufficiently approximate to permit us to foretel eclipses with a remarkable degree of accuracy; and Dr. Halley found that if the period of 18 years, 10 days, 7 hours, 43¾ minutes, were added to the middle of the time of any eclipse, the return of the corresponding one might be predicted within 1h. 30m. If only four leap-years occur in the interval, the period would be enlarged to 18y. 11d. 7h. 43¾m. It may, however, happen that when the eclipse is very slight, or an *appulse* occurs, that at the succeeding period of 18y. 11d. it will not be observed. Since the position of the heavenly bodies at any epoch, as well as the laws which govern their motions, are at present equally well known, the eclipses of the sun and moon are now rigorously calculated, although, to save time and trouble, the above period of 18y. 11d. (the period of 521y. 3h. 3m. would be still more exact) is still made use of. The *Nautical Almanac* contains the exact positions of the sun and moon in relation to the earth at any given time; and it is from these data that we shall determine the beginning and end of an eclipse at any given time.

In order to *calculate* an eclipse of the moon, the following data are necessary, and the manner in which they are used will be seen by the diagram (Fig. 126) and explanation.

Fig. 126.



Suppose the moon's place at opposition to be at b, the centre of the earth's shadow being at a at the same time, the latter passing through the space T a, the path of the ecliptic, whilst the moon's centre describes the line L b, the path of the moon's motion (which may be regarded as straight lines, as well as those of L c, a, b):

Let m = moon's horary motion in longitude.
n = moon's horary motion in latitude.
s = sun's horary motion in longitude.
λ = moon's latitude when in opposition at b.
t = time taken by moon to pass from L to b.
d = distance from T to L.

The moon's motion in longitude will be $a\,c$ in the interval it takes to pass from L to $b = m\,t$. Its motion in latitude, during the same time, or $\mathrm{L}\,c - a\,b = n\,t$. The sun's motion in longitude, or the distance $\mathrm{T}\,a = s\,t$ in the same manner. Then

$$\mathrm{L}\,c = a\,b + n\,t = \lambda + n\,t \text{ and } \mathrm{T}\,c = a\,c - \mathrm{T}\,a = m\,t - s\,t$$
$$d^2 = \mathrm{L\,T}^2 = \mathrm{L}\,c^2 + \mathrm{T}\,c^2 = (\lambda + n\,t)^2 + (m\,t - s\,t)^2.$$

Expanding this expression, we obtain a quadratic equation of which t is the unknown quantity (the others being derived from the above data), and will depend on the value given to d. Such values may be given to d as correspond to the phases of the eclipse, and the interval between the time of opposition, and the occurrence of the phases will thus readily be obtained, the time of *opposition* being known, from the position of the sun and moon as given by the tables. Arranging them, we obtain

$$d^2 - \lambda^2 = t^2\left[(m-s)^2 + n^2\right] + 2\,t\,\lambda\,n.$$

Substituting $\tan.^2\,\theta = \dfrac{\sin.^2\theta}{1-\sin.^2\theta}$ for $\dfrac{n^2}{(m-s)^2}$, we obtain, instead of the above,

$n^2\,t^2 + 2\,\lambda\,n\,\sin.^2\theta\;t = (d^2-\lambda^2)\sin.^2\theta$; or, completing the quadratic,

$$n^2t^2 + 2\,\lambda\,n\,\sin.^2\theta\;t + \lambda^2\sin.^4\theta = (d^2-\lambda^2)\sin.^2\theta + \lambda^2\sin.^4\theta$$
$$= \sin.^2\theta\,(d^2-\lambda^2)\,(1-\sin.^2\theta)$$
$$= \sin.^2\theta\,(d^2-\lambda^2\cos.^2\theta).$$

$$\therefore t = \frac{1}{n}\left(-\lambda\sin.^2\theta \pm \sin.\theta\,\sqrt{d^2-\lambda^2\cos.^2\theta}\right).$$

And from this expression the values of the times for any values of d may be obtained. For the determination of the time, t, at which the moon immerges into the earth's penumbra, d = moon's horizontal parallax + sun's horizontal parallax + the sun's semi-diameter + moon's semi-diameter $= \mathrm{P} + p + \frac{\mathrm{D}}{2} + \frac{\delta}{2}$; the first value of t giving the instant of immersion, the second that of emersion. At the time of immersion in the umbra $d = \mathrm{P} + p + \frac{\delta}{2} - \frac{\mathrm{D}}{2}$. At the period when the whole disc has entered the shadow d = sum of the parallaxes — sum of the semi-diameters, or $\mathrm{P} + p - \frac{\delta}{2} - \frac{\mathrm{D}}{2}$. The time at which the middle of the eclipse occurs (or the *greatest phase*) is when the two halves of t are equal, or when $d^2 - \lambda^2\cos.^2\theta = 0$, and $t = \frac{\lambda\sin.^2\theta}{n}$. In this case the distance $d = \lambda\cos.\theta$. When the latter term is known, the *magnitude* of the eclipse may be determined. Some part must be eclipsed when $\lambda\cos.\theta$ is less than the distance $\mathrm{P} + p + \frac{\delta}{2} - \frac{\mathrm{D}}{2}$, as the latter quantity shows when the moon's limb just touches the shadow, and the portion of diameter eclipsed is $\left(\mathrm{P} + p + \frac{\delta}{2} - \frac{\mathrm{D}}{2}\right) - \lambda\cos.\theta$. The portion of the diameter of the moon which is not eclipsed will, therefore, be $\lambda\cos.\theta + \frac{\delta}{2} + \frac{\mathrm{D}}{2} - \mathrm{P} - p$. The eclipse will be *exactly* total when this is nothing, and will be *more* than total when it is negative. The part eclipsed may be expressed either in digits or twelfths of the lunar diameter (δ), or in decimal parts, the moon being taken for unity.

Example.—Partial eclipse of the moon, April 20th, 1856.

By the tables of the sun and moon, the time of opposition is at 9h. 13m. ·6 morning, Greeenwich mean time.

Moon's lat. at time of opposition $\lambda = 33'\;18''$
,, horary motion in lat. . $n = \;\;2\;46$ lat. increasing.
,, horary motion in long. . $m = 30\;\;8$
Sun's horary motion in long. . $s = \;\;2\;27$
Moon's apparent diameter . . $\delta = 29\;44$
,, horizontal parallax . . $\mathrm{P} = 54\;33$
Sun's apparent diameter . . $\mathrm{D} = 31\;52$
,, horizontal parallax . . $p = \;\;\;\;9$

$$\mathrm{Tan.}\,\theta = \frac{n}{m-s} = +\frac{166''}{1661} \;\therefore\; \theta = +\,5^\circ\,43'\,10''.$$

The middle of the eclipse, or

$$-\frac{\lambda\sin.^2\theta}{n} = +\frac{1998}{166}\sin.^2(5^\circ\,43'\,10'') = -7\text{m.}\cdot16.$$

Therefore the midddle of the eclipse will occur at 9h. 6m. ·4 morning, reckoning from opposition. The times at which it entered the shadow and emerged from it are calculated by finding the value of d at those times:—

$d = \frac{\delta}{2} - \frac{\mathrm{D}}{2} + p + \mathrm{P} = 53'\;38''$, and adding the one-sixtieth part of $\left(\mathrm{P} + p - \frac{\mathrm{D}}{2}\right)$ for the effect of the earth's atmosphere, $d = 54'\;17''$. Introducing this value into the expression $-\frac{\lambda\sin.^2\theta}{n} \pm \frac{\sin.\theta\,\sqrt{(d^2-\lambda^2\cos.^2\theta)}}{n}$ we obtain for the two values of t:

	m.		h. m.		h. m.
End of eclipse	= 7·16	+	1 32·68	=	1 39·84
Beginning	= 7·16	—	1 32·68	=	1 25·52

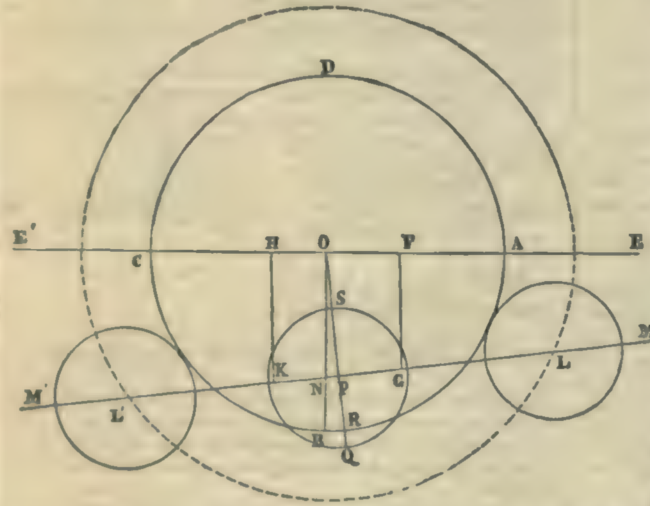
The commencement of the eclipse accordingly took place at 7h. 33m. ·8 morning, and the end at 10h. 39m. morning. The distance of the centres corresponding to the middle of the eclipse, or $\lambda \cos. \theta = 33' 8''$; and the eclipsed part, or $\frac{\delta}{2} - \frac{D}{2} + p + P - \lambda \cos. \theta = 21' 9''$, (allowing for the effect of atmosphere), or the magnitude of the eclipse, reckoning the moon's diameter at 1 = 0·71.

In order to determine the time at which the moon entered the *penumbra*, we assume, $d = P + p + \frac{D}{2} + \frac{\delta}{2} =$ 86′ 9″·8, whence the two values of t are 2h. 44m. ·32 and 2h. 58m. ·64, which, applied to the time of opposition, 9h. 13m. ·6, gives the time of commencement at 6h. 15m. ·0 a.m., and the time of ending at 11h. 57m. ·9 a.m.

GRAPHICAL CONSTRUCTION OF A LUNAR ECLIPSE.—Instead of calculating the various phases of a lunar eclipse, they may be obtained by the following graphical process, applied to the eclipse of November 13th and 14th, 1845.

At Paris, mean noon of November 13th, the longitude of the sun exceeded that of the moon by 186° 20′ 7″·4. On the 14th, at the same hour, it exceeded it by 174° 45′ 8″·6. Finding, by interpolation, the instant at which the difference of longitudes was exactly 180°, or the moment at which the moon was in opposition, we obtain, November 14th, at 1h. 4m. 20s. ·9 morning. At this time the parallax of the moon was 55′ 39″·6; that of the sun, 8″·7; the semi-diameter of the moon, 15′ 10″·1; and that of the sun 16′ 12″·3; whence, as before, we conclude that the semi-diameter of the shadow of the earth was 39′ 36″, or increasing it by $\frac{1}{60}$ = 2415″·6. In addition to this, we find that at 0h. 30m. on the morning of the 14th, the longitude of the sun exceeded that of the moon by 180° 16′ 33″·7; and that the latitude of the moon was 0° 25′ 57″·6 S. At 1h. 30m. of the same morning, the excess of the longitude of the sun was 179° 47′ 37″·7, and the latitude of the moon 0° 28′ 51″·5 S. Let the circle A B C D (Fig. 127) represent the dimensions of the shadow of the earth at the distance of the moon (semid. = O A = 2415″·6), let E E′ be the ecliptic.

Fig. 127.



At 0h. 30m. of the morning of the 14th, the longitude of the sun surpassed that of the moon by 180° 16′ 33″·7, the longitude of the centre, O, of the shadow, therefore, only exceeded that of the moon by 993″·7. According to the scale adopted, set down O F = 993″·7. Make F G perpendicular to E E′, and mark off F G = 25′ 57″·6, which is the latitude of the moon at the time, and G is the position of the centre of the moon at 0h. 30m. morning. In the same manner, take O H = 12′ 22″·3, or 742″·3, and H K = 28′ 51″·5, or 1731″·5; and K will be the position of the centre of the moon at 1h. 30m. morning. Draw a right line, M M′, through the points G and K; this line will represent the path of the moon during the eclipse, in reference to the shadow of the earth. The point N is the position of the moon at the moment of opposition, or at 1h. 4m. 20s.·9 morn.

With a radius equal to the sum of the radii of the shadow and of the moon, or 3325″·7 describe a circle with the centre O. The circumference will cut the line M M′ at two points, L L′; and it is plain that, if with those two points as centres, we describe two lesser circles with the radius of the moon, or 910″·1, these two circles will touch the circumference of the shadow A B C D, and represent the position of the moon at the beginning and end of the eclipse. If, moreover, the perpendicular, P O, be raised on M M′, the point P represents the position of the centre of the moon, at the middle of the eclipse.

As the moon employs an hour in passing from G to K, we may, by proportion, determine the time it takes in passing from N to P (if we make the figure large enough); and we thus find that it takes 5m. 41s. in going through this distance, or 5m. 41s. before the opposition, or it is at 0h. 58m. 40s. that the middle of the eclipse happens. In the same manner, we find that the moon should be 1h. 39m. 19s. in passing from P to L′; and it is therefore at 11h. 29m. 21s. of the evening of November 13th that the eclipse commences, and at 2h. 38m. of the morning of the 14th that it ends. The *magnitude* of the eclipse is found, likewise, by this graphical construction; and in this case we perceive that it is partial, since at the moment when the centre of the moon is nearest the centre of the shadow, a portion of its disc lies *without* the latter circle. If we draw the diameter Q S, directed towards the point O, and we take the proportion of this diameter S R, which is in the shadow, and the diameter itself, we find the magnitude. In the present case this amounts to 0·92, the diameter being 1·00. Should the diameter Q S be within the circle of the shadow, or the eclipse be total, the various phases, it will be seen, can be measured off with equal facility, as in the instance here given.

Instead of making use of latitudes and longitudes, the right ascensions and declinations of the sun and moon may be employed, as in the following example of the total eclipse of October 24, 1855 (Loomis Ast.) The Greenwich time of opposition in right ascension is 19h. 17m. 55s. ·6, or the Washington time = 14h. 10m. 29s. ·6, for which time the *Nautical Almanac* furnishes the following data :—

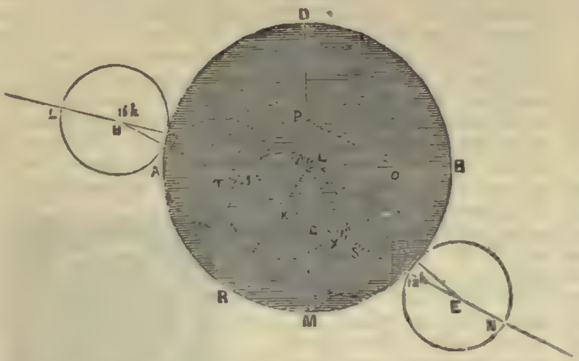
	°	′	″	
Declination of moon . . =	11	42	24·3	north.
Declination of sun . . . =	11	56	48·0	south.
Moon's horizontal parallax (lat. 45°) . . . . . =		59	39·0	
Sun's horizontal parallax =			8·6	
Moon's semi-diameter . . =		16	18·8	
Sun's ,, ,, . . . =		16	7·9	
Moon's hourly motion in R. A. . . . . . =		33	22·1	
Sun's ,, ,, ,, =		2	23·5	
Moon's hourly motion in declination . . . . =		15	40·1	north.
Sun's ,, ,, ,, =		0	52·0	south.

The semi-diameter of the earth's shadow, or CB (Fig. 128) = 59′39″·0 + 8″·6 — 16′7″·9 = 43′39″·7, to which adding one-sixtieth for refraction, C B = 44′23″·4, and the distance of the moon's centre, or C E = 60′ 42″·2. The hourly motion of the moon from the sun in right ascension is 30′ 58″·6, and this reduced to the arc of a great circle by multiplying it by the cosine of the moon's declination = 1819″·9.

From the centre C (Fig. 128), with the radius C B describe the circle A R B, or the shadow of the earth. Draw the line A C B to represent a parallel to the equator, and make C G perpendicular to it, equal to 14′ 23″·7, or the sun's declination minus the moon's declination, the point G being taken below C as the centre of the moon is south of the centre of the earth's shadow. Make C O

= 1819″·9 and C P, to the hourly motion of the moon in declination minus hourly motion of the sun in declination, or 14′ 48″·1; the point P being placed above C, as the moon was moving northward. Join O P and draw parallel to it through G the line N G H, which represents the path of the moon, and on N H let fall the perpendicular C K. At 14h. 10m. 29s. ·6 the moon was at G. To find its position at 14h. we make the proportion :—As 60m. : 10m. 29s. ·6 : : O P : G X. The position of the moon's centre at 14h. is set at X, and its position at 16h., 15h., &c., may be laid down in the same manner by adding the distance O P. Subdividing those into sixty parts, the beginning, end, and middle of the eclipse will be ascertained, answering to the times when the moon's centre is at E, H, and K.

Fig. 128.



The calculation of the eclipse may be performed accurately as follows :—In the right-angled triangle O C P we have C O = 1819″·9 and C P = 888″·1, then C P : R : : C O : tan C P O.

C O = 1819″·9 = 3·2600475
888″·1 = 2·9484619

C P O = 63° 59′ 16″ = 0·3115856 log. tan.

Sin. C P O : R : : C O : O P.

C O = 3·2600475
Sin. C P O = 9·9536150

O P = 2025″·0 = 3·3064325

The angle C P O = angle C G K, G K and O P being parallel. The angle C G E = 116° 0′ 44″; the side C G =863″·7, and the line C E=3642″·2. The angles C E G and the side E G of the triangle C E G are found thus :—

C E : sin. C G E : : C G : sin. C E G.

Comp. C E = 6·4386362
Sin. C G E = 9·9536150
C G = 2·9363629

C E G = 12° 18′ 18″ Sin. 9·3286141

Therefore the angle E C G = 51° 40′ 58″.

Sin. C G E : C E : : sin. E C G : E G.

Comp. sin. C G E = 0·0463850
C E = 3·5613638
Sin. E C G = 9·8946428

E G = 3179″·7 = 3·5023916

To Determine the Time of Describing E G.

As O P : 1h. : : E G (= 3179s. ·7) : 1h. 34m. 12s. ·8, which, subtracted from the time of opposition in right ascension, or 19h. 17m. 55s. ·6 (Greenwich time), gives the time of the beginning of the eclipse, or first contact with shadow, at 17h. 43m. 42s. ·8. The middle of the eclipse is found by the triangle C G K similar to C P O, in which the angles and hypothenuse are given to find C K and K G.

R : C G : : sin. C G K : C K : : cos. C G K : G K.

Sin. C G K=9·9536150 Cos. C G K=9·6420319
C G=2·9363629 C G=2·9363629

C K = 776″·2=2·8899779 G K=378″·8=2·5783948

To Determine the Time of Describing G K.

2025″ : 1h. : : 378″·8 : 673s. ·4 = 11m. 13s. ·4, which, added to the Greenwich mean time of opposition, gives 19h. 29m. 9s. for the middle of the eclipse. The duration of the eclipse will consequently be 3h. 30m. 52s. ·4, and the end 21h. 14m. 35s. ·2 Greenwich mean time. The magnitude of the eclipse is found by subtracting C K = 12′ 56″·2 from C R = 44′ 23″·4, whence K R = 31′ 27″·2; to which adding the moon's semi-diameter, we obtain R L = 47′ 46″·0. Dividing this by the moon's diameter, or 32′ 37″·6, the magnitude of the eclipse=1·464 on the northern limb.

The beginning and end of total darkness is found as follows :—With the radius of the earth's shadow, or C B diminished by the moon's semi-diameter, or 44′ 23″·4—16′ 18″·8=28′ 4″·6, or 1684″·6, describe a circle about the centre C cutting H N in the points S and T, which will represent the points of beginning and end of total darkness.

In the triangle C G S, C G=863·7, C S = 1684·6, and the angle C G S=116° 0′ 44″. Hence C S : sin. C G S : : C G : sin. C S G.

Comp. C S = 6 7735032
Sin. C G S = 9 9536150
C G = 2·9363629

C S G=27° 26′ 12″. Sin. = 9 6634811

And the angle S C G = 36° 33′ 4″.

Sin. C G S : C S : : sin. S C G : S G.

Comp. sin. C G S = 0·0463850
C S = 3 2264968
Sin. S C G = 9 7749107

G S=1116·3 = 3·0477925

To Determine the Time of Describing G S.

2025·0 : 1h. : : 1116·3 : 1984·6 = 33m. 4s. ·6, which being subtracted from 19h. 17m. 55s. ·6, gives 18h. 44m. 51s. for the time of disappearance or beginning of total darkness. The duration of total darkness is therefore 1h. 28m. 36s., and the time of the end of total darkness or reappearance = 20h. 13m. 27s., the *middle* of the eclipse occurring at 19h. 29m. 9s.

The semi-diameter of the penumbra is equal to the semi-diameter of the shadow + the sun's diameter, or 44′ 23″·4 + 32′ 15·8=76′ 39″·2. Let the circle A R B represent, in this case, the limits of the penumbra, then C E=76′ 39″·2 + 16′ 18″·8=92′ 58″·0. In the triangle C G E, the angle C G E=116° 0′ 44″. C G=863·7 and C E=5578″·0.

C E : Sin. C G E : : C G : sin. C E G.

Comp. log. C E = 6·2535215
Sin. C G E = 9·9536150
C G = 2·9363629

C E G=7° 59′ 56″ Sin. = 9·1434994

And angle E G G=55° 59′ 20″.

Sin. C G E : C E : : sin. E C G : E G.

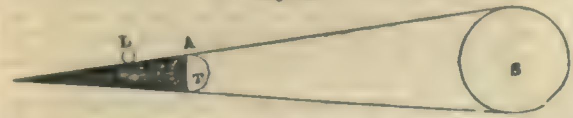
Comp. sin. C E G = 0·0463850
C E = 3 7464785
Sin. E C G = 9·9185174

E G=5144″·9 = 3·7113809

As 2025 : 1 h. : : 5144·9 : 2h. 32m. 26s. ·5, which gives the time of describing E G. This subtracted from 19h. 17m. 55s. ·6, gives 16h. 45m. 29s. ·1 for the time of first contact with the penumbra; and the whole duration being 5h. 27m. 19s. ·8, we get the time of ending, 22h. 12m. 48s. ·9 for the last contact with the penumbra.

An eclipse of the moon can only be seen at those parts of the earth where the moon is above the horizon, as well as the shadow of the earth, or at least a portion of this shadow. As this can only take place when the sun is below the horizon, it is only during the night that eclipses of the moon are visible. It may happen, however, that the eclipses may be seen for a few moments before the setting of the sun, or after its rising. This is due to the refraction of the atmosphere, which, when the sun is altogether below the horizon, as well as that part of the moon which is eclipsed, elevates both objects above the horizon, and an observer at A (Fig. 129) will be able to see the sun at one side, and the eclipsed moon on the other.

Fig. 129.



Eclipses of the Sun.—Whilst eclipses of the moon follow from the interposition of the earth, and prevent the light of the sun from reaching to, and illuminating the surface of our satellite in the usual manner; eclipses of the sun are due to the contrary cause, being the shadow of the moon falling on certain parts of the earth (passing over it like the shadow of a cloud), and hiding the disc of the sun at those districts. The dimensions of the shadow at the surface of the earth may be found in the same manner as in the former case; and an idea of the different kinds of solar eclipses may be gathered from the following diagrams. Let L be the position of the moon (Fig. 130) situated exactly in a line with the sun S, and the earth T, and at a distance L T, which corresponds to the distance of the sun and moon at the time. The smallest distance of the centres of the earth and moon being equal to 55·947 semi-diameters of the former body, and the greatest value of the shadow O L (calculated in the manner already mentioned) being 59·73 semi-diameters of the earth, it would follow that, under those circumstances, the shadow of the moon would extend beyond the centre of the earth, and consequently, that at that region of the earth where the shadow would fall (as at *a b* Fig. 131), the eclipse would be total—the moon completely obscuring the sun's disc.

Fig. 130.

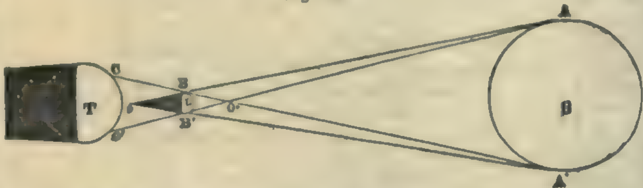


Fig. 131.

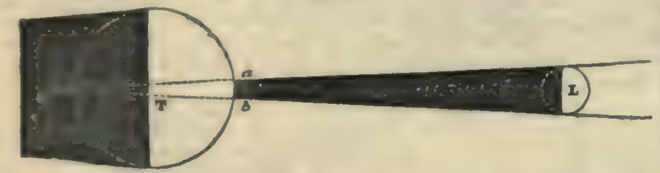
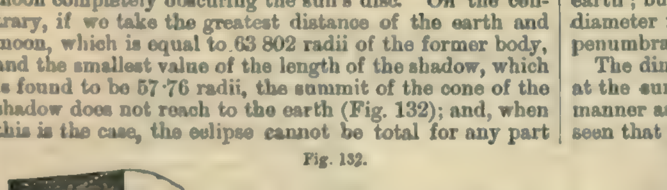


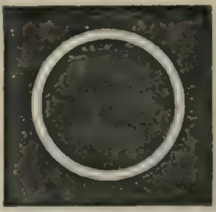
On the contrary, if we take the greatest distance of the earth and moon, which is equal to 63·802 radii of the former body, and the smallest value of the length of the shadow, which is found to be 57·76 radii, the summit of the cone of the shadow does not reach to the earth (Fig. 132); and, when this is the case, the eclipse cannot be total for any part of the earth; on all that hemisphere turned towards the sun, we perceive a portion, though not the whole of its disc.

Fig. 132.



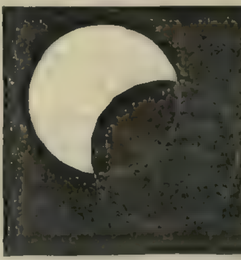
There is, however, a peculiarity to be noted; which is, that if we prolong the cone of the shadow of the moon beyond the summit O, the base of the second cone formed will be situated on the portion of the surface of the earth *c d*, and for all this part the eclipse will appear *annular*—*i. e.*, the moon will appear projected upon the disc of the sun at all those parts of the earth, and the exterior portion of the disc of the sun will consequently appear under the form of a luminous ring. When the moon is placed between the sun and the earth, the eclipse will be either total or annular for certain parts of the earth, according as the distances of the sun and moon are more or less great. This is also apparent from considering the respective dimensions of the discs of the sun and moon at different periods. The apparent diameter of the moon, as seen from the surface of the earth, may increase to 34′ 6″, whilst the diameter of the sun may decrease to 31′ 31″; and if an eclipse take place under those circumstances it must be total. As the diameter of the moon, on other occasions, may decrease to 29′ 22″, whilst that of the sun can attain its maximum value of 32′ 35″·6, it will follow that when an eclipse happens under such circumstances, it must be annular, and that for a few moments, at such parts of the earth as are exactly in a line with the centres of the sun and moon, the moon will be seen projected upon the sun; the exterior parts of the sun will continue visible, and shine with their usual brilliancy (Fig. 133).

Fig. 133.



At the parts of the earth adjoining those which are exactly in a line with the centres of the sun and moon, the eclipse cannot be total or annular, as only a portion of the moon can be projected on the disc of the sun. This will be apparent from Fig. 130, in which it is easy to perceive that at all those points situated to the interior of the cone C O′ C′, and not comprised within the real shadow B O B′, a similar appearance will be produced as in the case of the *penumbra* of the earth's shadow, on the lunar disc, during an eclipse of the moon. From any such point we should consequently perceive the circular disc of the moon intercepting a portion of the surface of the sun (as in Fig. 134); and the nearer the observer is situated to the real cone of shadow B O B′, or the further he is distant from the surface of the cone C O′ C′, the greater will be the portion of the solar surface covered by the moon.

Fig. 134.

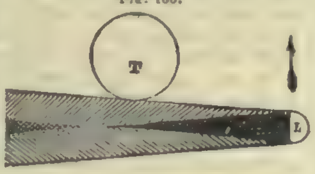


We have seen, in the case of lunar eclipses, that the whole disc of the moon can be hid by the shadow of the earth; but the moon's shadow only covers an area whose diameter is 180 English miles at the greatest; while the penumbra may reach to nearly 5,000 miles in diameter.

The dimensions of the lunar shadow, here mentioned at the surface of the earth, are calculated in the same manner as that of the earth's shadow. We have already seen that the semi-diameter of the latter is equal to the parallax of the sun added to that of the moon, and from which the apparent semi-diameter of the sun is to be subtracted; in the same way the semi-diameter of the moon's shadow at the earth is equal to the parallax of the earth added to the parallax of the sun at the distance of the moon, from which sum we subtract the apparent semi-diameter of the sun, as seen from the moon. The latter quantity is found by increasing the semi-diameter as seen from the earth, in the proportion of the distances of the moon and earth from the sun at those times, or the apparent semi-diameter of the sun seen from the moon, = apparent semi-diameter of the sun $\left(\frac{D}{2}\right)$ as seen from the earth $\times \frac{K}{k}$, K being the distance of the earth from the sun, and k the distance of the moon from the sun. The sun's horizontal parallax at the moon is equal to the sun's horizontal parallax at the earth, increased by the ratio of the distances, and diminished by the ratio of the diameters of the sun and earth; or the sun's horizontal parallax at the moon = sun's horizontal parallax on the earth (p) $\times \frac{r}{R} \times \frac{K}{k}$, r being the moon's *true* semi-diameter, and R the earth's *true* semi-diameter. Substituting those values in the preceding expression, the semi-diameter of the moon's shadow will be $\frac{\delta}{2} - \frac{D}{2} \times \frac{K}{k} + p \cdot \frac{r}{R} \cdot \frac{K}{k}$. The parallaxes of the sun and moon may be used instead of the ratio of their distances in this expression, and as $p = \frac{R}{K}$ and $P = \frac{R}{K-k}$, consequently $\frac{K}{k} = \frac{P}{P-p}$. As $\frac{r}{R} = \frac{\delta}{2 P}$, we also find $\frac{\delta}{2} + p \frac{r}{R} \cdot \frac{K}{k} = \frac{\delta P}{2 (P-p)}$; and the apparent semi-diameter of the moon's shadow $= \frac{\delta - D}{2} \times \frac{P}{P-p}$. We perceive from this that when the moon's diameter is equal to that of the sun, the apparent diameter of the moon's shadow is nothing, or the apex of the cone just reaches to the earth. When the moon's diameter is less than that of the sun, the expression is negative, and the shadow cannot reach the earth's surface. The formulæ for the dimensions of the penumbra may be adapted to the moon's shadow in a similar manner. If the apparent semi-diameter of the earth, or the moon's horizontal parallax, be added to the apparent semi-diameter of the shadow, the distance of the centre of the moon's shadow and the centre of the earth is found; and the limits of the distance of the moon from her nodes, when an eclipse can happen, will readily be obtained, and is found to be 17° 27′.

It is thus seen that the same formulæ apply to the calculation of both lunar and solar eclipses, in so far as the times at which the earth in general would become enveloped in the shadow of the moon, are concerned; but this would only have reference to an observer situated on the moon, who would thus be enabled to foretel and note the duration, times, and magnitude of an eclipse, the instant at which the penumbra entered upon the enlightened disc of the earth, and the period of total eclipse. In Figure 135 we perceive the phenomena which would follow from the interposition of the moon between the sun and earth; the fictitious observer situated at L, as the moon moved in the direction of the arrow, carrying with it the real shadow and the penumbra, would first see the penumbra touch the disc of the earth T, then (if the eclipse were total) the contact of the real shadow; and the above formulæ would give the instant at which those appearances would happen. The two cones, that of the real shadow and the penumbra, would continue to traverse the portion of the hemisphere turned towards the moon, covering, successively, the various parts of its disc, advancing on new regions, and leaving those which it had previously shadowed. Finally, the cone of the shadow, then that of the penumbra, would again become tangents to its surface; and the instant at which this would take place, would mark the end of the eclipse. But in the case of a solar eclipse on the earth's surface, the time at which it became generally visible on the earth, or the period of first contact, would not be of such interest to any observer, as the time at which it would become visible, or total, at his own particular locality; and the position of the observer at different parts of the moon was not taken into consideration in the foregoing calculations, the latitude and longitude of the several places on the moon being a matter of indifference to an observer on the earth. But to an observer on the earth it is a matter of great consequence to know the exact time at which the eclipse would commence at his own station (for it will not begin for him until such period), and also the extent and duration of the shadow of the moon, when it passes over a known station of any assigned latitude and longitude. The calculation of an eclipse of the sun is, therefore, more difficult than that of the moon, because more is required to be determined. The foregoing formulæ may be applied to the case of an eclipse of the sun, viewed from the centre of the earth, to which they will exactly apply. But to the position of an observer on the surface of the earth, various corrections of parallax have to be applied on account of the angle which he makes with the centre of the earth, whether in latitude or longitude, as the various phases of the eclipse at the different parts of the earth, by which it is visible at some parts and not at others, are due altogether to parallax. In calculating a solar eclipse for any assigned position, it is necessary to correct the angular distances, or the longitudes and latitudes, for the effects of parallax. This requires a long and intricate calculation; but the principal appearances and phenomena, as likewise the times of contact, greatest eclipse, duration, and magnitude, may be determined in the following simple manner :—

Fig. 135.



GEOMETRICAL OR GRAPHICAL CONSTRUCTION OF A SOLAR ECLIPSE.—If an observer be supposed to be situated at the centre of the sun, and the moon be interposed between the sun and earth, he will observe the moon passing across the disc of the earth in the same manner as an observer on the earth sometimes perceives the satellites of Jupiter traversing the bright disc of the latter planet. In the same manner, likewise, as an observer on the earth perceives the equator and axis of the sun inclined at different angles to the north and south points and to the ecliptic, at the various seasons of the year (pages 929, 930, Figs. 27 and 28), the observer at the sun would perceive the poles and equator of the earth change their situations in respect to the ecliptic, but in a greater degree, the solar equator being only inclined at an angle of 7° to the ecliptic, whilst that of the earth is inclined at 23½°. At the time of the vernal equinox, the plane of the equator passes through the sun, and the north and south poles of the earth will consequently appear to an observer at the sun situated at the margin of the disc, the parallels of latitude describing straight lines, as in Fig. 136. At the summer solstice, the north pole of the earth will be turned towards the sun, the south pole will be invisible, and the parallels of latitude will, to an observer on the sun, be projected into ellipses, as at Fig. 137. At the autumnal equinox, the parallels of latitude will again appear as straight lines, but the poles of the earth will be on the opposite side of the poles of the ecliptic, as at Fig. 138. Finally, at the winter solstice, the south pole will be turned towards an observer on the sun, and the parallels of latitude projected into ellipses, as in the former case, but in the contrary direction (Fig. 139).

Fig. 136.

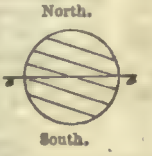


Fig. 137.

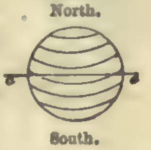

Fig. 138.

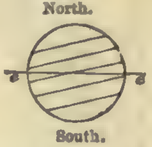

Fig. 139.

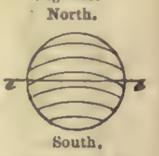
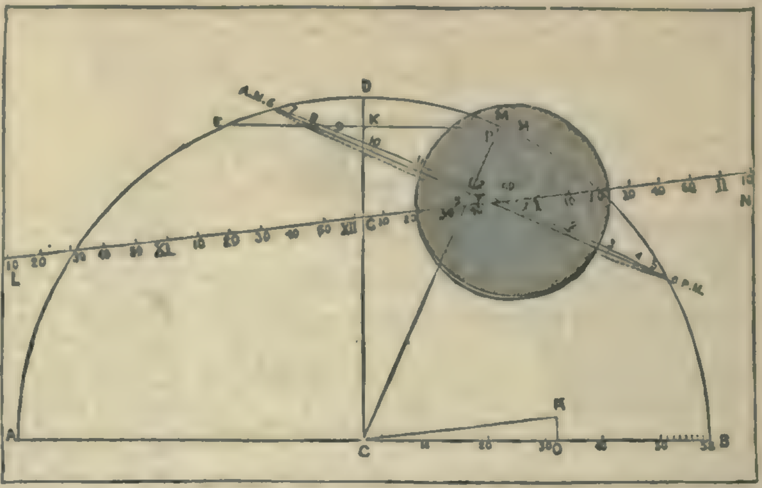


By projecting in this manner the surface of the earth at the various seasons of the year, as it appears to a spectator on the sun, we can represent any parallels of latitude. By doing so for the day on which the eclipse is expected to occur, we can mark along the projection, the position of the place at the different hours of the day; and the moon's apparent path across the earth's disc may be laid down in a similar way, and its position from hour to hour noted. In order to determine the time at which the eclipse appears greatest at this locality, we must find that point in the moon's path and the path of the observer marked with the same times, and which are at the *least* distance from each other. The beginning or end of the eclipse will be determined by finding those points in the moon's path and in the path of the spectator which are marked with the same times, and whose distance is equal to the sum of the semi-diameters of the sun and moon. As an illustration of this method we will choose the solar eclipse which was visible in the British Islands, March 15th, 1858 (Figs. 140 and 141), and generally seen throughout the north of Europe. This is the greatest which has occurred or will happen in this country for many years. The times and phases of the eclipse are for the latitude of Greenwich, or 51° 28′ 38″.

Fig. 140.



By the *Nautical Almanac* the time of new moon is March 15d. 0h. 12m. 0s., mean time, corresponding to March 15d. 0h. 2·9m. apparent time, the equation of time being — 9·1m. The following elements are calculated for that epoch ;—

	°	′	″
Sun's longitude	354	38	38
Sun's declination	2	7	15 S
Moon's latitude	0	37	43 N
Moon's hourly motion in longitude .	0	34	18
Sun's hourly motion in longitude .	0	2	29
Moon's hourly motion in latitude .	0	3	9
Moon's equatorial horizontal parallax	0	58	15·2
Sun's equatorial horizontal parallax .	0	0	8·6
Moon's true semi-diameter . .	0	15	54·6
Sun's true semi-diameter . .	0	16	6 5

The *geocentric* latitude, which is found by applying the angle of the vertical (p. 922) to the *geographical* latitude (and which in this case is 11′ 13″), = 51° 17′·4. The moon's *equatorial* horizontal parallax being that which is given by the tables, the horizontal parallax for any other latitude will be found by applying the following correction :—

Latitude.	Moon's Horizontal Equatorial Parallax.		
	53′	57′	61″
°	″	″	″
15	0·7	0·8	0·8
20	1·2	1·3	1·4
25	1·9	2·0	2·2
30	2·6	2·8	3·0
35	3·5	3·7	4·0
40	4·4	4·7	5·0
45	5·3	5·7	6·1
50	6·2	6·7	7·2
55	7·1	7·7	8·2
60	8·0	8·6	9·2
65	8·7	9·4	10·0
70	9·4	10·0	10·8
75	9·9	10·7	11·4
80	10·3	11·0	11·9
85	10·6	11·4	12·1
90	10·6	11·4	12·2

The moon's horizontal parallax for Greenwich will therefore be 58′ 8″·0 ; and as the relative positions of the sun and moon will remain the same if the sun be supposed to retain a fixed position, and the moon be supposed to be affected with the difference of both their parallaxes, the relative parallax, or that which affects the relative positions of the two bodies, will be 57′ 59″·4, which is the semi-diameter of the earth as seen from the moon, that of the moon seen from the earth being 15′ 54″·6. The relative sizes of their discs will be in the same proportion if viewed from any distance. With a radius A C (Fig. 140) equal to 57′ 59″·4, or if practicable with one of 3,479 parts from any scale of equal parts, describe the semicircle A D B with the centre C, which represents the northern half of the enlightened part of the globe of the earth viewed from the sun. If the place were in south latitude, the lower half of the earth's disc should be that represented. The line A C B represents the ecliptic, and the perpendicular C D the axis of the ecliptic. Take from a sector, or any other convenient scale, the chord of 23° 28′ (which is the obliquity of the ecliptic) to the radius C B, and set it off from D to H and E in the periphery of the circle, or the angle D H = 23° 28′ may be at once set off. Draw the straight line E H, cutting C D in K. By considering Figs. 136, 137, 138, 139, it will be seen that the north pole of the earth, as viewed from the sun, will constantly appear on this line E K H, E being its position at the autumnal, H at the equinox, and K at the solstices. Its distance from H at any time will be equal to the versed sine of the sun's longitude, or its distance from K will be the sine of the difference between the sun's longitude and 90° or 270°. To the radius E K take the sine of 354° 38′·6 – 270° = 84° 38′·6, and set it off from K to P, the north pole of the earth ; for when the sun's longitude is between 270° and 90°, the north pole lies to the right of the pole of the ecliptic, and to the left when it is in the other six signs. Draw C P, which is the northern half of the earth's axis, and produce it until it cuts the circle A D B in M.

In order to draw the parallel of latitude of Greenwich on the earth's disc as seen from the sun, from sunrise to sunset, the following method may be taken :—If the latitude of the place were exactly equal to the sun's declination, it would be vertical at noon, and the place of observation would be at the centre C. But as the latitude of the place exceeds the sun's declination by 53° 24′, it must be seen that distance north of the place where the sun is vertical, or when projected on the disc ; this will be the sine of that angle which is set off from C to 12, which is the apparent position of Greenwich at noon of March 15. The position of Greenwich at midnight is determined in the same manner by taking C S equal to the sine of 49° 10′ to the radius A C, and the point S will be its position at midnight. It is easily seen that the line 12 S will be the shortest diameter of the ellipse into which the circle of latitude is projected. To determine the length of the longest diameter, as it is not shortened by being viewed obliquely, it will be equal to the diameter of the parallel of latitude, or to the cosine of the co-latitude = 38° 43′ ; and setting off this distance from the point T (which is situated exactly between S and 12) on the line perpendicular to C M, we obtain the extremities of the longest axis of the ellipse, or the points at which Greenwich will appear at 6 A.M. and 6 P.M. At the times of the equinoxes these hours will be projected at the edges of the disc (as they are almost so in the present instance), but at all the other times of the year they will be more or less distant.

In order to obtain the position of Greenwich at any other hour of the day, we take, with a radius equal to T 6, the sine of 15°, or one hour of time, which is set off on each side of the point T. The sines of 30,° 45°, 60°, 75° may be obtained and set off in the same way. Through these points draw lines parallel to C M. With a radius equal to S T take the sines of 75, 60, 45, 30, 15, which are marked off on each side of the line T 6 respectively at the points 15°, 30°, 45°, &c., as before. By drawing an elliptic curve through those points, the several positions of Greenwich at each hour of the day from sunrise to sunset are readily obtained; and by continuing it on the opposite side, its position (here represented by the dotted line) is represented during the night. The points at which the ellipse touches the circle A D B show the time of sunrising and sunsetting. It will be seen that the ellipse will be more open near the time of the solstices, and more eccentric near the equinoxes (as is the case in the present instance). The points 6, 7, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5, 6, represent the position of Greenwich at those hours, which are marked from noon towards the right. If the sun's declination had been north, the diurnal path of Greenwich would be on the lower or dotted portion of the ellipse. If possible, the figure should be constructed on such a scale that the hours might be divided into minutes with sufficient certainty.

Having represented the position of Greenwich at the various hours of the day, as they appear to a spectator on the sun, the next thing to be done is to draw the moon's apparent path across the earth's disc. From the same scale of equal parts used in the radius C B, measure off an interval equal to the moon's latitude, or 37′ 43″; and, as the moon's latitude is north, make it equal to C G, above the ecliptic A B. Take in the same scale, C O, equal to 31′ 49″, and apply it on the line C B, from C to O. This quantity represents the hourly motion of the moon from the sun in longitude. Draw O R perpendicular to C B, and make it equal to 3′ 9″, the hourly motion of the moon in latitude; and as the moon is moving northwards, set it above the line C B. The line C R, joining the points C and R, represents the relative hourly motion of the sun and moon; and parallel to this line draw the orbit of the moon, or L G N, on which, by means of the hourly motion C R, we can mark the position of the moon from hour to hour; and as the moment of new moon at Greenwich is at three minutes past noon of apparent time, the position of the moon at apparent noon is found by taking the proportion of 60m. : 3m. : : the distance C R, to the distance G XII., which is measured to the left of the point G, and shows the position of the moon at twelve o'clock, or noon. By taking the line C R in the compasses, the other hours may be marked off which represent the places of the moon at those times. If the scale be made sufficiently large, those spaces may be subdivided into sixty parts or minutes.

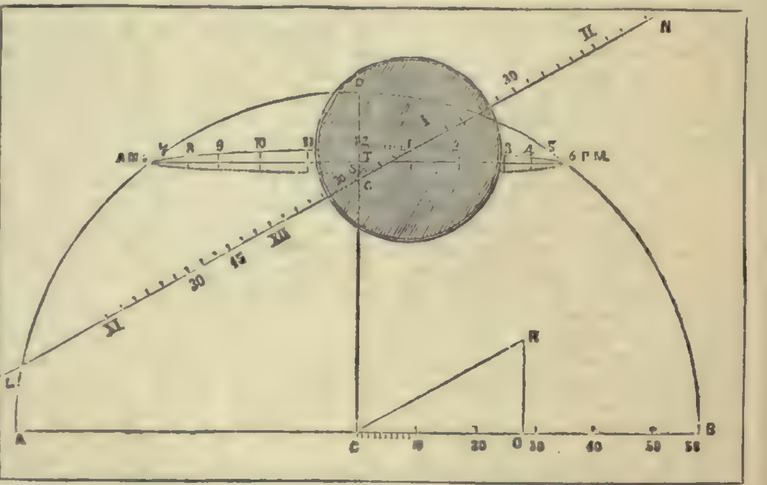
In order to find the times at which the eclipse is greatest, those times must be found on the path of the spectator, and the path of the moon, which are marked with the same times, and which are at the *least* distance from each other. The times which best correspond to those conditions in the present case are those of 12h. 52m., or 52 minutes past noon of apparent time. The appearance of the moon at any hour may be shown by taking its semi-diameter to the adopted scale of equal parts—and which in this instance = 15′ 54″·6—and with this radius to describe a circle whose centre is the point where the moon's centre is at the given time. The position of the disc of the sun at the same moment may be represented in the same manner, by taking a radius equal to the semi-diameter of the sun = 16′ 6″·5, and describing a circle taking the *same* time on the path of the spectator for a centre. The relative positions given in the diagram are those at which the eclipse are greatest, when the magnitude of the eclipse = 0·976, on the northern limb, the sun's diameter being 1·000; and as the moon's semi-diameter is less than that of the sun, the eclipse will be annular and partial. The sun's centre must be invisible over all that portion of the earth, represented as being covered by the moon's disc, and throughout a much larger area some portion of the sun's disc will be obscured. The extent of this area will be found by describing a circle with the same centre, and whose radius is equal to the sum of the semi-diameters of the sun and moon, measured on the adopted scale.

In order to determine the times of the beginning and end of the eclipse, we take from the scale of equal parts a distance equal to the sum of the semi-diameters of the sun and moon = 32′ 1″·1, and beginning near L, place one foot of the compasses on the moon's path, and the other on the path of the spectator, and shift them backwards and forwards until the *same times* are found on the two paths, which are this distance apart. This will give the time of the beginning of the eclipse, which in the present case is 11h. 32m. A.M., *apparent* time. In the same manner find the corresponding times on the other side of the moon's path, and the end of the eclipse will be determined, which in the present case is 2h. 9m. P.M., of apparent time. We thus determine :—

	Apparent Time.	Mean Time.
Beginning of Eclipse .	11h. 32m. A.M.	11h. 41m. A.M.
Greatest Obscuration .	0h. 52m. P.M.	1h. 1m. P.M.
End of Eclipse . . .	2h. 9m. P.M.	2h. 18m. P.M.

When this projection is made on a sufficient scale, and carefully finished, it will give the above times accurately to one or two minutes, and furnish a useful chart of the various phases of the eclipse. By drawing different parallels of latitude, we can determine the phases of the eclipse for any place. The results are obtained in apparent time, because both the moon's path and the path of the spectator correspond to apparent time.

Fig. 141.



Projection by Right Ascensions and Declinations.—Instead of employing longitudes and latitudes in the projection of a solar eclipse, we may make use of right ascensions and declinations; and as those are the elements given in the *Nautical Almanac* for these phenomena, it may be convenient to append an example for this eclipse, but for a different latitude and longitude. The radius of projection, C B (Fig. 141), is the same in this case as in the last, being the difference of the horizontal parallaxes of the sun and moon ; C D is the meridian or circle of declination ; the ellipse represents the projection of the parallel of latitude ; L G N the moon's apparent path ; C G the difference of *declination* of the sun and moon at the conjunction in right ascension, and C 12 the sine of the sun's zenith distance at noon. The elements for the above eclipse, given in the *Nautical Almanac*, are as follows, and the place may be considered as situated 0° 6′ west of Greenwich, and at 52° 41′ of north latitude :—

Greenwich mean time of conjunction in right ascension = March 15, 0h. 44m. 7s. ·6, or March 15, 0h. 43m. 44s.·2 of the mean time at the given place.

The apparent time will be March 15, 0h. 34m. 37s. ·8, the equation of time being—9m. 6s. ·4. The moon's hourly motion in right ascension = 30′ 16″·4 ; and the sun's, 2′ 17″·1 ; and the relative hourly motion of the moon from the sun on right ascension 27′ 59″ 3, = which must be reduced to the arc of a great circle by being multiplied by the cosine of the declination, or 1° 24′ 21″·8 = 27′·98.

The radius A C = 58′·0 as in the last case.

Hourly motion of moon from sun . .	= 27′·98
Moon's hourly motion from sun in declination	= 15′ 31″
Moon north of sun	= 42′ 53″
Sum of semi-diameter of sun and moon	= 32′ 1″
Difference	= 11″·9

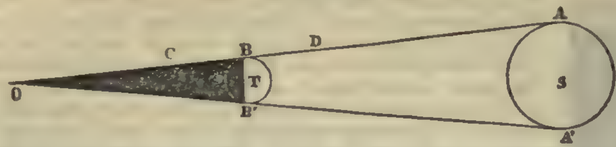
The semicircle A D B represents the northern half of the earth's disc drawn with a radius, A C, equal to 58′ 0, as in the last case C D is the axis of the earth. The position of a point of 52° 41′ of north latitude, or 52° 30′ of geocentric latitude, will be obtained in a similar manner to the last, and its place on the axis of the earth at noon and midnight will be 54° 37′ and 50° 23′ to the north of the point where the sun is vertical. Obtain, by means of a sector or graphically, the sines of those angles to the radius C B, and set them off on the line C D from C to S. The position of the locality whose latitude is 52° 30′ at 6h. in the evening, will be obtained by taking the cosine of the latitude, and marking it off on the line T 6 — T 6, perpendicular to C D on each side of T, that point being the bisection of the two points S 12. These distances may likewise be obtained, and with more exactness, by multiplying the radius C B = 58′ by the sines of 54° 37′, and 50° 23′, the former of which gives the distance C 12, and the latter C S, the distance T 6 being obtained by multiplying 59′ by the cosine of 52° 30′ ; and those quantities may be marked off by means of the same scale of equal parts, as adopted in the radius C B. The other times in path of the observer, are determined as in the former instance. The moon's path, according to right ascension and declination, is laid down as before. Take the difference of the declinations of the sun and moon = 42′ 53″, and set it off, from C to G above the line A C B, because the moon is north of the sun. Take C O equal to the hourly motion of the moon from the sun in right ascension, reduced to a great circle, and set it off from C to O. Make O R, which is perpendicular to C B, equal to 15′ 31″, the moon's hourly motion in declination from the sun. The line C R represents the hourly motion of the moon from the sun in regard to right ascension and declination, and the line L G N, drawn parallel to this, represents the moon's path across the earth, the point G being the position of the moon's centre at the moment of conjunction in right ascension. The even hours may therefore be marked off on this point, by taking the point G to be 34m. 38s. past noon on March 15th ; and the line C R to be the hourly motion of the moon, and the position of the moon at noon will be found by the proportion as 60m. : 34m. 38s. : : C R : G XII. : : 31·6 : 18·2. The hours on the moon's path should, if possible, be subdivided to minutes, and the same on the path of the spectator. The sum of the semi-diameters of the sun and moon being taken on the adopted scale = 32′ 1″, that distance is taken in the compasses, and those are shifted backwards and forwards, as in the former case, until the *same* times are found on the moon's path and the path of the spectator, which are exactly at this distance apart. When the left leg of the compass is on the moon's path, and the right leg on that of the spectator, this will give the commencement of the eclipse ; and when the *right* leg of the instrument is on the moon's path, the left on that of the spectator, and the corresponding times are again found at the same distance apart, we obtain the end of the eclipse in the same manner. By applying the side of a small square to the moon's path, and moving it along until the other side cuts the same hour and minute on both lines, we obtain the nearest approach to the centre of the sun and moon. If the scale of the projection be made of sufficient dimensions, the distance of those two points will show whether the eclipse be total or annular ; if less than the difference of the semi-diameters of the sun and moon, it will be annular at that locality. By describing a circle whose radius is equal to that of the moon, and whose centre is situated on the moon's path at the time of the nearest approach of the centres, we have a circle representing the moon's disc. Taking the radius of the sun in the same manner, and the corresponding time on the path of the spectator for a centre, we describe the position of the solar disc, and their intersection will represent the phase of the eclipse at the moment of greatest darkness. With the points of the compasses at a distance apart, equal to the differences of the semi-diameters of the sun and moon, the times of the formation and rupture of the annulus may be determined in a similar manner, as the beginning and end of the eclipse. In the present case we obtain for the beginning and end of the eclipse at the given position 11h. 32m. A.M., and 2h. 8m. P.M. of apparent time, which is equal to 11h. 41m. and 2h. 16m. of mean time. The time of greatest obscuration is 12h. 52m., found by taking the shortest distance between the corresponding times on the paths of the moon and spectator, answering to 1h. 1m. P.M. of mean time as before.

From the relative dimensions and positions of the sun and moon, it will be seen that the eclipse is central and annular at this locality—viz., at 0° 6′ (of arc) of west longitude and at 52° 41′ of north latitude, or at a point which is a little to the east of Peterborough. The line of central eclipse passed across England from Bridport in Dorsetshire (at 2° 51′ of west longitude, and 50° 43′ of north latitude) to the Wash, and a little to the north of the towns of Sherborne, Marlborough, Oxford, Buckingham, and Wisbeach. The diameter of the moon so closely approaches to that of the sun, that this eclipse might be *total* in the vicinity of the island of Madeira by the augmentation of the former value. At the station for which the above calculation is made, the duration of the annulus was only 12s. ·3.

Annular eclipses are more common than total eclipses, and the prediction of their times and duration shows more palpably than anything else, the great accuracy to which the tables of the sun and moon have been carried ; but astronomers still rely upon the careful observation of those phenomena, in order to correct the places of those bodies as given by theory ; and the times of the eclipse of March 15th, 1858, are liable to be slightly affected by small errors in the tabular places of the sun and moon ; whilst errors which are known to exist in the received diameters of those bodies affect the duration of the annulus. These errors, however, only amount to a fractional part of a second at most. How different is this from the prediction of the eclipse which was to have happened at Rome in 1684, which the tables at that time in use predicted would be *total*, whilst in reality only three-fourths of the sun disappeared. In the prediction of the eclipse of 1706, the tables of La Hire were four or five minutes in error.

Annual Number of Eclipses of the Sun.—Eclipses of the sun on the earth generally are more frequent than eclipses of the moon, in the proportion of three to two, as it will be seen should follow from the following considerations. In order that there be an eclipse of the moon, it must happen that the moon penetrates the cone of shadow B O B′ at C (Fig. 142); and it is easily seen, that in order that there be an eclipse of the sun at *some portion* of the earth, it must penetrate into the cone A O A′ at the point D. As the diameter of the cone is larger at D than at C, it consequently happens that the moon passes more frequently through the former than the latter, and that eclipses of the sun will be more frequent than those of the moon. Theory and observation alike prove, that in the period of 18 years 11 days, in which, as before mentioned, the moon passes to the same position in respect to the sun and its nodes, there are in general seventy eclipses, of which forty-one are of the sun, and twenty-nine of the moon. There cannot be more than seven eclipses in one year, nor less than two; and if the latter, they must both be eclipses of the sun. In any *given place*, however, the eclipses of the moon will appear to be more frequent than those of the sun, as will be apparent when we come to consider that the former are due to the total or partial extinction of light on the surface of our satellite, and are seen on every occasion on that hemisphere of the earth, where the moon is above the horizon. Eclipses of the sun, on the contrary, can only be seen at one zone of the earth, and that a very narrow one; for, in addition, it will be seen that the dimensions of the shadow of the moon are small as compared with that of the earth. Out of the forty-one solar eclipses, which may occur in eighteen years, there are in general twenty-eight of those which may become central according to circumstances—that is, either total or annular. It results from Du Séjour's calculations, that the greatest possible duration of an eclipse of the sun cannot be more than 4h. 29m. 44s. for a place situated at the equator, or 3h. 26m. 32s. for the latitude of Paris. In total eclipses, the greatest possible duration of total obscuration may only be 7m. 58s. at the equator, and 6m. 10s. at the latitude of Paris. In the case of annular eclipses, the greatest possible duration of the phase is 12m. 24s. at the equator, and 9m. 56s. at the latitude of Paris. Such combinations are of course very rare. The total eclipse of 1706 lasted for 4m. 10s.; that of 1715, at London, 3m. 57s.; the total eclipse of 1806, at Kinderhook, in America, continued for 4m. 37s.; and that of 1724, at Paris, for 2m. 16s. In the eclipse of 1778, the darkness continued for four minutes.

Fig. 142.



Phenomena observed during a Total Eclipse.—The great and sudden darkness which takes place at the moment of a central eclipse is, of course, the great phenomenon to be witnessed in solar eclipses, but many other curious circumstances have been unexpectedly noticed by the telescopic observers during the eclipses of 1842 and 1851, which serve to throw some light on the constitution of the sun; so true is it, as Arago observes, that, in the intellectual world as in the terrestrial, we cannot advance a step without discovering a new horizon. It is not, however, to be strictly understood that those appearances were first perceived on these occasions, but rather that they were observed with greater care; and from the number of observers engaged, and the different instruments they made use of, the results are placed beyond doubt, and confirm the desultory notes of former astronomers.

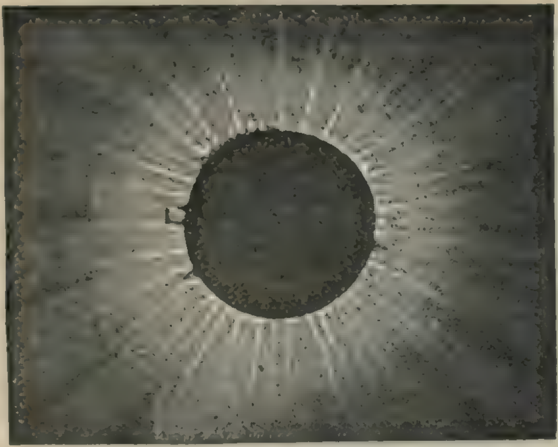
The darkness which follows the total obscuration of the sun's disc, though momentary, is generally very great, though not complete. The total eclipse which occurred in England, on June 17th, 1433, was long remembered under the name of the "Black Hour." That of 1598 was equally imprinted on the memories of the peasantry, and called to mind by the name of the "Black Saturday;" whilst the total eclipse of 1652, is recorded in Scotland by the name of "Mirk Monday." Nor, if we are to allow the testimony of Dr. Halley, are those titles misapplied in such cases. "I forbear," he says, in his communication to the Royal Society, on the eclipses of 1715, "to mention the chill and damp which attended the darkness of this eclipse, of which most spectators were sensible and equally judges. Nor shall I trouble you with the concern that appeared in all sorts of animals, birds, beasts, and fishes, upon the extinction of the sun, since ourselves could not behold it without some sense of horror." In the eclipse of 1706, during the period of total darkness at Geneva, bats flew about as at dusk, swallows were seen flying about, and cage-birds put their heads under their wings. The stars appeared as thickly strewed as at the time of full moon. In the eclipse of 1842, several stars of the first magnitude, as well as the planet Mars, were distinctly visible. The colour of the sky at those times does not appear, however, either to belong to the darkness of night nor the hue of twilight; in some places it was even noticed to be of a violet tint; and *red* stars, such as those of *a* Orionis, Aldebaran, and others, were noticed to be *white*. At Montpellier, in the eclipse of 1842, the light had acquired a livid tint, imparting to the human countenance an aspect which it was painful to contemplate; and the spectacle was generally allowed to be of an extraordinary and appalling character. An owl was seen to leave the tower of St. Peter, the bats left their retreats, the swallows disappeared, the fowls went to roost, and the cattle stood still in the field. A heavy dew fell at Perpignan, Turin, and Vienna, during the obscuration. Similar appearances were noticed during the total eclipse of 1851, by the numerous observers stationed in the path of central eclipse in Sweden.

Even during the greatest obscuration, and when the disc of the sun is completely hidden by that of the moon, its place is still made apparent by the brightness in the part of the heavens in which it is situated. This light appears in the remarkable form of a corona or lustrous ring, and it has sometimes been so bright as to be observed and mistaken for an *annular* eclipse. This luminous ring was seen during the eclipse of 1567, and was mistaken for the margin of the solar disc; it was equally visible in that of 1598. Its *radiating* appearance seems to have been first noticed in the eclipse of 1652, and appeared to be endowed with a sort of rotatory motion. In every subsequent eclipse, observed under any favourable circumstances, the corona has been observed with equal plainness, generally of about one-tenth or one-twelfth of the diameter of the moon, and of a pearl-white colour, or, in the words of an observer, "of that bluish tint which distinguishes the colour of quicksilver from that of a dead white." In the eclipses of 1842 and 1851, it was the principal circumstance to which the attention of the observer was directed; and M. Arago was able to perceive what might be termed *two* rings—the inner one, or that which bordered on the moon's limb, being of a uniform brightness, whence it faded imperceptibly outwards, and terminated irregularly. The inner ring was 3′ or 4′ in breadth; but the whole breadth of the corona was differently estimated by various observers, as 8′, 16′, and 25′ in breadth. Several luminous jets of light were noticed in the corona by M. Struve, at Lipesk, as in the following diagram (Fig. 143); and it had a decidedly radiating appearance; but the observers in France only perceived one or two radiations, and in some cases only the brighter or inner ring of light was observed. In the eclipse of 1851, the same discordance in the estimation of the breadth, and in the radiating aspect of the corona, existed between the several observers. The direction of the diverging rays did not seem to be perpendicular to the circumference of the moon, but were greatly inclined; and M. Arago noticed, that at one part of the corona, the rays were entwined within each other, like a skein of thread which was entangled. (See, also, page 165, *ante*).

The appearance of this ring of light is now generally attributed to the effect of the atmosphere of the sun, rather than to anything of the same nature in the case of the moon. The latter was the supposition of Kepler;

and before the want of an atmosphere to our satellite was established by numerous proofs, it was the most natural one which could be imagined; although the great breadth of the ring would go to prove that its height must be three or four hundred miles, or ten times the extent of the earth's atmosphere. No such difficulties exist in the case of its being supposed to be the solar atmosphere, while its concentric form, in regard to the sun at the different periods of observation, tends still further to confirm this conjecture. By what has already been stated of the photosphere of the sun, and the different strata which surround its surface, as well as the appearance of the zodiacal light, this may be deemed to be, in every respect, the most probable conjecture.* The corona, however, cannot be identified as forming the zodiacal light, for it has mostly been observed of a circular form, whilst the latter is elliptical; even where the corona has been noticed to be protuberant on opposite sides, the greater axis does not take the direction of the ecliptic.

Fig. 143.



Red Flames.—In the eclipses of 1715 and 1733, when the sun was wholly eclipsed, and only the corona was visible, the margins of the moon were noticed to be marked with some red spots, which remained visible for some seconds. Whilst observing the corona in the eclipse of 1842, these appearances again became unexpectedly conspicuous to the different observers. They were first observed a few seconds after the time of total obscuration, and were of a fine crimson tint—being compared by one observer to the peaks of the Alps illumined by the setting sun; and, by another, to beautiful sheaves of flames, which remained visible even after the sun had emerged. The length of the most considerable was, by actual measurement, found to be equal to 1¾ minutes of arc. Only two or three isolated prominences were perceived by the observers stationed in the south of France; but to MM. Struve and Schidlowsky, these rose-coloured flames burst out at several parts of the lunar disc—a *very large portion* of the periphery being garnished with this reddish bordering. M. Littrow noticed that they changed their colour as the eclipse advanced, being at first white, then rose colour, and finally violet, passing afterwards in a reverse order through the same tints. In the eclipse of 1851, these crimson projections were beautifully seen, and by some observers in great number. Some seen were, in this instance, crooked, and resembled a flame bent aside by the wind, but their colour was of the same remarkable tint as in the former case. In the eclipse of 1706, observed by Captain Stannyann, at Berne, "a blood-red streak of light" was noticed; and Halley, in 1715, saw a similar "long, and very narrow streak, of a dusky but strong red light" Equally with the corona, these appearances have been conjectured to be in the atmosphere of the sun, and to be in no way connected with the moon. Their reddish light would seem to show that they were of a cloudy nature, resembling our terrestrial clouds, and absorbing all the rays of the spectrum, with the exception of the red. (See, also, page 165, *ante*).

Baily's Beads.—In some cases when the margin of the moon comes in contact with that of the sun, instead of the faint and regular thread of light which would be supposed to ensue under those circumstances, the appearance presented is a broken glimmer of light, which was first noticed by the late Mr. Baily, who compared it to *beads* of light. These are noticed in total as well as annular eclipses, and were seen by different observers in the eclipse of 1851. They are generally regarded as being due to the rough and mountainous edges of the moon coming in contact with the margin of the sun, and the light proceeding from the latter shining through the *chinks* or valleys of the moon, the effect being greatly increased by irradiation.

Method of Observation.—We can follow the different phases of a solar eclipse without the help of a telescope, and by merely making use of a piece of coloured glass; that colour which is technically termed by opticians *London Smoke* being the most convenient for this purpose. If a pin-hole be made in a piece of card, and the image received on a screen, the disc of the sun, and the various phases it assumes from the interposition of the moon, likewise become very apparent, and we have thus a still more simple method of following the phases of an eclipse. The *form* of the aperture, or the pin-hole, is of little consequence in this instance, provided it be small.

Application of Photography.—For particulars on this subject, the reader may refer to the article on Celestial Photography, in the section on Light (page 164).

Occultations of Stars by the Moon.—The occultations of stars by the moon are analogous to eclipses of the sun, and their graphical projection may be made with some slight modifications as in that case, and the same formulæ may be applied to their prediction. All the planets may be occulted by the moon, but only such of the fixed stars as are situated near the ecliptic, and within the limits of the moon's latitude. Among the brighter stars which can suffer eclipse—those of Regulus, Spica, Aldebaran, Antares, and the group of the Pleiades, may be mentioned. An occultation can be seen at many different parts of the earth's surface, and their accurate observation forms one of the best means of determining the longitude, being much more exact than the occultations of Jupiter's satellites, as the moments of immersion and emersion are instantaneous. The portion of the earth's surface at which the star appears to be occulted at the same instant, will have a diameter equal to that of the moon, and will pass, like the shadow of the moon, over a certain zone of the earth. As the star has no perceptible diameter, there can be no penumbra in such a case, even if the light of the star were sufficient to cast a shadow. This circumstance renders the calculation more simple, which likewise follows from the star having neither motion nor parallax.

[The lunar eclipse of June 1, 1863, afforded some beautiful phenomena of the kind described at page 974; and the evening being remarkably fine, was highly favourable for observation. At 10.45 P.M., being the commencement of the total eclipse, the limb last occulted showed a blood-red colour. On complete immersion, the disc was still visible, and continued so to the end of the eclipse, appearing occasionally red, with a strange flickering appearance, like that produced by a "London fog" on the sun, in November. A beautiful phosphorescence was noticed, at 11 P.M., over the whole disc, and this alternated with a red, or rather rose-coloured tint, until the reappearance of the illuminated edge. The course of the phosphorescence was the same as that of the earth's shadow, for it immediately preceded both the immersion and emersion, and was greatest on the limb of the moon on which each took place. In observing the above, we preferred the naked eye to the telescope, so distinctly were the phenomena visible.—ED.]

CHAPTER X.

ON UNIVERSAL GRAVITATION.

All experience shows, that every heavy body requires force, effort, or support, in order to prevent its falling to the earth. What are called light bodies, also require a similar counteracting force when their tendency to fall is not resisted by the presence of the air, as numerous experiments with the air-pump have sufficiently proved.

This influence of the earth upon all bodies suspended over it, and which renders force necessary to *keep* them suspended, is itself called force—the *force of gravitation.* Such is the name which philosophers give to the hidden cause, whatever it be, which forces bodies to fall to the earth when left to themselves, instead of remaining suspended wherever they may be placed, or moving in any other direction.

That this force of gravitation or attraction is not exclusively expended on terrestrial bodies, was a doctrine entertained by several astronomers before Newton's time. Kepler had a steady conviction that the moon gravitated towards the earth; but he conceived that some additional force, animal or spiritual, was in operation to check the gravitating influence, and prevent the two bodies from rushing into collision.

It was reserved for Newton to prove that the single principle of gravitation, combined with one single impulse given to each planet, was sufficient to account for all the celestial movements, and to render clear and intelligible the entire mechanism of the heavens.

In addition to the first distinct enunciation of the *principle*, Newton also discovered the *law* of gravitation. The principle is, that all particles of matter mutually attract each another; the law is, that the intensity of the attraction varies inversely as the square of the distance at which it acts.

To verify these important propositions, observations of a peculiar kind were indispensable. These, fortunately, had already been supplied by Kepler; they are embodied in the three following statements, which have, however, a greater degree of generality than Kepler's observations strictly warrant. His *laws*, as they are called, thus generalised, have been mentioned at page 944: it is convenient to repeat them here.

1. If a line be supposed to connect any planet with the sun, this line will describe equal areas in equal times.

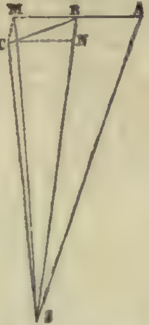
2. The planets revolve about the sun in elliptic orbits, the sun occupying one focus of the ellipse.

3. The squares of the times in which any two planets perform their revolutions about the sun, are as the cubes of their mean distances from it.

The first of these three laws is not peculiarly connected with astronomy, and is of no special importance in establishing the physical theory of the planetary motions; for, as shown by Newton, it is a universal truth, that a body, moving round a point of attraction in any orbit and attracted by any force, *must* describe equal sectorial areas in equal times. This truth, therefore, is quite independent of every specified law of attraction, and is irrespective of all considerations as to the distance of the revolving body, or the form of its orbit. If only the direction of the force be towards a fixed point, the equable description of areas necessarily has place; and, conversely, if this latter have place, the direction of the attractive force is always towards the same fixed point. This is proved as follows, after the manner of Newton:—

Suppose that a planet, moving at any distance from the sun, be subjected to the influence of an attractive force tending to draw it directly to that body; and imagine this force, instead of acting continuously, to act by successive impulses, after certain equal intervals of time. Let A B (Fig. 144) be the path described by the planet during one of these intervals, which path will, of course, be a straight line, since in describing it the planet is not acted upon by any force.

Fig. 144.



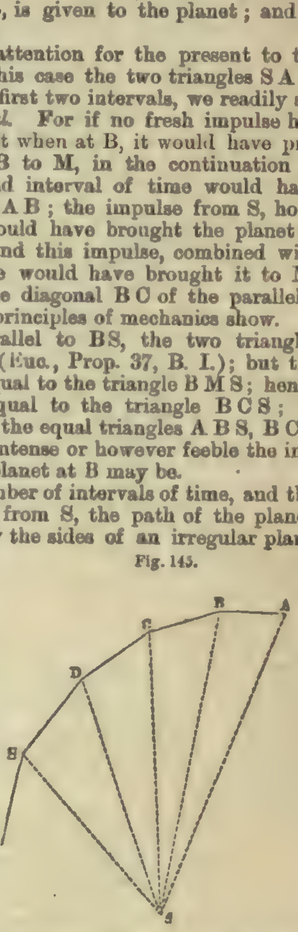
Arrived at the point B, the attractive force at S, acting merely as an instantaneous impulse, changes both the direction and velocity of the planet, which takes another rectilinear path, B C, described in an interval of time equal to the former interval; at the end of which, another impulse, in the direction C S, is given to the planet; and so on.

Now, confining our attention for the present to the two sectorial areas (in this case the two triangles S A B, S B C) described in the first two intervals, we readily see that they must be *equal.* For if no fresh impulse had been given to the planet when at B, it would have proceeded onwards from B to M, in the continuation of A B, and in the second interval of time would have described B M equal to A B; the impulse from S, however, if acting alone, would have brought the planet to some point N in B S, and this impulse, combined with that which acting alone would have brought it to M, causes it to describe the diagonal B C of the parallelogram M N, as the first principles of mechanics show.

Now M C being parallel to B S, the two triangles B M S, B C S are equal (Euc., Prop. 37, B. I.); but the triangle A B S is also equal to the triangle B M S; hence the triangle A B S is equal to the triangle B C S; so that in the equal times, the equal triangles A B S, B C S are described, however intense or however feeble the impulse from S upon the planet at B may be.

By increasing the number of intervals of time, and the corresponding impulses from S, the path of the planet would be represented by the sides of an irregular plane polygon, as in the diagram (Fig. 145); and however these sides may differ in length and direction, it is plain, from what is shown above, that they are the bases of *equal triangles* of which the point S is the common vertex. As each triangle is described in the same time, by the line joining the planet and the sun, it follows that equal areas are always described by this line in equal times.

Fig. 145.



It is obvious that this conclusion has nothing to do with the length of time which has been supposed to intervene between the impulses upon the planet, but only upon the equality of the intervals. We may therefore imagine these equal intervals to be as small as we please, and therefore the impulses to succeed one another with the utmost rapidity, and, in fact, to unite in one continuous force; in which case the sides of the polygon, becoming shorter and shorter, must unite in one continuous plane curve, the centre of attraction being itself in that plane. We infer, therefore, that a planet moving in virtue of a primitive impulse, and diverted from its rectilinear path by an attractive force residing in the sun, describes a curvilinear orbit round the source of attraction, such that equal sectorial areas are generated by the *radius vector* of the planet in equal times.

However accordant this description of equal areas in equal times may be with actual observation, we could not fairly infer that the centre of force is necessarily in the sun, unless it were further proved that such equal areas could not be described if the centre of attraction were situated elsewhere than at the common vertex of the equal sectors. And this may be done thus :—If the force acting on the planet when at B (see Fig. 144) had a direction out of the line B S, B N would make some angle with B S, and C M, which is parallel to B N, would not then be parallel to B S; and the two triangles B C S, B M S, on the same base B S, would have their vertices at unequal distances from that base; so that the surfaces of those triangles would be unequal. The triangle A B S, always equal to B M S, would no longer be equal to the triangle B C S; nor, consequently, would the triangles A B S, B C S, C D S, &c. (Fig. 145), described by the radius vector in equal times, be equal. We conclude, therefore, that, 1st, if the force acting on a planet be constantly directed towards the sun, the areas described by the straight line joining the planet and sun are proportional to the times of describing them; and, 2nd, if the force which acts on the planet be not directed towards the sun, the proportionality of the sectorial areas to the times does not exist. The first law of Kepler, therefore, warrants the conclusion that the attractive force acting on a planet, is constantly directed towards the sun; and this is the only conclusion derivable from that law. As respects the intensity of the attractive force—how it varies with the distance of the planet, or whether it varies at all, are particulars of which nothing can be learnt from the observed fact of the equal description of areas; for, as the preceding reasoning shows, equal areas are always described about a point, provided only the force acting on the moving body be in the direction of the line from the body to the point, however the intensity of the force may vary. But if the body move in a circle round the centre of attraction, then we may infer, from the law of equal areas, in equal times, that its motion must be uniform; for only equal arcs of circles can belong to equal sectors; and from the constancy of the distance, or radius vector, we cannot but infer the constancy of the attractive force.

Kepler's other two observed laws of planetary motion evidently imply a certain law of attractive force. If the attraction be such as to cause the planet to describe an elliptic orbit, any alteration in the force acting upon the planet at any particular point in that orbit, would necessarily alter its path. And if two planets revolve round a centre of force, and it be observed that their mean distances from that centre and their times of revolution bear the same relation to one another, a uniform law of force is again implied. Let us endeavour to discover what this law is from Kepler's third proposition; namely, that the squares of the times are as the cubes of the mean distances.

It will be observed that the enunciation of this truth involves no condition in reference to the *eccentricities* of the planets; the proposition should hold, therefore, for all eccentricities, and even for *circles*, in which the eccentricities are zero. For simplicity, then, we shall consider the case of planets revolving in circular orbits, and consequently, as shown above, moving uniformly; and shall thence endeavour to discover the law of force necessary to justify the proportion, that the squares of the times of revolution are as the cubes of the radii of the circular orbits.

The intensity with which a force acts upon a body, is measured by the addition it imparts to the body's velocity in the direction of that force in a second of time. If no force act, no addition can be made to velocity; if a body be at rest, or move uniformly in a straight line, we infer at once that it is not acted upon by any force. If a force act continuously, and in the same direction, it must generate equal increments of velocity in equal times; and the motion of the body is thus said to be uniformly accelerated. It must be borne in mind, however, that the force must act with the same intensity upon the body throughout. The attraction of the earth, or terrestrial gravity, may be regarded as such a constant force in all our experiments and observations respecting bodies falling to its surface, because these observations and experiments can never be made in a region so remote from the surface as to render the variation in the force of the earth's attraction sensible.

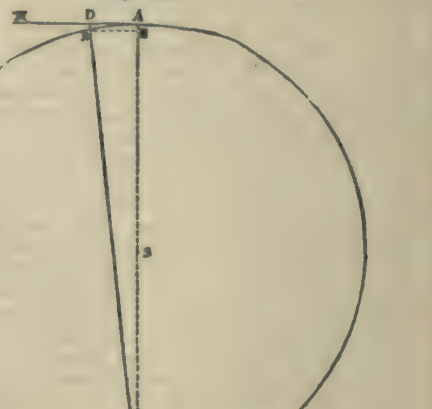
If a body fall from rest to the surface of the earth, it will acquire a velocity at the end of the first second, which, as stated above, is the measure of the earth's attraction; throughout this second, the velocity increases uniformly from nothing up to the final velocity which measures the force. The velocity midway is, therefore, half this final velocity; and if the body were to move *uniformly* with this midway velocity, it is pretty obvious that in one second it would describe the same length of path, as in falling from rest as above supposed.*

The length of path in uniform motion is evidently found by multiplying the uniform velocity (the length passed through in a second) by the number of seconds; that is, calling the length of space s, the velocity v, and the number of seconds t, we have $s = v\ t$, or if $t = 1$, $s = v$. Now, if v be the final velocity at the end of the second of accelerated motion, adverted to above, and S the space actually passed through in that second; then, putting $\frac{1}{2}$ V for v, and S for s, we have $S = \frac{1}{2}\ V$; therefore $V = 2\ S$; that is, the final velocity, or the measure of the force of gravity, is twice the space described by a body falling from rest in the first second of time.

The same conclusion applies, however remote from the surface of the earth the falling body be conceived to be placed; the intensity of gravity *there* would still be measured by double the space through which the body would fall from rest in one second; for during so short a time, the force may, as before, be considered as constant. And a like conclusion applies whatever centre of force be considered; the measure of its intensity on a body anywhere subjected to its action, will always be accurately expressed by twice the space through which the body falls towards that centre in one second.

Let the circle in Fig. 146 represent the path of a planet revolving about the sun at S. When at A, the planet is actuated by a velocity in the direction of the tangent A M, and in this direction it would, of course, continue to move uniformly if no force diverted it from its path. But it is acted upon by a force which is constantly directed towards the sun, S, and which tends to draw it towards that body, or to deflect it more and more from the tangent. It may thus be said to fall towards the sun, just as a body near the earth, projected forwards in a straight line, A M (Fig. 147), falls towards

Fig. 146.



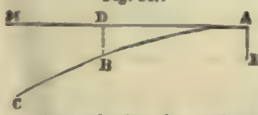
---

* See *ante*, *Mechanics*, p. 734, *et seq.*

the earth's surface, the actual motion in either case being in a curved line, A B. Let A B, on the orbit of the planet, be the portion of that orbit described in one second of time; the distance D B will be that which the planet has fallen, from its wonted path, towards the sun, in this second of time, and the double of D B will measure the attractive force of the sun at that distance.

Now, to find the length of D B we proceed as follows:—From the point B draw B E perpendicular to the radius S A; draw also from B a straight line to the point A′ of the orbit diametrically opposite to the point A, and make A E equal to D B. It is plain that the arc A B differs insensibly from its chord, and may be replaced by it; so that the angle A B A′, being in a semicircle, is a right angle. In the right-angled triangle A B A′, we have the proportion A E : A B :: A B : AA′ (Euc. 8 of VI.), for B E cannot differ sensibly from parallelism with D A; therefore, $\frac{AE}{AB} = \frac{AB}{AA'}$, $\therefore AE = \frac{AB^2}{AA'} = \frac{AB^2}{2AS}$ As the arc A B is the portion of the orbit described by the planet in a second of time, it measures the uniform velocity with which it moves; and we see that the distance A E, or B D, which the planet falls in that time towards the sun, is found by dividing the square of the velocity by twice the radius of the orbit. We have seen that the attractive force of the sun, acting at that distance, is measured by double the distance fallen in a second. The intensity of the force, therefore, at the planet, is expressed by the quotient of the square of its velocity by the radius of the planet's orbit.

Fig. 147.



We may now compare together the intensities of the forces which act at different distances, or on different planets, by means of the third law of Kepler. In order to this, let us suppose that planets, moving uniformly in circles round the sun, be situated at distances from that central body proportional to the numbers

1, 2, 3, 4, 5, &c. . . . . (A).

To obtain the velocity of one of these planets in its circular orbit, we must divide the length of the circumference by the number of seconds occupied in describing it; and to get the square of the velocity, we must divide the square of the circumference by the square of the number of seconds. But the squares of circumferences are as the squares of their radii; that is, in the present case, as the numbers

1, 4, 9, 16, 25, &c.

Also, from the third law of Kepler, the squares of the times of revolution are as the cubes of the radii of the orbits; that is, in the present case, as the numbers

1, 8, 27, 64, 125, &c.

The squares of the velocities of the several planets will, therefore, be related to one another as the numbers

$$1,\ \frac{4}{8},\ \frac{9}{27},\ \frac{16}{64},\ \frac{25}{125},\ \text{\&c.}$$

Or as the numbers

$$1,\ \frac{1}{2},\ \frac{1}{3},\ \frac{1}{4},\ \frac{1}{5},\ \text{\&c.} \quad . \quad . \quad . \quad . \quad \text{(B).}$$

And as the force acting on each planet is measured by the square of its velocity divided by its distance, we shall evidently discover the law by which the intensity varies, from one planet to another, by dividing the several numbers (B) by the corresponding numbers (A); that is to say, the forces at the several distances (A) will be as the numbers

$$1,\ \frac{1}{4},\ \frac{1}{9},\ \frac{1}{16},\ \frac{1}{25};$$

or inversely as the *squares* of the distances (A). And in this way is the law of solar attraction established; and not only does this follow from the third law of Kepler, but this law itself may be shown to be a necessary consequence of the law of force just established. For, since the length of orbit, divided by the uniform velocity, gives the periodic time in seconds, and that circumferences vary as their radii, the periodic time varies as the radius divided by the velocity. Hence, calling the periodic time P, the radius R, the velocity v, and the force F, we have in symbols,

$$P \propto \frac{R}{v} \therefore P^2 \propto \frac{R^2}{v^2}. \quad \text{Now } F = \frac{v^2}{R}.$$

$$\text{If, then, } F \propto \frac{1}{R^2} \therefore \frac{v^2\ 1}{R^2\ R^2} \therefore \frac{R^2}{v^2} \propto R^3 \therefore P^2 \propto R^3; \text{ so}$$

that if the force vary inversely as the square of the distance, and bodies move round the common centre of attraction in circles of different radii, the squares of the periods of revolution will be to one another as the cubes of the distances.

Having proved that the relation observed by Kepler between the periodic times and the distances is a necessary consequence of the above-named law of gravitation, Newton sought to determine whether the forms of the planetary orbits were not also a necessary consequence of the same law; and he accordingly found that, under the influence of that law of attraction, it was impossible for a body to move in any other curve than a *conic section;* that is to say, the orbit must be either an ellipse (of which a circle is a particular case), a parabola, or an hyperbola.* This may be proved as follows:—

Let v be the velocity in a circle of radius R; v' the velocity in a parabola, ellipse, or hyperbola, whose radius of curvature at perihelion is R′; then

$$F = \frac{v^2}{R} = \frac{v'^2}{R'}; \therefore R' = R\frac{v'^2}{v^2}$$

Now R′ is what, in the doctrine of the conic sections, is called the *semi-parameter* of the curve; and R being the distance of the focus from the vertex of the curve, it is also proved in that doctrine, that the curve will be a parabola, an ellipse, or an hyperbola, according as R′ is $= 2$ R, $\angle\ 2$ R, or $>\ 2$ R. Hence, if $\frac{v'^2}{v^2} = 2$, the orbit is a parabola; if $\frac{v'^2}{v^2} \angle\ 2$, the orbit is an ellipse; and if $\frac{v'^2}{v^2} > 2$, the orbit is an hyperbola. And as one or other of these conditions must necessarily have place, whatever be the velocity v', it follows that the planets and comets must all move in one or other of these three curves.

The above established law of force is thus competent to account for the revolutions of all the planets and comets round the sun, as also for the motions of those comets in the system, if any there be, which describe parabolic or hyperbolic orbits, and which consequently proceed onward in space continually, and never return.

The same law of force accounts, in like manner, for the revolutions of the satellites round the planets to which they belong, for these all describe elliptic orbits.

This general statement, however, is, in strictness, only an approximation to the truth, although an approximation so close, as to be but very little at fault in explaining the great phenomena of the planetary motions, and therefore regarded by Kepler as strictly accurate. In the foregoing reasonings the attracting body has been supposed to be absolutely fixed in space. This is not entirely consistent with Newton's laws of *universal gravitation*, according to which all bodies in the universe mutually attract one another with a force directly proportional to their masses, as well as inversely proportional to the squares of their distances. On account of the masses of the planets being very small in comparison with the mass of the sun, the rejection of the planet's attraction on the latter body involves an error comparatively insignificant.

---

* See *ante*, *Mathematics*, p. 608, *et seq.*

"It is true, that when observations are carried to a high degree of precision, and when each planet is traced through many successive revolutions, and its history carried back, by the aid of calculations founded on these data, we learn to regard the laws of Kepler as only *first approximations* to the much more complicated ones which actually prevail; and that to bring remote observations into rigorous mathematical accordance with each other, and at the same time to retain the extremely convenient nomenclature and relations of the ELLIPTIC SYSTEM, it becomes necessary to modify, to a certain extent, our verbal expression of the laws, and to regard the numerical data or *elliptic elements* of the planetary orbits as not absolutely permanent, but subject to a series of extremely slow and almost imperceptible changes. These changes may be neglected when we consider only a few revolutions; but going on from century to century, and continually accumulating, they at length produce considerable departures in the orbits from their original state."—*Herschel.*

From the principle of universal gravitation, the third law of Kepler, from which the law of attractive force has been deduced above, requires to be modified as follows:—The cubes of the mean distances of the planets from the sun are as the products of the squares of the periodic times, by the sum of the masses of the attracting and attracted bodies. In the original enunciation of the law, the mass of the attracted body was neglected; the trifling amount of error thus introduced—seeing that even Jupiter, the largest of the planets, has less than a thousandth part of the matter contained in the sun—is evidently such as to render the departure from strict accuracy too minute to be detected, except by delicate observations extended over a long period of time.

PERTURBATIONS OF THE PLANETARY MOTIONS.—In consequence of the law of universal gravitation, each planet exercises an influence over every other planet; these mutual disturbances necessarily modify, in a slight degree, as just noticed, the orbits of all, and occasion what are called *perturbations* and *inequalities*. But all these are fully accounted for, and satisfactorily explained, by referring them to Newton's great principle. Calculations founded upon this principle, enable us to predict the position of a planet at any future time with a degree of accuracy that appears little short of marvellous, when we consider the complication involved in the mutal actions of the sun and all the planets on one another. "The motion of Jupiter, for instance, is so perfectly calculated, that astronomers have computed, ten years before hand, the time at which it will pass the meridian of any specified place; and we find the prediction correct within half a second."—*Airy.*

No physical law has ever been enunciated which long and careful observation more completely verifies than Newton's law of universal gravitation. The distances and masses of the planets being known, the effect of the attractions of all, in modifying the path of each, can be correctly ascertained, though only by aid of investigations of the most difficult and recondite character; but one of the most remarkable attestations to the truth of this universal principle, is that which has been furnished in our own day by Mr. Adams, of Cambridge. Knowing that there were certain small perturbations of the orbit of Uranus that the combined attractions of all the other planets of the system were insufficient to account for, and fully confiding in the competency of Newton's law to explain every movement of the heavenly bodies, he had the boldness to pronounce that a yet unseen planet existed beyond the bounds of what had till then been regarded as the remotest planet in our system; and taking the unaccounted-for perturbations of Uranus as data, he had science enough to assign the place where, at a specified time, the new planet would be found. An eminent French mathematician, Leverrier, had independently, and but a short time afterwards, arrived at a similar conclusion; and upon transmitting the necessary instructions to a German astronomer, Galle, the predicted planet, Neptune, was revealed to his telescope on the evening of the day that the communication reached him.

One of the most important results to which the various researches into the planetary perturbations have conducted is, that the major axes of the variable elliptic orbits always preserve the same values. The disturbances to which each planet is subjected, by the action of the others, affect all the elements of its elliptic path, except its major axis, which throughout every other change continues itself invariable; this invariability insures at the same time the invariability of the period of revolution, agreeably to the third law of Kepler. And thus the stability of the system is secured. We are indebted for this great truth to the genius and researches of Lagrange.

MASSES OF THE PLANETS AS COMPARED WITH THE SUN.—The mass of a planet is ascertained by observing the disturbances which its attraction produces in the orbits of other planets, or, if it have a satellite, by determining the force exerted upon that satellite. The mass of the sun being represented by unit, the masses of the planets have been estimated as in the following table.*

Names of the Planets.	Masses.	Names of the Planets.	Masses.
Mercury	$\frac{1}{2025810}$	Jupiter	$\frac{1}{1050}$
Venus...	$\frac{1}{401841}$	Saturn	$\frac{1}{3500}$
Earth	$\frac{1}{354936}$	Uranus	$\frac{1}{21000}$
Mars	$\frac{1}{2680337}$	Neptune	$\frac{1}{14446}$

It must be understood that the *mass* of a body is not the same thing as its bulk or volume. The mass is estimated by volume and density; if one body have only half the volume of another, but be twice as dense, their masses are equal. If a planetary body be so minute in volume, or so feeble in density, as to render its attractive energy too small to perturb sensibly the motions of the other planets, the mass of that body cannot be determined. On these accounts there is still some uncertainty as to the mass of Mercury; and respecting the masses of the small planets between Mars and Jupiter—asteroids, as they have been called—we know nothing. In like manner, as respects the comets, all we know is, that their masses must be exceedingly small; that is, that they contain but a very small quantity of matter, as they produce no appreciable disturbance of the planetary movements. It has happened that a comet has crossed among the satellites of Jupiter without occasioning any observable disturbance even in the motions of these comparatively small bodies.

Before concluding this section on the principle of universal gravitation, we must devote a short article to one of the most noticeable effects of that principle on our own planet—the phenomena of the tides.

THE TIDES.—The principal physical cause of those periodical oscillations of the surface of the ocean called *tides*, is the attraction of the moon; the sun contributes to the general results, but in a far less degree.

Suppose the earth were entirely covered with water: from the mutual attraction of all its parts, its surface would assume an exactly spherical form. Its rotation on its axis, however, would cause the equatorial parts to recede from the centre, and to bulge out.

This receding from the centre, of the equatorial regions of the earth, is caused by a new force, opposed to that of gravitation, being brought into operation by the planet's rotation. It is called the *centrifugal force*, from its imparting a tendency in the outer particles of the rotating mass to fly off or recede from the centre. Just such a tendency would be excited if the earth were at rest, and an attractive external influence were uniformly diffused round its equatorial regions, and penetrating only to a small depth below the surface. If, however, the external attractive influence, instead of being thus diffused as a ring round the earth, were confined to a limited place, the bulging out of the waters would of course be confined to the place immediately under the attracting body; and if the force of attraction extended to the centre of the earth, the elevation of the waters would evidently be due, not to the force acting on their surface, but only to the difference of the forces acting on the surface and on the centre. The waters would, as it were, be drawn away from the earth by the influence of this difference.

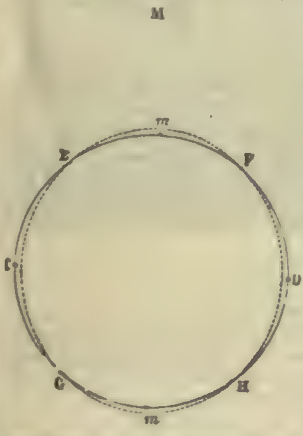
---

* See Note, *ante*, p. 926.

If the attractive force of the external body extended to the opposite part of the earth's surface, then the force on the centre being greater than that on the remote surface, the earth would, as it were, be drawn away from the waters at the further surface, and there would in consequence be also a bulging out there; and as the difference of the forces on the centre and near surface must be very nearly the same as the difference of the forces on the centre and remote surface, the waters will be heaped up to nearly the same extent at both places.

The application of these general considerations to the moon and the tides, will sufficiently show that the bulging out of the waters by the attraction of the moon M (Fig. 148), is nearly equal at the two places under the moon marked *m* on the earth's surface, diametrically opposite to each other, causing the waters of the entire globe to assume a spheroidal form, the elevations at *m* necessitating a subsidence or depression at C and D. As different portions of the earth's aqueous surface are brought under the direct influence of the moon, those portions in like manner bulge out, producing a continuous succession of tides.

Fig 148.



If the moon alone acted, and always moved directly over the equator, the interval between two consecutive high tides would be just half a lunar day. In like manner, did the sun alone act on the waters, its motion being supposed to be directly over the equator, the interval would be just half a solar day: but the combined action of both these bodies causes, of course, the intervals to vary.

In the actual state of the earth, whose surface presents both land and water, the phenomena of the tides cannot be expected to be in strict agreement with what they would be if no solid matter existed on it. Headlands, coasts, the shallowness and contraction of channels, &c., continually obstruct the free motion of the tide-wave; these obstructions often greatly delay the time of high water, and cause a much greater rise than would take place if the advance were unimpeded. Such local influences, indeed, greatly modify the results of pure theory, both as to the time and height of high water at different ports. Special observations, therefore, at each place are necessary to supply the proper data for predicting the time of high water, and to determine what is called the "establishment of the port." The height of the tide, too, often depends upon the set and force of the wind; but, "of all the causes of difference in the height of the tides, local situation is the most influential. In some places, the tide-wave, rushing up a narrow channel, is suddenly raised to an extraordinary height. At Annapolis, for instance, in the Bay of Fundy, in Nova Scotia, it is said to rise 120 feet. Even at Bristol, the difference of high and low water occasionally amounts to fifty feet."—*Herschel.*

The same influences which produce the tides of the ocean, operate also on the surrounding atmosphere of the earth; and produce tides in *it.* It is popularly supposed, too, that the weather is subjected to the moon's influence; but careful and long-continued observation, by competent persons, has shown this supposition to be fallacious. A change in the moon is imagined to be attended with an immediate change in the weather; it being overlooked that the moon changes her position, and passes through her several phases, by imperceptible gradations; which is incompatible with a sudden change in the weather. The predictions frequently given in almanacks, in reference to this point, will generally be found to prove fallacious.

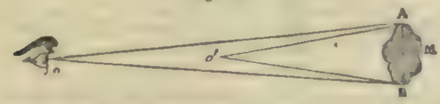
CHAPTER XI.

PRACTICAL ASTRONOMY.

We have now reached—perhaps we are somewhat beyond—the point where the astronomer's labours must have ceased but for the intervention of instruments, by which he has been enabled to sweep the heavens, and reveal some of their hidden mysteries. We propose, at this stage of our labours, to give some description of these instruments, of the principles on which they are constructed, of the manner in which they tend to the augmentation of our power of sight, and the most convenient methods of mounting them, with directions for their practical application.

The apparent size of an object, as perceived by its image on the retina, depends on the distance between the eye and the object. Thus, for instance, if the object be M (Fig. 149), and the eye be placed at *o*, the right line which joins the extreme points, A and B, will be seen under the angle A *o* B. If the eye be placed at the point *o'*, or at half the distance at which it was previously situated, the line A B will, in the same manner, be viewed under the angle A *o'* B, which will be the double of the preceding, supposing that the line A B is small in comparison with the distance of the object M from the eye of the observer. In the same manner, the angle A B will be three or four times greater, as the distance of the object is one-third or one-fourth of the primitive distance. The angle A *o* B is, therefore, the measure of its *apparent* size (which is different from its *real*, the latter being invariable), and is called the *visual* angle, or the apparent *diameter* of the object. The surface of the body becomes four, nine, and sixteen times greater, as the distance is decreased to one-half, one-third, and one-fourth of the primitive distance. In other words, the diameter of an object varies inversely as the distance of the eye from it, and its apparent area varies inversely as the square of this distance. The power of the eyesight is limited; and it is generally held, that when the diameter of an object is less than a minute, the object ceases to be visible. But, the *brightness* of the image performs as important a part in this respect as its *size*, as is easily proved by the visibility of the fixed stars and of the planets, none of the former of which can subtend an angle as great as a second. Where the colour or brightness of an object, however, differs less from the ground on which it is placed, the above rule holds true.

Fig. 149.



The *distinctness of vision*, as every one is aware, depends likewise on the distance of the eye from the object; and this distance is variable for different persons. Even the one eye of the same individual may have a longer range of vision than the other. Every one knows, also, that if an object be held at a greater or less distance from the eye than that which is customary or natural, in either case it becomes indistinct.

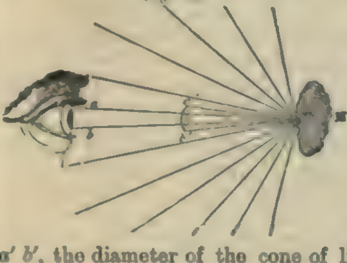


Fig. 150.

In regard to the *brightness* of any object, according as it is more or less removed from the eye, the following considerations are to be taken into account. From any bright object as M, rays of light are sent in all directions; and from the point *m*, as from any other point on its surface, these rays are sent before it, as represented in Fig. 150. Of all the rays of light, the eye only receives those which penetrate through the pupil *a b*. If the eye now approach the object M, so that its distance is one-half of what it was in the previous case, and its position *a′ b′*, the diameter of the cone of light will be only one-half of what it was in the previous case, and consequently the area of the section in that part, is only one-quarter of that at the base *a b*, where it was equal in area to the surface of the pupil of the eye. Hence it follows that the opening of the pupil at *a′ b′* will take in a greater number, by four times, of rays, than when it was situated at *a b*, so that the light received from the point *m* will be four times as much in the latter case, as in the former. At the same time, however, as the eye approaches the object M, a greater portion of its surface is taken in, and the position *m* becomes four times as great. The bright light is thus spread over a greater surface, and in a like proportion; and it follows that the brightness of the surface is unchangeable. If it happen that this is not the case in nature, it must be remembered that the interposition of the air causes a loss of light, and even a change in the colour of objects; for distant mountains appear blue, as likewise does the sky—being the effect when viewed through great depths of the atmosphere. Without this, a white object would appear of equal brightness whether it were seen close at hand or at a distance.

LENSES.*—Many solid bodies, and a greater portion of liquid ones, are transparent; but, in order that the former become perfectly so, it is necessary that their surfaces should be highly polished, which condition is fulfilled, in liquids, by the natural effect of gravity. In the grinding and polishing of glass and crystal, or even reflecting metals, into various shapes, it was early discovered that various effects were produced; but none more extraordinary than those which took place in the apparent magnitude of objects when viewed through these artificial media. The fundamental law on which all those changes are based is, that when a luminous ray passes obliquely from one transparent medium into another, it departs from its primitive direction, and undergoes a *refraction*. On this law the theory of lenses is based.

Fig. 151.

Fig. 152.

Fig. 153.

There are two different species of lenses, the surfaces being, in both cases, spherical, or one of the faces may be plane. The first are those in which the surface is convex or converging, and the other in which it is concave and diverging. The converging glasses are those which are doubly convex (Fig. 151), the form being *lenticular* (whence they derive their general name of lenses)—2° those which are plano-convex (Fig. 152), and 3° concave-convex (Fig. 153), the convexity being, in this case, more considerable than the concavity—and which are likewise known by the name of *menisci*, in consequence of the form of their section. The converging glasses are those which are doubly concave, as in Fig. 154; plano-concave, or convex-concave, the concavity being more considerable than the convexity, and likewise known as menisci. The *radii* of lenses are the radii of the spheres of which their surfaces are the segments.

Fig. 154.

Fig. 155.

Fig. 156.

If we expose a convex glass to the rays proceeding from the sun, they will be converged to a point, A (Fig. 157); and if we remove the lens more or less away from the surface on which the converging rays are received, this bright spot (A) will be of greater or smaller extent. To that point where it is of the smallest dimensions, the name of *focus* has been given, and its distance from the nearest surface of the lens is called the *focal distance*. If we turn the lens round, the same effect is produced; and if both the surfaces have the same radius, the distance will be alike in both cases, though it will vary but very slightly should they be different—even in the case of a *meniscus* lens.

Fig. 157.

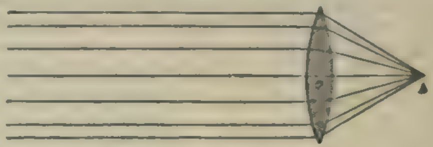

Fig. 158.

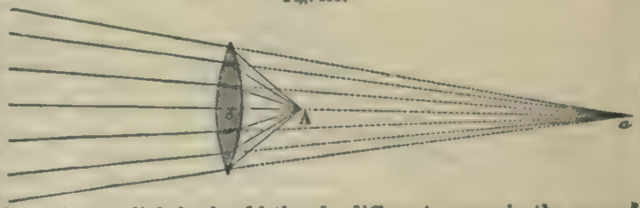

The line *a* A (Fig. 158) is termed the *axis* of the lens, and the point *o* its optical centre. In the above case the rays are supposed to pass parallel to the optical axis; but if they proceed from a luminous point, A, a short distance from the axis (Fig. 159), or rather, if the parallel rays make a small angle with the optical axis, the manner in which they converge to a focus, *a*, is the same. In both cases they pass through the optical centre *o* of the lens (Fig. 160). In concave lenses, the parallel rays of light which pass from an object are rendered divergent; or if already divergent, are rendered more so by their interposition, as in Fig. 166, p. 992.

Fig. 159.

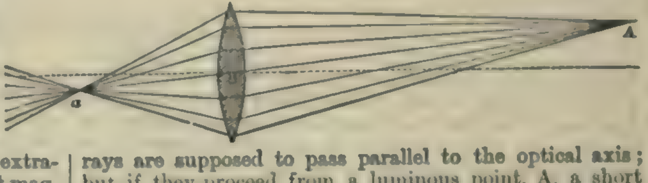

Fig. 160.

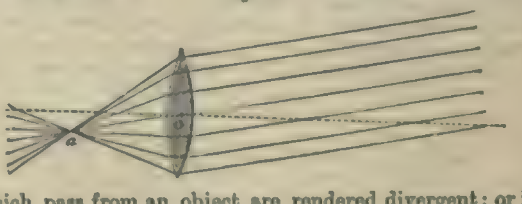
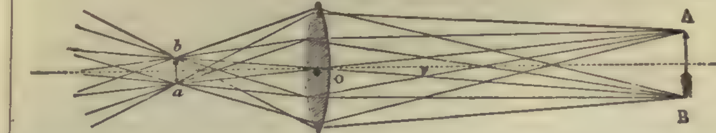


Supposing that, instead of proceeding from a point, A, the rays of light from a luminous object, A B (Fig. 161), pass through a convex lens. In this case the rays of light coming from the point A, will, as in Fig. 161, converge to the point *a*; and those from the point B to the

---

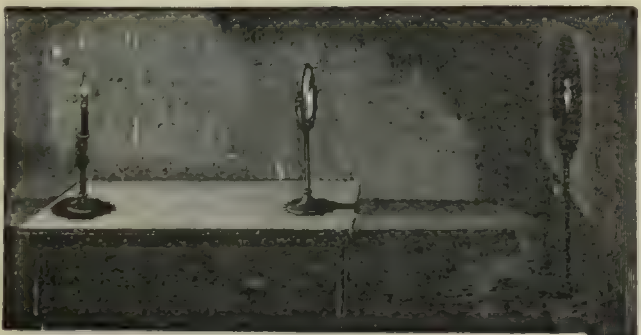
* The construction of many of the following arrangements has already been described, under the head of Optical Instruments, in the section on Light, but not specially in reference to astronomy, to which the succeeding remarks are mainly directed.—ED.

Fig. 161.



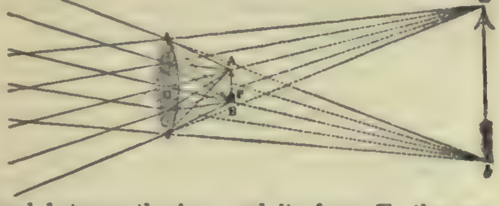
focus *b*; and in the same manner, all the other points of the object A B will be represented by opposite points in the image formed by the lens. It thus follows that the image is reversed; and if the eye be placed at the focus *a b*, the object A B will appear turned *upside down;* but in all other respects, a perfect picture of the object A B will be perceived. This effect may likewise be seen by placing a candle, A (Fig. 162), in a dark chamber, at a certain distance from the mounted lens B, the light from the candle passing through the optical axis of the lens, to the opposite wall, C, which is at the proper distance from the lens to receive a well-defined image of the flame of the candle. A reversed image of the candle may here be perceived, as well as of that portion of the candle which is illumined by the flame.

Fig. 162.



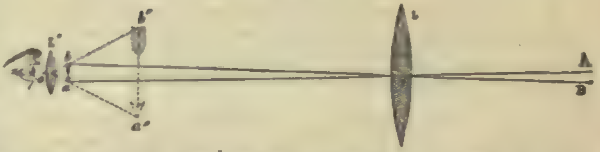
The well-known effect of convex glasses in magnifying small objects, will be seen from the following diagram (Fig. 163). The object A B being placed between the lens and its focus E, the rays of light proceeding from the point A do not lose all their divergence, but appear to come from a more distant point *a*, formed by the prolongation of the line O A; and in the same manner the point B seems to be situated at *b*, formed by the prolongation of the line B O. To the eye situated at the other side of the lens, therefore, it will appear as if the object A B were replaced by the image *a b*, and the latter object will appear more or less distant from the eye, according as the object A B is nearer or more removed from the focus of the lens. The lens can be so shifted in respect to the object, that the image *a b* will appear distinct and well defined, as well as magnified. We can readily perceive that the image *a b* is greater and more distant when the focal distance is smaller, and, in consequence, that a lens magnifies so much the more as its focal distance is less. The magnifying power of lenses is somewhat illusory, and nearly every one judges differently in estimating the magnified size of the object under examination. This may arise from two causes—in the first place, the distance of distinct vision is different for almost every person; and, in the second place, when we look through magnifying glasses, almost every guide which serves to regulate the judgment, on the distance and size of the object looked at, is removed.

Fig. 163.



Telescopes.—Every convex glass, as we have seen, produces an image of the object from which it receives rays of light; and by a combination of such glasses, viz., by examining the image formed by one lens (as if it were a real object) by means of another, and thereby magnifying the image as explained in the last paragraph, distant objects can be seen with a distinctness unapproachable with the naked eye. The most simple and most common description of the telescope, used by the astronomer, is that formed by two convex lenses, L and L′ (Fig. 164); the first of which, from being turned in the direction of the object, is termed the *object-glass;* the second the *eye-piece.* In this, the rays of the object A B, passing through the convex lens L, form an image *a b* in the focus of the lens. The second lens serves to magnify the reversed image *b a* in the same manner as if it were a tangible object. The image *b a* is not always at the same distance from the object-glass, but varies more or less according to the distance of the object; and when the latter is so far removed that the rays which fall on the object-glass may be considered as parallel—which is the case with all celestial objects—the image *b a* falls in the focus of the lens. As the object should be seen with the requisite distinctness at *b′ a′*, which is the distance of distinct vision, and as the latter varies almost with every person, it is necessary that the eye-piece should be drawn in or out from the image *b a*, in order to give perfect definition. It will be seen from the diagram, that the telescope does not, like the microscope or magnifying-glass, increase the *natural* size of the objects viewed; for the image *b′ a′* is much smaller than the object A B, which is at a great distance from the object-glass: it only tends to increase the *apparent* size of an object when viewed from a distance.

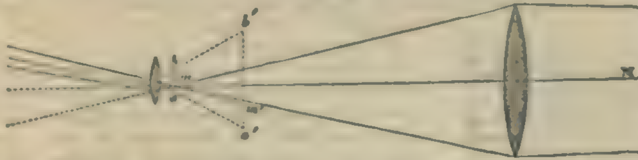
Fig. 164.



To compare the size of a distant object when viewed with natural and telescopic sight, we have only to compare the angles A *o* B (Fig. 164), or *a o b*, which is the angle subtended by the object to the unassisted vision, and the angle *a′ o′ b′*, which is the angle subtended by the image to the eye of the observer. The proportion between the relative sizes of the object A B, and the image *a′ b′*, is consequently the same as that between the angles *a o b* and *a o′ b;* and this is what is termed the magnifying power of the telescope. The angle *a′o′b′* and *a o b* being always small, they may be regarded as in the inverse proportion of the two points *o* and *o′* from the image *a b;* or, in other words, that as these distances may be regarded as the focal lengths of the object and eye-glasses, that the magnifying power of the telescope is in the same proportion. This instrument allows a large *field of view* (or the circular space which the eye would take in without the assistance of any telescope), for this depends on the dimensions of the instrument at *a b*, or the common focus of both lenses. Equally important with the perfect definition of the object, is, as already stated, the *brightness* with which it appears when under examination. If a ray of light pass from any point, M (Fig. 165), of an object, it will fall on the whole surface of the object-glass, and thence through the same point,

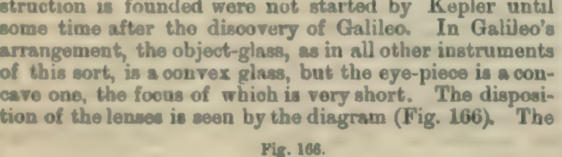
m, of the focus, $a\,b$, after which it will form a pyramid of rays, the divergence of which will be lessened by passing through the eye-piece in such a manner that they will appear to come from the point m' in the image $a'\,b'$. If the eye viewed the image $a\,b$, without the interposition of the eye-piece, it would only receive a portion of the light and rays emitted from the point M, many of the outer diverging rays having been lost, the opening of the eye being too small to take the whole in. But by employing a second convex glass, the divergence is diminished, and the eye receives the whole of the light emitted from the point M, which falls on the object-glass. Comparing, therefore, the brightness of an object, as seen with the naked eye and seen through a telescope, and supposing, in the latter case, that all the light passes through the lenses, it would follow that the light received by the eye, in using a telescope, would be as many times greater than that received by the unassisted eye, as the surface of the object-glass exceeds that of the pupil of the eye. This, however, is only theoretically true, for there is a considerable absorption of light effected by its passing through the lenses, as well as by reflection from their surfaces. If the size of the objects were increased by the telescope in the same proportion as the brightness of their surfaces, it would follow that the brightness would always remain the same. The magnifying power, however, is quite distinct from the illuminative power of the telescope, the first depending on the proportion between the focal distance of the two lenses, the latter upon the area of the object-glass. It thus happens that the brightness of the image will vary greatly with the power applied; and, with high powers applied to the same telescope, the objects become dim and indefinite, and the two excellences of brightness and good definition are very difficult to be obtained.

Fig. 165.



This description of telescope was not, however, the first invented. The optical principles on which its construction is founded were not started by Kepler until some time after the discovery of Galileo. In Galileo's arrangement, the object-glass, as in all other instruments of this sort, is a convex glass, but the eye-piece is a concave one, the focus of which is very short. The disposition of the lenses is seen by the diagram (Fig. 166). The reversed image of distant objects produced by the object-glass L is formed in $a\,b$, but the concave eye-piece is placed between the two, in such a manner that the eye placed behind the lens L′, will see $a'\,b'$, instead of the image $b\,a$; and the eye-piece can be so adjusted that the image $a'\,b'$ will appear well defined. This telescope magnifies the apparent diameter of objects as many times as the focal distance of the eye-piece is contained in the focal distance of the object-glass. It will not admit of any considerable magnifying powers, the field of view being very small, on which account it is never used at the present time as an astronomical telescope. On the other hand, it is very convenient as a pocket telescope, as it does not reverse objects; and as the eye-piece is placed between the object glass and its focus, it is shorter than the common telescope. In the common opera-glasses, which are of this construction, the magnifying power does not exceed three; but in some of those made by Galileo the magnifying power reached to thirty-two. Another form of the erecting or terrestrial telescope is that imagined by Rheita, in which three convex glasses, of equal but short focus, are fixed in a tube, and form the eye-piece. The first of those lenses, or that most distant from the eye, would give a reversed image, which, passing through the second one, produces an erect image, and finally, as it is before the focus of the third lens, it is viewed and magnified by this one. The magnifying power of this is measured as in the preceding ones, being in the proportion of the focal distances of the object-glasses and one of the lenses of the eye-piece. The magnifying power of a telescope may be roughly determined by comparing the sizes of an object, such as the moon, as seen with it and with the naked eye, and the extent of the field of view may be found by taking the diameter of the moon at about half a degree.* The former, however, is determined more exactly by an instrument called the *dyanometer*, which serves, when a telescope is directed towards the sky, and a sheet of paper is held behind the eye-piece, to measure the diameter of the luminous circle which falls upon the white surface, and the best definition of which is found by trial. By dividing the diameter of the object-glass by the diameter of this circle, the magnifying power of the telescope is obtained. The luminous circle is itself an image of the object-glass, and is contained as many times in the latter as the telescope magnifies distant objects.

Fig. 166.



Hitherto the object-glass has been supposed to be formed of one piece and of one sort of glass, but in all modern instruments this is not the case. The image formed by a convex glass is situated at a greater or a less distance from it, according to the refracting power of the glass, and is so much shorter as the refracting power is more considerable. In addition to this, the different colours of which white light is composed, are not equally refracted, and cannot have the same focus. If the eye of an observer be situated at the focus of the lens, he will not see the image perfectly defined and colourless, but it will appear surrounded with the prismatic colours; the violet rays of the object are more strongly refracted than the red ones, and will be thrown nearer the lens. In addition to this source of indistinctness of the image, there is another less important one known by the name of *spherical aberration*, which depends on the figure of the lens, there being no curvature in which all the rays of light coming from any object are *exactly* united in a common focus. In order to get rid of the first source of indistinctness, in using a single lens for the object-glass, it was found necessary, with high magnifying powers, to have the lens of very long focus (some of those used by the earliest observers were 300 feet in length); for by this means the causes which led to the formation of the colour, viz., the considerable curvature of the lens, were diminished, and the larger images were formed. By an examination of different species of glass, Dollond found that some sorts refracted light, and dispersed the colours, much more than ordinary glass; and by passing a ray of light through two prisms made of different glass, he had the satisfaction of finding that a white light was transmitted. After this, he employed the two sorts of glass in forming an object-glass, which would transmit light without decomposing it. This he effected by uniting a convex lens of crown-glass, of a greenish colour, with a concave lens of flint-glass, of a white tint (Fig. 167). When a ray of light falls upon this object-glass, it is acted upon by both—that of the crown-glass renders it convergent, and decomposes it; the concave flint lens, on the contrary, destroys the effect of the first, and an uncoloured image is formed at the focus. By this beautiful discovery, the refracting telescope has been made a convenient and easily managed instrument, to which higher powers can now

Fig. 167.

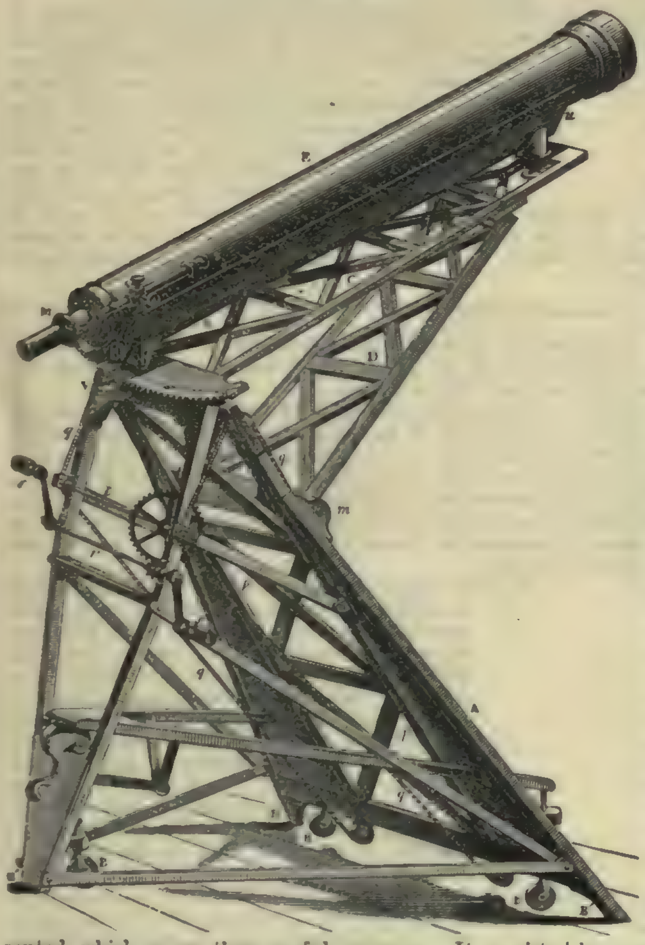
---

* The observer should not try this experiment by directing the telescope to the sun, as, if shining fully, its light and heat would destroy the pupil of the eye.—EDITOR.

be applied, and with better effect in one of 10 feet in length, than to those formerly made, which were some hundreds of feet in focal distance.

It is a matter of considerable moment to have the telescope mounted as steadily as possible, and to be able to direct it easily to any particular part of the heavens, so as to follow any object with the requisite facility. In the following figure (Fig. 168) a telescope-stand is represented, which serves these useful purposes. It consists of a firm support, A, resting on the ground by means of the feet B′ B′ B′ and the rollers B B B, and two movable supports, C and D, the former of which directly supports the telescope E, and is connected with the stand A by means of hinges at M M, by which it can be inclined more or less to the horizon. The second support, D, is connected with the first in a similar manner by the hinge *n*, by which means the angle between the two supports, C and D, may be varied at will. The inferior beam, *o o*, of the branch D, should slide along the inclined side of the stand A, and this motion produces the requisite elevation or depression of the extremity *n*, which turns on the hinge *m*. Two endless chains, *q q*, pass round the stand A, and are attached to the ends *o o* of the branch D. An axis, *r*, terminated by two handles, *s s*, carries a pinion which works in a wheel mounted on a second axis, *t*; this second axis is furnished with two pinions at both ends, of which the teeth catch in the links of the endless chain *q q*. In turning round the handle *s s*, the chain is thus worked up and down; the portion *o o* of the support D slides on the inclined plane, *p p*, and the projecting branch is raised more or less. The telescope, E, rests in *u u*, the latter part being connected with the support C by a pin at the object end, round which it can easily be turned as on a pivot. At the eye end of the telescope, the support *u u* rests upon two wheels, and a milled head, V, attached to a pinion, works in the toothed edge of the support C in such a manner, that in turning the milled head it turns the telescope to the right or left. The observer, by turning one of the handles, *s s*, with the one hand, and the milled head, V, with the other, is thus able to change the direction of the instrument according to his wish. A smaller telescope, Z, is commonly attached to the tube of the larger one, and is known by the name of the *finder*. Having a larger field of view than the principal telescope, the observer can discover the object he is in search of with greater facility; and by placing it in the centre of the finder, he guides the larger telescope directly upon it.

Fig 168.



REFLECTING TELESCOPES.—If an object A B be placed before a concave reflecting mirror M (Fig. 169), a similar effect is produced as when the rays of light proceeding from such an object pass through a convex lens. The ray of light passing from the point A will be reflected to the point *a*, while those passing from B will take the direction *b*, and the inverted image *a b* will be produced. The image *a b* can be magnified in the same manner as the image formed by a convex lens, though evidently not with the same facility; for here the image is formed between the object and the mirror, and there is a difficulty in knowing in what manner the eye-piece is to be placed. To obviate this difficulty, the inventor of this telescope, the celebrated Gregory, thought of placing a smaller concave lens N (Fig. 170)—which would only intercept a portion of the rays proceeding from any object—after their passage through the image *a b*, and to send them through the opening at the centre of the mirror M, in such a manner as to produce a second image, *a′ b′*, which could be examined with the requisite distinctness by the eye-piece *o*. By this combination an erect image would be produced, and the telescope would be used in precisely the same manner as the Galilean telescope. The telescope independently invented a few years later by Sir Isaac Newton, is more simple than the former, receiving the rays which pass from the great mirror on a plane reflector N (Fig. 171), inclined at an angle of forty-five degrees, before they arrive at the focus *a b*, and produce the image *a′ b′*, which can be examined by means of the eye-piece O. In this form of the reflecting telescope, the observer looks in a direction perpendicular to that of the object observed. In order to obtain as much light as possible, a considerable portion of which was lost by being reflected from successive surfaces, Herschel conceived the plan of inclining the great

Fig. 169.

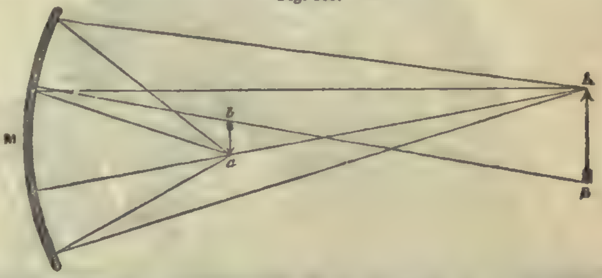


Fig. 170.

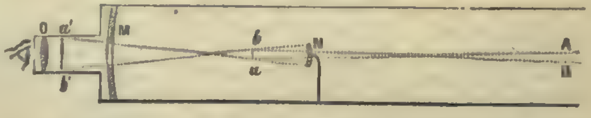
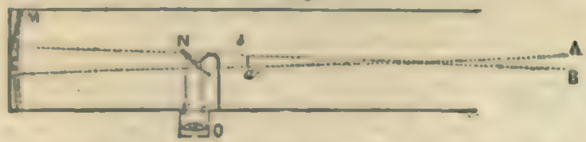


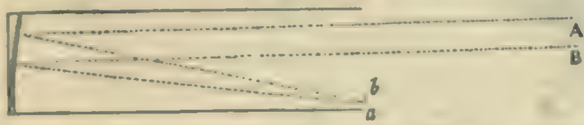
concave mirror at a small angle to the object observed, by which means the rays of light proceeding from the

Fig. 171.



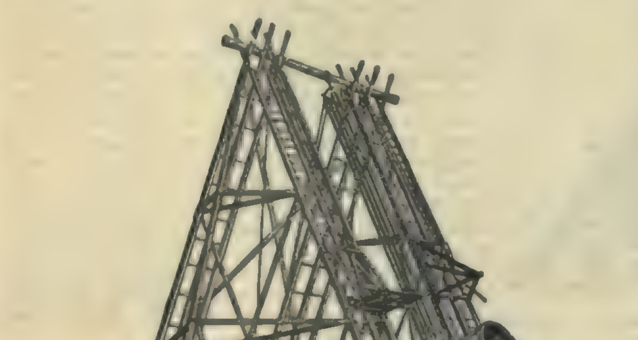
object A B (Fig. 172) were reflected to *b a*, and the image thus formed could be examined in the ordinary manner by the eye-piece, the back of the observer being turned to the object. This disposition (termed by Herschel *front view*) is, however, only suited for instruments with large apertures, in which the loss of light is less than when reflected from a second mirror.

Fig. 172.



The great forty-feet telescope of Herschel, with a mirror of four feet in diameter, was mostly used in this manner, the observer being placed in a gallery at the end. The engraving below gives a view of this magnificent instrument, which was moved upwards and downwards by means of numerous ropes and pulleys, whilst the motion to the right and left was facilitated by rollers. With this mighty tube Herschel was able to apply a magnifying power of six thousand! Unfortunately it was too much exposed to the weather; the polished mirror was dimmed in one night by the damp atmosphere; and the instrument remained in use for only a very few years, when it was found unfit for service.

Fig. 173.



INSTRUMENTS FOR MEASURING THE ANGLE.—Hitherto our attention has been directed to instruments of great magnifying power, intended to bring distant objects apparently nearer to the observer. We have now to speak of graduated instruments of more delicate construction, by which the astronomer is enabled to measure, with wonderful accuracy, the size and distance of celestial objects. The true solar time is also obtained, by comparing their angular distances from other well-known objects; in other words, by measuring their angle.

The length of the arc of a circle is described between the two sides of an angle, valued by means of a particular arc taken as unity. This arc, by common consent, is taken as the three hundred and sixtieth part of the entire circumference, which is called a degree, marked thus, 1°; and the angle which corresponds with it is the angle of a degree (Fig. 174).

It rarely happens, however, that the angle we seek to determine comes out exactly in degrees. It becomes necessary, therefore, to divide the degrees into fractional parts; and for this purpose the degree is divided into sixty parts, called minutes, written thus, 1′. For further accuracy the minute is again subdivided into sixty parts, called seconds, written thus, 1″. When the instruments which we are about to describe are properly arranged, and the two telescopes are presented to their proper side of the object whose position or magnitude is to be measured, the angle is read off the graduated scale, which surrounds the circumference of the circle, by means of an index, which extends its limb over the whole length of the arc.

Fig. 174.

In measuring the angle by the visual rays which abut on each side of an object, two operations are required. The two rays of the graduated circle must coincide with the two sides of the angle. This is effected by viewing it successively in the direction of each of its sides; the object being to value the degrees, minutes, and seconds contained in the arc of a circle comprised between the two rays.

THE REPEATING CIRCLE consists of a graduated circle A A (Fig. 175) divided into 360°, with their respective fractional parts, and fitted with two telescopes furnished with micrometers, the telescopes varying in power according to the size and value of the instrument, and the whole mounted on a pedestal, as represented in the figure. It is also so arranged as to permit of its being turned in any required direction. The circle, A A, turns on its own plane round an axis implanted in it perpendicularly, and in its centre. This axis traverses a socket, B, which is fixed to the horizontal axis, C, and is terminated by the weighted drum of the pedestal D. This weighted drum is intended as a counterpoise to the circle and its telescopes, and to prevent it from swinging while turning on the axis C; the extremities of the axis C are supported by the mounted frame E, which is arranged so as to turn freely in the openings left by the mounting. In short, the pedestal, F, can itself turn, with all it carries, round an axis which penetrates its interior, and which is fixed in the foot of the instrument. By this disposition of its parts in turning the circle round the axis C, and at the same time turning all the instrument round the axis of the pedestal E, the plane of the circle can be trained in any desired direction.

A telescope, S S, is fixed on the upper face of the circle in the direction of one of its diameters, and turns freely round its centre. A second glass, I I, is adapted, in the same manner, to the under-face of the circle at an angle with the other, but so adapted as to turn freely and independently of the circle. The eccentricity of the under telescope, and the great distance of the objects usually under observation, render the errors scarcely appreciable.

In Fig. 176 an enlarged portion of the circle is represented, showing the graduated scale and the extremity of the piece K (Fig. 175). The piece *a* (Fig. 176) is pierced with a rectangular opening, traversed in its middle by the screw *b*, which is formed to turn upon itself in the collars fixed at the two extremities of the opening. Screw *c* acts upon *b*, and is besides attached to the clamp *d*, which clasps the edge of the limb above and below. The screw *c* is to regulate the place of the clamp on the opening, pressing the edge of the limb between its jaws, and thus fixing the screw, *c*, to the limb. When it is required to displace the telescope rapidly, it is necessary to press the screw *c*, which throws it loose, so as to move round the circle under the impulse of the hand. When the glass has nearly attained its proper position, it is trained more exactly by turning the screw *a*. The vice *d* and the screw *c* are acted on and fixed again to the limb, and by turning the screw *b*, a slow movement is communicated to the screw *a*, which trains the telescope to the exact spot required.

Fig. 175.

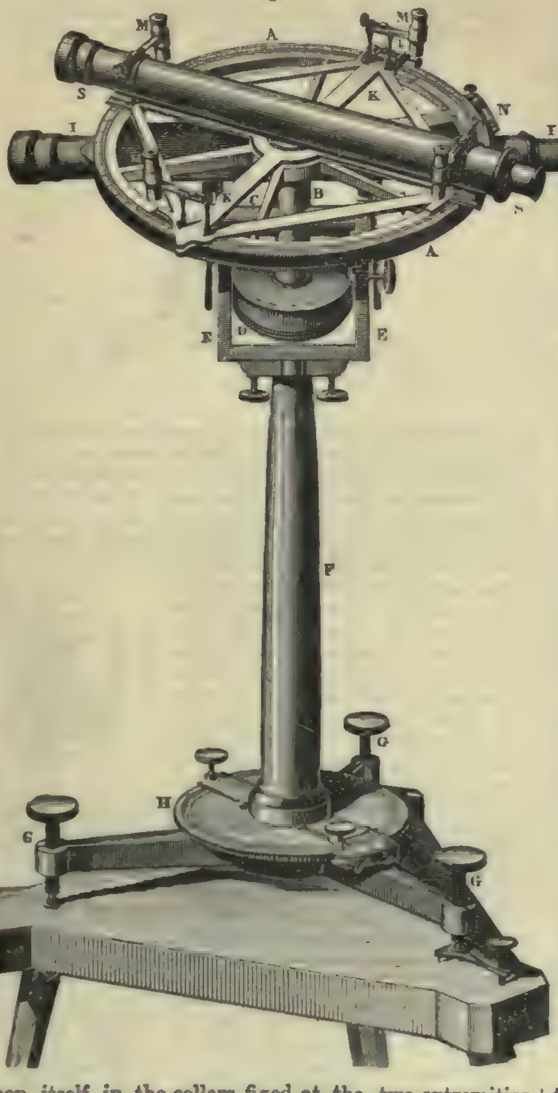


Fig. 176.

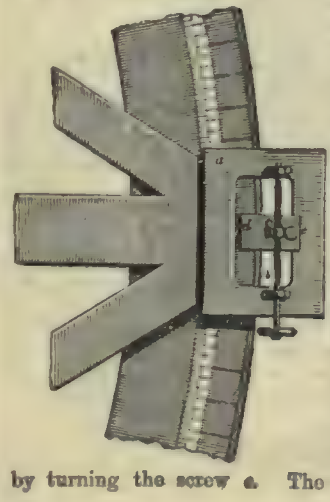

Another disposition has been adopted for producing, in an analogous manner, the movement of the circle round its centre. The axis, after having traversed the socket B B (Fig. 175), and the cylindrical counterpoise D slightly inclined from below, carries a toothed wheel of the same diameter as the counter-weights. An endless screw is connected with this wheel, and is carried by a collar fixed to the counterpoise D, as is shown in Fig. 175. If the endless screw *a b* be moved by turning one of the two milled heads, the toothed wheel with which it is connected will receive a rotatory motion, in which the circle to which it is fixed by the same axis will necessarily participate. But the screw *a b* may be withdrawn from the toothed wheel in such a manner as to stop all communication between them. To do this, it is only necessary to turn the finger *a* of the screw when the two are disengaged, as in Fig. 178. Having thus explained the mechanical details of the repeating circle, its application to measuring the angle is as follows:—

Fig. 177.

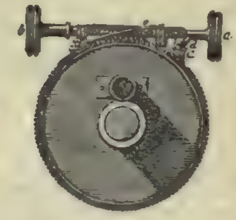

Fig. 178.

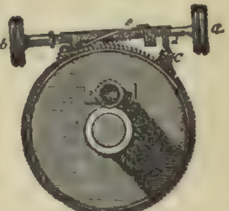

Let A and B (Fig. 179) be the two distant points, which are the sides of the angle to be measured. Having placed the upper glass at zero of the graduated scale, and fixed it to the circle in that position, the circle is now placed in the plane of the angle and made to turn in this plane, so that the telescope of the face is directed towards the point A, the other telescope being directed to the point B, the circle remaining in the position Fig. 179. The circle is now to be turned until the lower instrument is directed towards the point A, as in Fig. 180. The circle being again fixed, the upper telescope is detached and trained so as to be directed to the point B, as in Fig. 181. The upper instrument is thus made to describe an angle exactly double that sought for, and the index travels over the limb the exact measure of this double angle, which it represents in degrees, minutes, and seconds; dividing this number by two, the exact value of the angle is obtained. Supposing the operation to require confirmation, the same process may be repeated, turning the whole instrument round the axis of the circle, so that the upper telescope is again directed towards the point

Fig. 183.

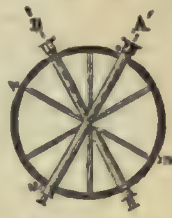

Fig. 182.

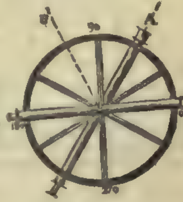

Fig. 181.

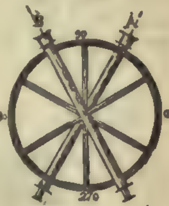

Fig. 180.

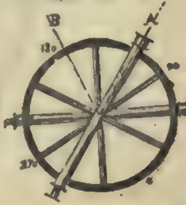

Fig. 179.

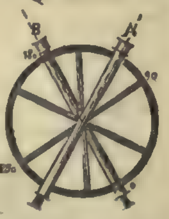

A, as in Fig. 182, the other detached and turned towards point B, as in Fig. 183, when the instrument stands exactly in its first position, as at Fig. 179; the only difference being, that the index, which at the beginning of the first operation was at zero of the graduated scale, has, at the end of the first operation, travelled over it double the distance of the angle sought; and, at the end of the second operation, this distance from zero is quadrupled; therefore, to get the exact value of the angle, the portion of the circle thus travelled over has to be divided by four. In order to diminish the chances of error in reading off the scale at the end of these operations, four different verniers, regularly subdivided, are fixed upon the circle; one of the indexes only which accompany these verniers, is employed to determine the entire number of divisions of the limb which the telescope has turned; but the four verniers give each a value of the fraction of division which is to be added to the entire number, and it is the mean of their indications which is given as the value of this fraction of division. The microscopes M M (Fig. 175) are so disposed that the divisions of the vernier can be easily observed, as well as the coincidence of one of them with the scale of the limb itself. It is hardly necessary to add that the repetition of the operation secures immunity from error, and that it also gives its name to the instrument.

To Measure the Zenith Distance.—In measuring the angle, we have real objects to deal with; it is otherwise in the present operation. We name that point of the heavens the zenith to which the vertical line is directed, and this direction is indicated by the plumb-line (Fig. 184). The zenithal distance of a point is the angular distance of this point and of the zenith—that is to say, the angle that the ray directs towards the point made in the vertical, at the place of observation. The zenith is not, as we have said, a point that we can observe with an instrument; but the zenith distance is, nevertheless, to be found by the following operation:—In order to render the repeating circle available for measuring the zenith distance, the axis of the column F (Fig. 186) is rendered perfectly vertical. For this purpose three powerful screws, G, are required, on which the instrument is to rest; these screws are turned until it is perfectly level, which is ascertained by means of a spirit-level (Fig. 185) fixed to the tube of the lower telescope, in a horizontal position, while the circle itself is nearly vertical, as in Fig. 187; the screws, M *n q* (Fig. 187), being used to regulate the position, and render the whole perfectly square.

Fig. 184.

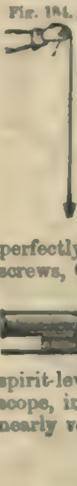

Fig. 185.

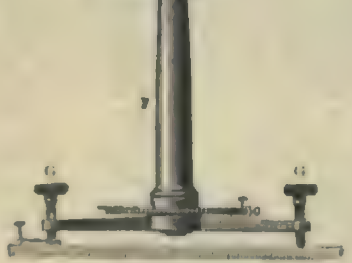
Fig. 186.



This position being attained, turn the whole instrument round the axis, F (Fig. 186), until the spirit-level is parallel to the line *p q*, and perpendicular to the line *m n* (Fig. 187).

The axis of the column of the circle and the plane of the circle being thus rendered perfectly vertical, the upper telescope is to be turned upon the circle so that its index stands at zero of the graduated scale, and the circle is fixed in this position. The circle is then turned with the telescope, first around the axis of the column so as to lead the vertical plane of the circle by the point A Fig. 188), and afterwards round the axis of the circle so as to train the optical axis of the glass exactly towards the same point. The circle being fixed in this position by means of the tangent screw acting on the extremity of its axis, a half turn is given to all the instrument, which carries it round the axis of the column, placing it in the position indicated (Fig. 189), detaching the instrument, and training it along round the axis of the circle in such a manner as to point towards A (Fig. 190). It is clear that in this movement the telescope has made an angle double the zenithal distance A O Z (Fig. 193), which is to be determined; and that by reading the number of degrees, minutes, and seconds of the graduated scale to which the index, which accompanies the telescope, corresponds, we have only to take the half of this number to have the value of zenithal distance.

Fig. 187.

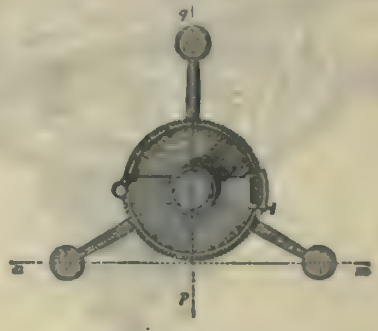


Fig. 192.

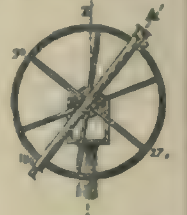

Fig. 191.

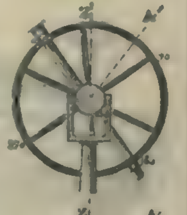

Fig. 190.

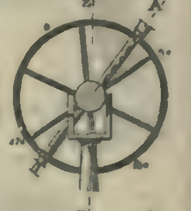

Fig. 189.

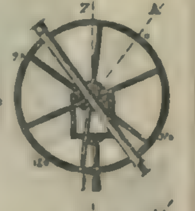

Fig. 188.

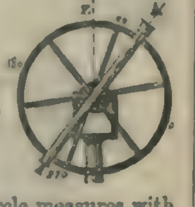
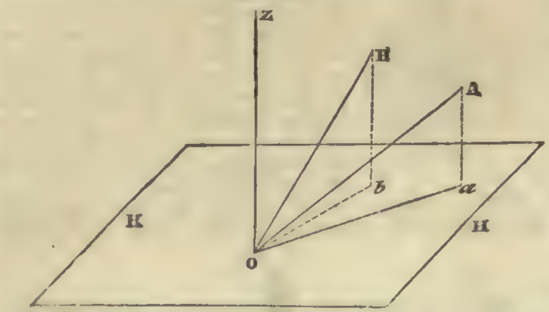


The operation may here terminate, if the operator be satisfied with the measure obtained; but should he wish to verify the calculations by increasing the multiple of the angle, he may continue the operations by making a half turn round the axis of the column, crossing the circle in its plane, so that the telescope, which remains fixed, is again directed towards the point A (Fig. 190).

The instrument is now in exactly the same position as in Fig. 188, in the first operation; but the index, in place of being at zero, is now at an angular distance from zero just double the data we seek to value. A new operation, exactly like the first, consequently gives, at its termination, a value of four times the value of the zenithal distance, and the sum found, divided by four, will give the precise value.

The Theodolite.—The repeating circle measures with great exactness the angle A O B (Fig. 193), formed by the right lines joining the two points A and B at the point O. But it frequently happens that the angle comprised between the vertical plane Z O A, Z O B, which passes between these two points, is required—that is, the angle *a* O *b*, formed by the intersections, O *a* O *b*, of the two planes, vertical with the horizontal plane, H H. Our knowledge of the angle A O B, measured by the repeating circle, added to that of the angles, Z O A, Z O B, which are the zenith distances of the points A and B, enables us, by deducting the angle *a* O *b*, either by geometrical construction, or by trigonometrical calculation, to determine the angle. But it is sometimes more convenient to ascertain its value by direct measurement; and the theodolite we are about to describe enables us to do this with great exactness.

Fig. 193.



This instrument is represented in Fig. 194. It is composed of two graduated circles, of which the one is vertical, the other horizontal. The first of these two circles, A, is adapted to the horizontal axis B, round which it turns. The axis B is carried by the upper extremity of the vertical axis C, round which the circle A and the axis B can be turned by one common movement. The weight D acts as a counterpoise to balance the circle A, preserving it steadily on the vertical axis C. The second circle, E, has its centre upon the same vertical axis C, and turns on its plane round the axis. The foot of the instrument is furnished with three double screws like the repeater, by means of which the instrument can be rendered perfectly vertical, which is ascertained by means of the spirit-level, F, on the axis B. This spirit-level is not carried round with the circle, as in the repeater, but a slight motion can be given to it by means of the screw *a*, thus slightly raising or depressing one of its extremities, and making it turn round a small axis at its other extremity. In this manner it is so managed that the bead of the level will be exactly in the centre of its tube when the axis C is in a vertical position; and, consequently, the plane of the circle A will be vertical also. As a test of the circle and the axis C being perfectly vertical, and the axis B horizontal, the movable spirit-level (Fig. 195) is used. This instrument is made so as to rest on the axis B; the feet of the spirit-level being adapted to it for that purpose, while it is supported in its place by the fork *h* (Fig. 194).

Fig. 194.

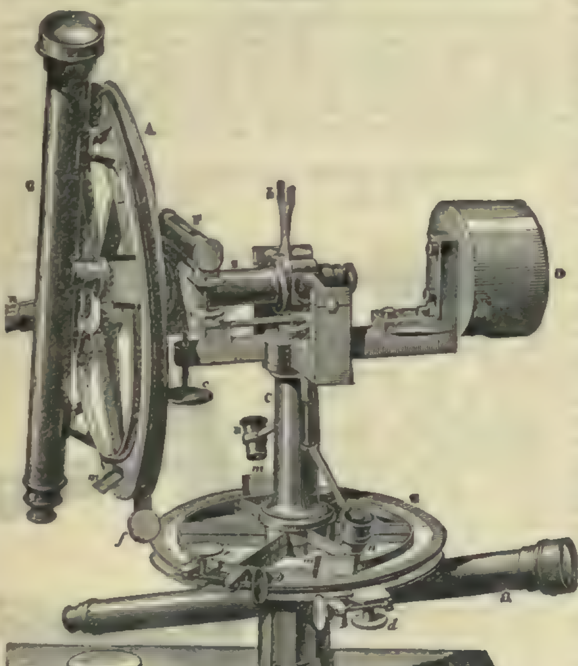


Fig. 195.

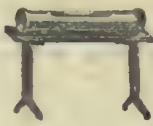


The telescope G is adapted to an inner circle, which moves round the interior of the circle A. In like manner the parts of the instrument attached to the horizontal circle, E, are fixed to an inner circle, which moves round its interior, the outer extremity of each circle carrying a graduated scale, to which the inner circle acts as an index guide. A clamp, *d*, having an adjusting and guiding screw, serves to fix the circle E to the pedestal; while another clamp, *e*, in a similar manner, serves to fix the upper parts to it; and a third clamp, *f*, serves to fix the limb A in such a manner as to be in opposition to it when turned round its centre. A fourth clamp, not seen in the figure, attaches the telescope G to the circle A.

A second telescope, H, is adapted to the pedestal of the instrument, having movements which, from its position, are very limited; it serves no other purpose, however, than to show that the foot of the instrument is steady while the observation is in progress. With this object, profiting by the limited movements it can take, its optical axis is trained in the direction of a point which can be easily recognised; and from time to time, while shifting the instrument, it serves to assure the observer that the telescope is directed to the same point as at the commencement of the operation. A guiding-screw, *g*, in the foot of the pedestal, serves as a slow movement, by which the optical axis of this glass may be trained to the required point.

To measure the angle comprised between the two vertical planes passing between two objects, turn the whole upper part of the instrument, independently of the graduated limb, E, so that the index traced upon the inner circle coincides with zero of the graduation, and fix this circle to the limb E in this position by means of the clamp *e*. By turning the limb E and all it carries, and at the same time moving the telescope G round the centre of the circle A, so that the optical axis is directed to the first of the two objects to be observed, the first operation is completed. Fix the limb E in this position, by means of the clamp *d*, for the second operation, throwing loose at the same time the clamp *e*, and turning the upper instrument round its axis so as to lead the telescope G direct to the second object. The index of the circle, moving in the interior of the limb E, has described upon this limb an arc representing the value of the angle sought, and of which we can read the amount on the graduated scale.

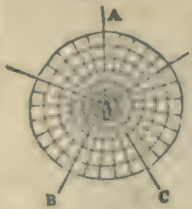
If it be intended to apply the principle of repeating the angle, fix the higher instrument to the limb E in the position it has now attained; loosen the clamp *d*, and turn the limb E, with all above it, so that the telescope G is again directed to the first object. By fixing the circle E in this position by means of the clamp *d*, and turning the upper part of the instrument until the telescope G is directed to the second object, it is clear that the index of the inner circle has described another arc equal to that already described in the first operation; and so on, by continuing the same series of operations until the multiple is sufficiently enlarged, a result may be secured free from error when it is reduced to its real value, which is done by dividing the gross result by the number of multiples. The readings on this instrument are accomplished by secured verniers, whose divisions are enlightened by small plates of polished glass, *m m*, and by the microscopes, *n n*, trained on the scale; by these means indications are easily read off.

THE ALTITUDE AND AZIMUTH INSTRUMENT.—This is the most useful of all the portable instruments, and to the scientific traveller an invaluable one, measuring with great accuracy both vertical and horizontal angles. (See folio plate).

In applying the instrument to astronomical purposes, it was formerly the custom to clamp it in the direction of the meridian, and, after taking an observation, or series of observations, with the face of the instrument one way, to wait till the next night, or till opportunity permitted, and then take a corresponding series of observations of the same object with the face reversed, by way of verification. This is now seldom practised, being obviously imperfect. The instrument consists of a central tripod, to which is fixed the azimuth circle, having a horizontal motion of about three degrees, so that its zero can be brought exactly in the meridian by means of a slow moving screw beneath the circle. The tripod rests upon foot-screws, which are described by Mr. Troughton, in the *Memoirs of the Astronomical Society*, as "being double; that is, a screw within a screw, the exterior one having its female in the end of the tripod, and the female of the interior screw being within that of the exterior," by which ingenious contrivance, three distinct motions are gained for regulating the azimuth. Brass cups are placed under the spherical ends of the foot-screws; this screw, invented by Mr. Troughton, is intended to give a very slow motion to one of the feet, and the foot of the tripod is designed to be placed either north or south. Above the azimuth circle, and concentric with it, is a strong circular plate, which carries the whole of the upper works. This plate rests on the axis of the azimuth, and moves concentrically with it. Rising from this plate are two strong conical pillars, on which the transit instrument is supported. Upon the axis, as a centre, is fixed a double vertical circle with the telescope between them, the circles being fastened together by small brass pillars, while the graduated scale is made on a narrow silver ring, inlaid on the outer face of one of the circles. Two reading microscopes are placed at each extremity of the circle, supported by two attached near the top of the pillars. The adjustments required are as follows:—The horizontal circle is first to be leveled, which is to be effected in the same manner as with a theodolite. The axis of the telescope must also be leveled, as in the transit instrument, and the spider-lines adjusted for collimation and verticallity. The meridional point on the azimuth is its reading when the telescope is pointed north or south. This may be determined by observing a star at equal altitudes, east and west of the meridian, and finding the point midway between the two observed azimuths; or the instrument may be adjusted to the meridian, in the same manner as a transit instrument. The horizontal point of the altitude circle is its reading, when the axis of the telescope is horizontal, and may be found, as with the mural circle, by alternate observations of a star directly, and reflected from the surface of mercury. The telescope usually carries, in its principal focus, a spider-like micrometer, as in the transit instrument, to be described presently.

THE MICROMETER.—We have had occasion to mention this instrument, and a short account of it may not be out of place here. It consists of a system of very fine wires (Fig. 196), by which the apparent magnitude of heavenly bodies may be measured, and the exact moment of their transit across the wires observed with great exactness. In the case of refracting telescopes, the micrometer is fitted in the instrument itself. In circular instruments, and the larger instruments of observatories, it forms a part of the microscope attached to the outer edge limb for reading off the graduated scale.

Fig. 196.



When a telescope is fitted with the micrometer, the right line of the optical axis *o* (Fig. 197), exactly coincides with the centre of the crossed lines B. When it receives the ray A, it is very obvious that, by a proper arrangement of wires, the utmost exactness of observation may be attained. The micrometer is usually formed of the finest platina wire, having three horizontal and four transverse wires. When the telescope is furnished with this instrument, the reticulated frame A (Fig 198) is placed at the end of the tube B C, near the eye-piece, which again shuts into the principal tube D of the telescope. On the other hand, the object-glass E, F, formed of two lenses, also shuts into the same tube, each requiring to have their focal distance from the object-glass adjusted either by the hand or by means of a guiding screw.

Fig. 197.

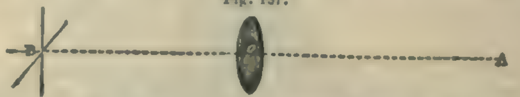


Fig. 198.

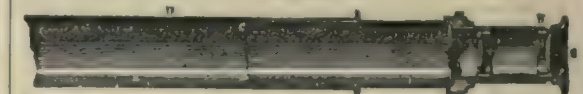

In the case of circular instruments, the micrometer is fitted in a microscope, as represented in Fig. 199. It is firmly fixed in its position, so as to enable the observer to read off the angle from the graduated scale on the outer side of the limb C D, Fig. 200. In small instruments, the screws which serve to fix the microscope in its position are usually arranged so as to regulate its distance from the limb of the circle. In the body of the microscope at A are placed two wires, crossing each other diagonally, which may be made to traverse the field of view, either horizontally or perpendicularly, by turning the micrometer screw *a*, working in the box underneath it. Figure 201 represents the field of view, with the magnified bars of the graduated scale as seen through the microscope. A small mirror, *l* (Fig. 199), is sometimes fixed to the micrometer, arranged in such a manner as to throw the light of a lamp, or a jet of gas upon the part of the limb which is opposite to the microscope; it is sometimes pierced with an opening in the centre, which receives the rays, and serves to illumine the microscope itself. In the larger instruments of observatories, they are fixed in the wall which supports the circle, the graduated scale being illuminated by a lamp

Fig. 199.

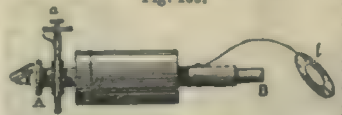

Fig. 200.

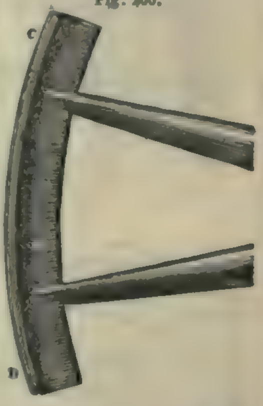

Fig. 201.

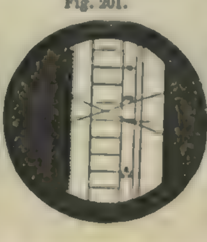

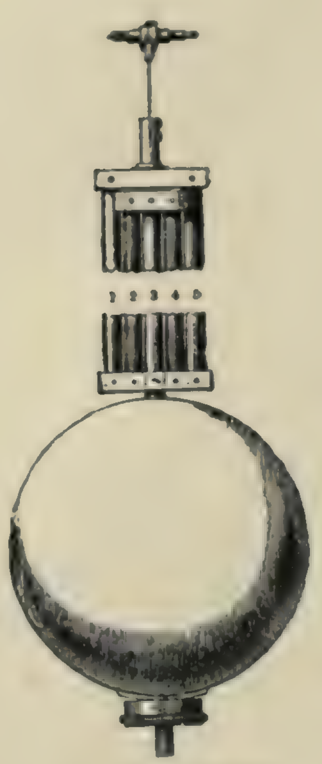

Fig. 1.—Gridiron Pendulum.

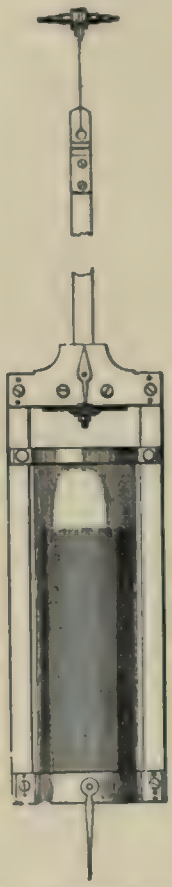

Fig. 2.—Mercurial Pendulum.

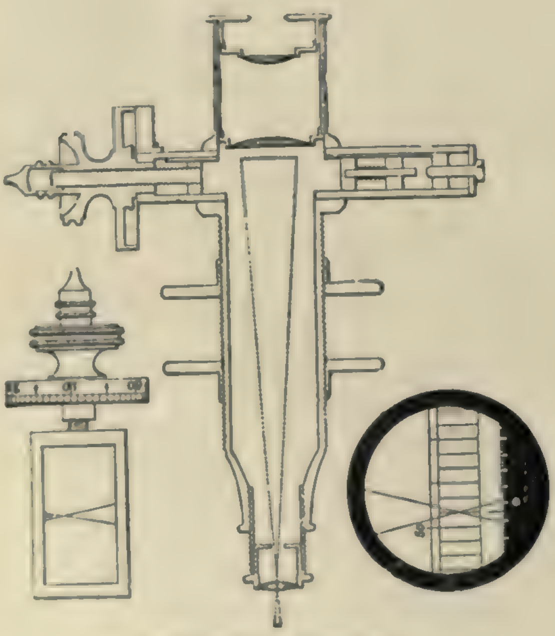

Fig. 3.—Micrometer-Microscope.

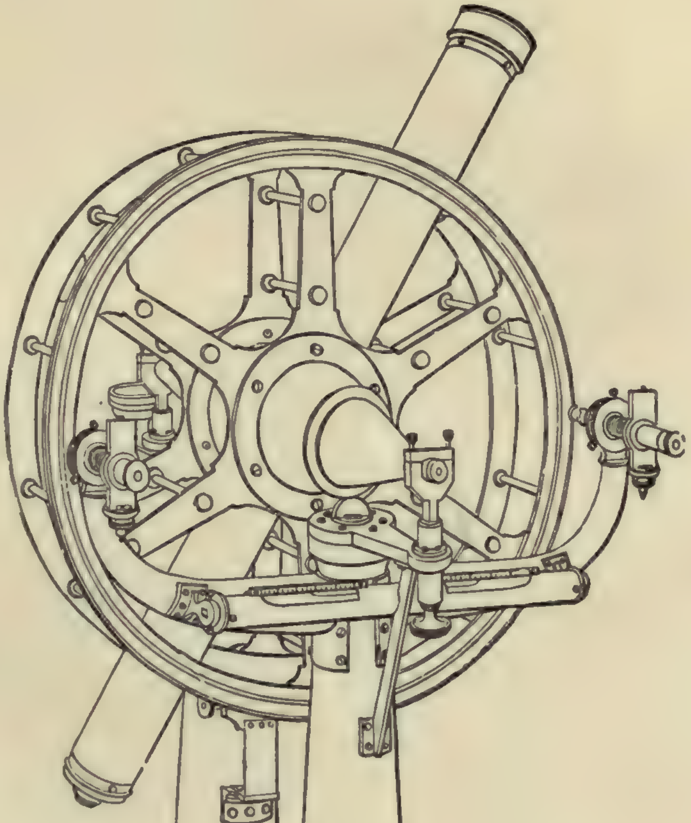
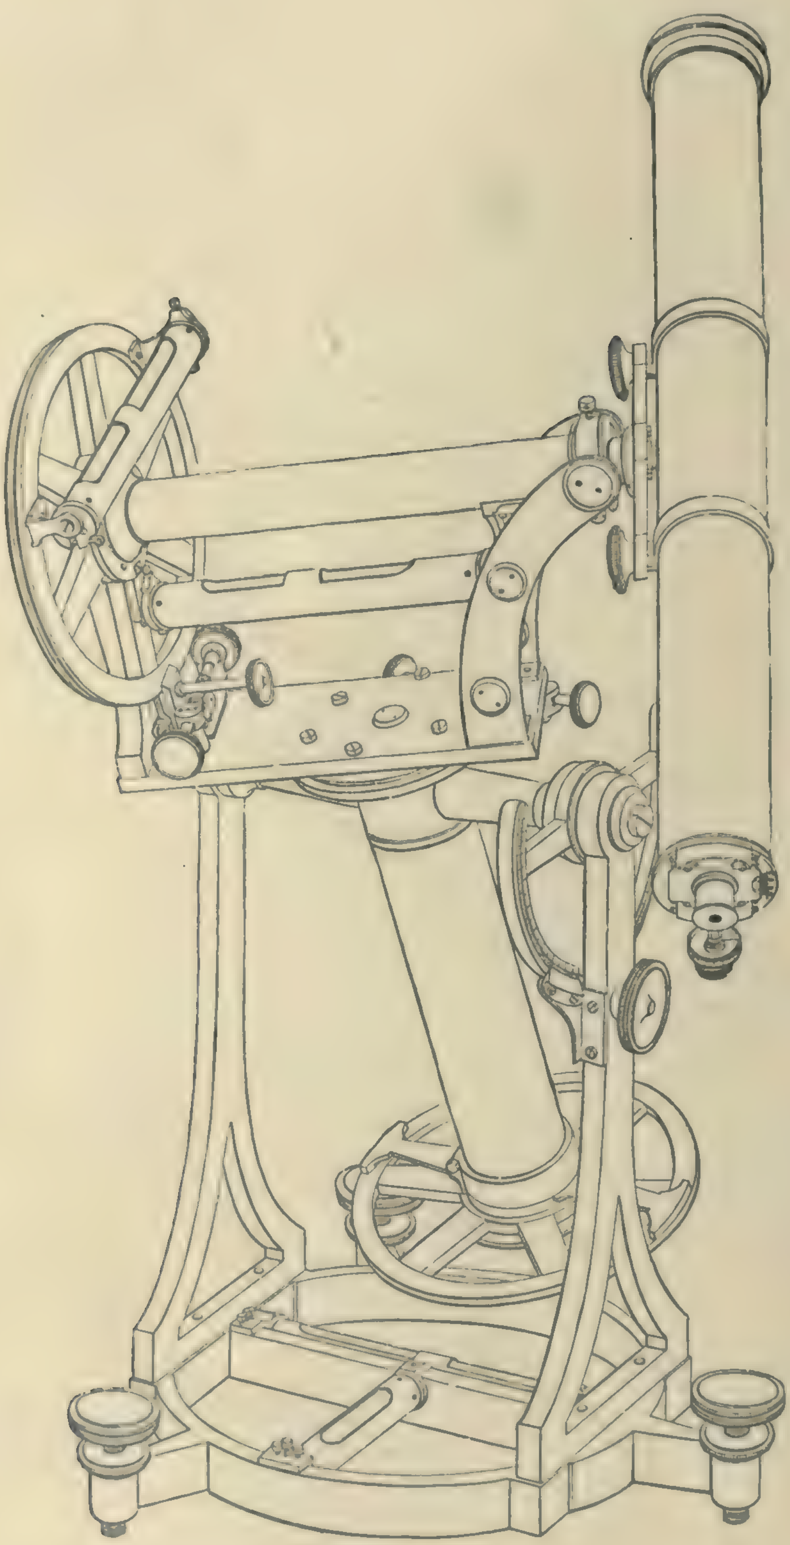
Figures 1 and 2 illustrate contrivances for overcoming the changes, produced by heat, in the pendula of clocks referred to at page 1001. In the Gridiron Pendulum, this is effected by employing rods of different metals, or the same metals, so fixed, as that whilst one series expands or contracts in one direction, the other shall do so in an opposite one. In the Mercurial Pendulum, a cistern containing mercury is employed, which, by its changes of length, compensates for those of the rod of the pendulum; that being the object of each arrangement.

Fig. 3 gives a sectional view of the Micrometer-Microscope, which has been already described at page 998.



The Altitude and Azimuth Instrument.

ASTRONOMICAL INSTRUMENTS.—(See page 998).



The Equatorial Instrument.

ASTRONOMICAL INSTRUMENTS.—(See page 999).

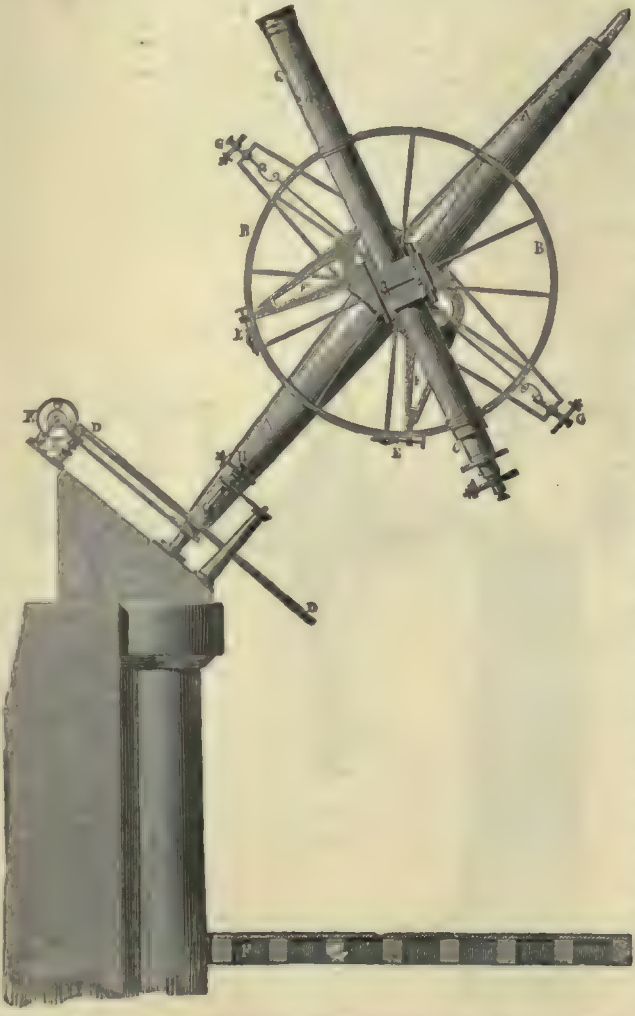
or jet of gas. The shaded part (Fig. 201) represents a diaphragm with the cross wires, *m*, the angle of which may, by turning the micrometer screw, *a*, be bisected by any line on the circle in the field of view. On the left hand of the diaphragm is a comb, or scale, each tooth of which represents one minute; and one revolution of the screw moving the wires over one tooth of the comb is equal to one minute of space.

The adjustment of the microscope consists in making the cross wires in its focus, and the divisions on the circle, both appear at the same instant of time, and free from parallax: the adjustment is such that five revolutions of the micrometer screw shall measure a five-minute space on the graduated circle. For the former of these adjustments in the telescope, the eye-piece is drawn out until the distinct vision of the wires is obtained, and the divisions or bars of the instrument are well defined.

The motion of the comb, or scale of minutes, is regulated by a screw; and the micrometer head, by friction, can be made to read either zero, or any required second when the cross wires bisect any particular bar, by holding the milled head of the micrometer screw.

THE EQUATORIAL.—The instruments we now come to describe belong exclusively to observatories, and in these establishments the equatorial is specially adapted to mark the diurnal movements of the heavens. The axis A A (Fig. 202), round which the whole of the instrument can turn, is so arranged as to follow the axis of our planet the earth, and it carries, laterally, the graduated scale B B, which can turn both in its plane and round its centre. The telescope C C, fixed to this circle, follows its movements, and its optical axis thus makes an angle variable with the earth's axis. A second graduated circle D D, whose plane is parallel to the celestial equator, and having the axis A A as its centre, is fixed in such a manner, that it follows all the movements of the instrument in its rotations round this axis; the position of this second circle determines the altitudes, and gives name to the instrument. The clamp E E, with guiding and reversing screws, intended to fix the circle and the telescope to the axis A A, when the circle turns round its centre, is carried by the pieces F F attached to the axis. Two micrometers, G G, are adapted to the extremities of the cross beam, firmly attached to the axis in such a manner as to permit of the divisions of the graduated scale, carried on the side of the limb of the circle, being read off. Other micrometers are attached to the masonwork which carries the extremities of the axis, and are intended to read the graduated scale of the second circle D D, which, in this instance, is on the upper face, and not on the outside of the limb. Such an instrument affords great advantages in measuring the relative position of two contiguous bodies, in measuring the diameters of the planets, &c. The circle which is connected with the polar axis is graduated into hours, minutes, and seconds of time, to indicate the right of ascension of the object under examination; while the circle connected with the declination axis is graduated into degrees, minutes, and seconds of arc, to indicate declination, or polar distance. (See, also, the folio plate.)

Fig. 202.



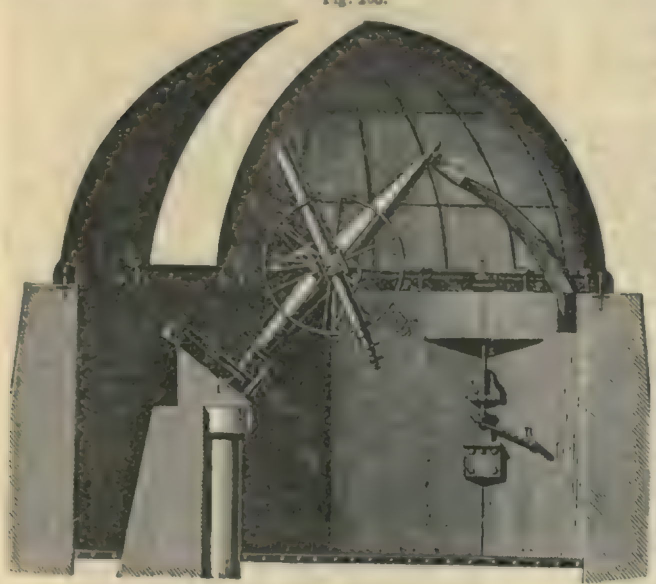
From this disposition of the instrument it will be seen that the optical axis or line of collimation of the telescope turns towards all points of the heavens, and, in making it turn with the circle B B round its centre, it can be made to form any angle with the axis of the earth. If the circle B B be fixed in one particular position, by means of the clamp E E, and an entire turn be made all round the axis A A, it is evident that the optical axis of the telescope meets the celestial sphere at various points of the same parallel.

A particular piece of mechanism, K, permits the equatorial circle, D D, to be put in communication with a clock movement, so disposed that the circle, D D, performs an entire turn on its axis in a sidereal day. If the optical axis of the telescope be directed to a star after the circle B B is fixed to the axis A A, and the circle D D put in communication with the clock-work, the whole instrument will be carried along with it, and the telescope will continue to follow the movements of the star; thus affording a means of verifying the uniform rotatory movement of the celestial sphere, after having made due allowance for the effects of atmospheric refraction.

The telescope of the equatorial requires to be in such a position that it can be directed to every part of the heavens above the horizon. This renders it necessary that the instrument should be so placed as to be clear of interruption from neighbouring objects. It is usual, therefore, to place it in the upper part of the observatory. The following engraving represents a section of the equatorial room of the Paris observatory, Fig. 203 representing a part of the instrument, of which we shall here give a brief description.

The axis is supported at its lower extremity by a massive piece of masonry, L, its upper extremity being supported by the iron beam M, made as light as the safety of the instrument, and its required steadiness will permit. The instrument is protected from the weather by a roof in the form of a hemisphere, having a long opening following its vertical plane, and formed with doors sliding laterally so as to leave a free opening in any required direction. By this arrangement the glass can sweep the heavens on its vertical plane from the zenith to the horizon; and by sliding the other parts of the roof, the whole of which is placed on friction rollers, and fur-

Fig. 203.



nished with a crank, R, for the purpose of moving it, every portion of the heavens can be swept with the instrument. The equatorial, consisting, as we have seen, of one circle, parallel to the plane of the equator, and of another circle which follows the axis of the earth, is arranged so as to coincide with any circle of declination, and is well adapted for measuring the differences of right ascension and declinations of two neighbouring stars.

The Transit Instrument.—The place of an object in the heavens is mostly defined by two elements; viz., by its right ascension and north polar distance. In the first approaches to accurate results of observation, these elements were generally determined by a mural arch or quadrant, firmly fixed in the direction of the meridian, the position of which was frequently checked by equal altitudes of stars. It was by means nearly similar, that Flamsteed observed his catalogue of three thousand stars, which has been so ably reduced and edited by the late Mr. Baily, and is generally known as the *British Catalogue*.

La Caille, at the Cape of Good Hope, observed his zones in like manner, using certain well-determined stars as "zero points," whose positions had been obtained by independent methods. The first astronomer was content with noting his observations to seconds of time—an accuracy, which, from the imperfection of his instruments, he considered to be quite sufficient. The invention of the transit instrument by Roëmer, in the year 1690, enabled astronomers to make great advances in the accurate determinations of right ascensions. This element, the most delicate and important, essentially depends upon time, and is, therefore, more difficult of direct estimation than the other, which consists of angular measurement, *read off* on graduated instruments, which modern artists have been enabled to bring to an astonishing degree of perfection. The transit instrument has been successively improved since the first idea of Roëmer. Dr. Halley, when Astronomer Royal, introduced its use at Greenwich, the construction being similar to that given by *Lerrebow* in his *Praxis Astronomiæ*. In this arrangement the telescope was placed twenty-six inches nearer one end of the axis, instead of being central—a construction which evidently rendered the determination of error of collimation very troublesome.

The form of the transit instrument used by Dr. Bradley (the next Astronomer Royal) differs little from that adopted in modern times—viz., a telescope fixed at right angles to a cross axis, and capable of taking all positions in the meridian of the place. This axis terminates in two cylindrical pivots, resting in Y's so that they only touch in two points for the purpose of diminishing the friction. One of these Y's is movable in such a manner as to correct either an error of horizontality of the axis, or an error of deviation from the meridian. The instrument is furnished with a graduated setting circle, sometimes placed at one extremity of the axis concentric to this axis (as was the case formerly with Troughton's Greenwich transit instrument), or two small divided circles placed near the eye end of the telescope. In the common focus of the object-glass and eye-glass, a system of wires is placed for the purpose of defining the position of an object as it passes through the telescope. These wires are of extreme tenuity, and generally consist of five or seven vertical wires and two horizontal (Fig. 204), the central vertical wire closely approaching to the meridian. The object of the lateral wires is to diminish the error of estimation of a star's transit, by taking the mean of all, since the time of transit over a single wire would be liable to some uncertainty. To prevent any error arising from parallax in the observation of the wires, the eye-piece is movable by a screw, so that the transit over each wire may be observed in the centre of the field. The adjustments of a transit instrument are, first, that its optical axis, or the line joining the centre of the object-glass and the middle wire, be perpendicular to the axis of rotation; secondly, that the axis be horizontal; and, lastly, that when corrected for the two preceding

Fig. 204.

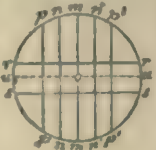


Fig. 205.

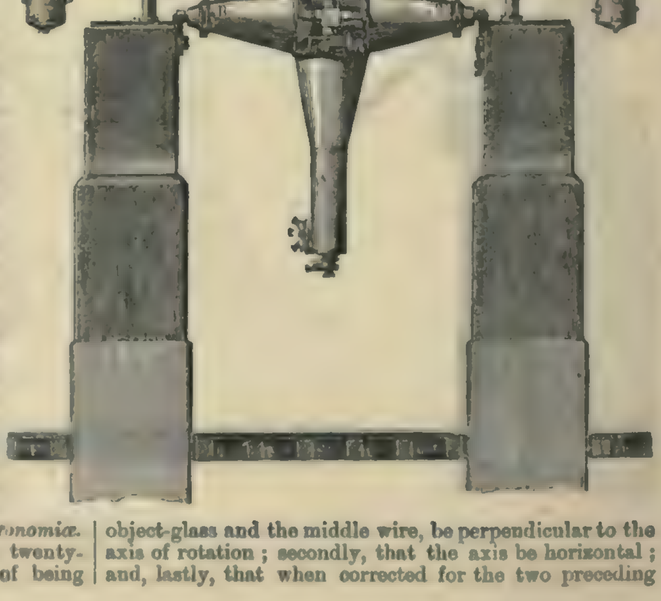

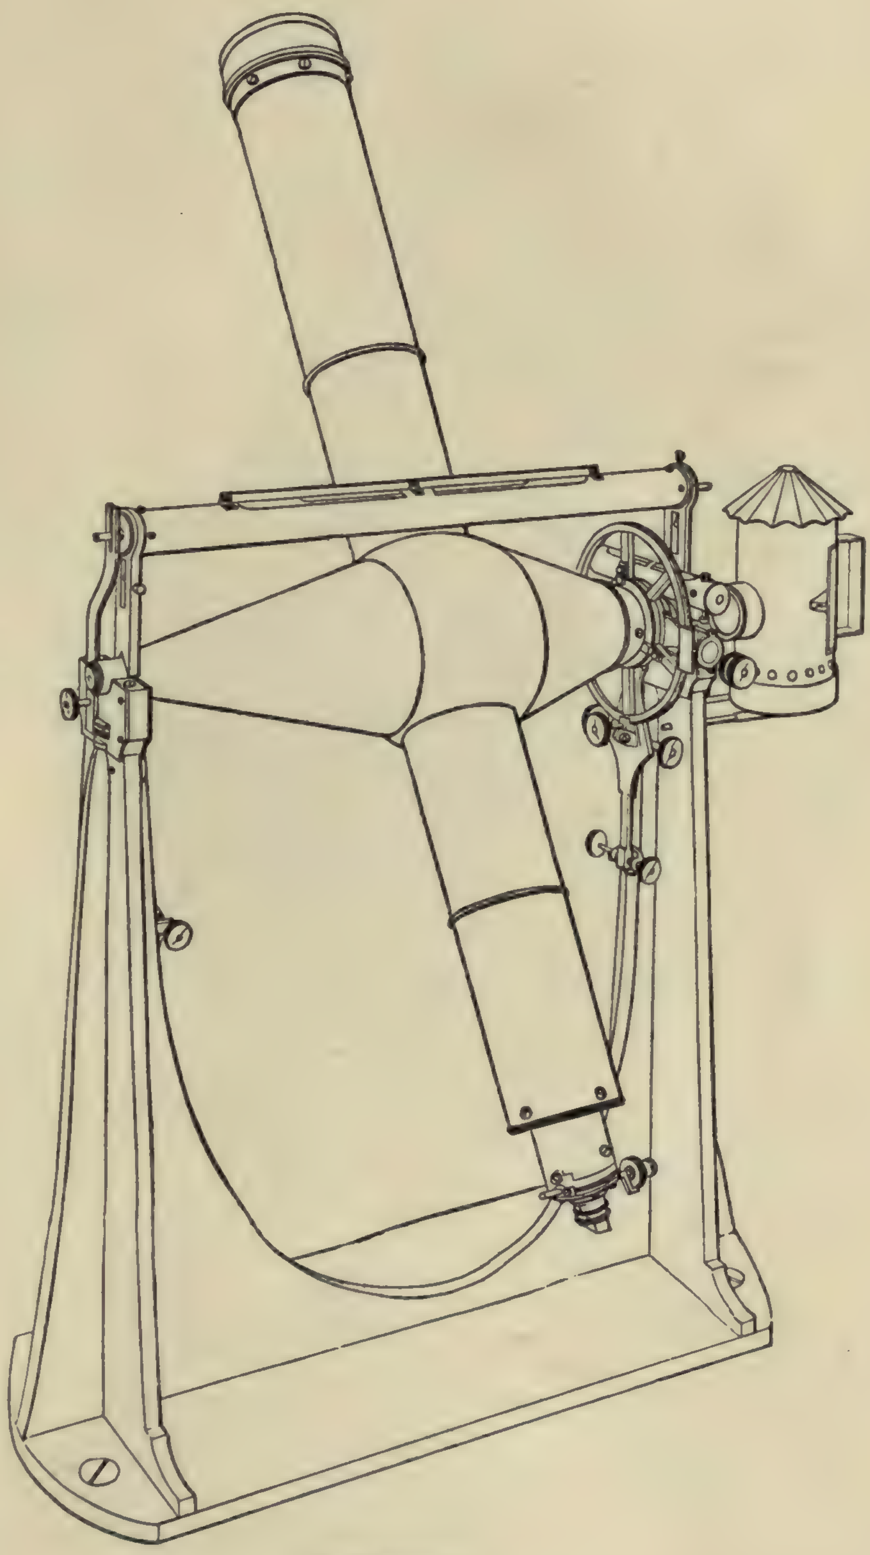

Transit Instrument.

ASTRONOMICAL INSTRUMENTS.—(See page 1000).

adjustments, the line of collimation describes the meridian. (See, also, the folio plate).

The other instrument, equally important in connection with a transit instrument, is a sidereal clock, beating seconds, and so regulated that the hour-hand will describe a complete revolution, or 86,400 seconds, from the time of a star's transit over the meridian fibre, to its return to the same point. The difference of the clock's gain or loss from this number is termed *its rate;* the excellency of a clock, therefore, depends on the steadiness of its rate, and every means are taken by mechanical refinements to preserve its uniformity. Astronomical clocks are generally furnished with mercurial pendulums for the purpose of compensating for extremes of temperature.

The transit clock requires to be mounted on a pier of solid masonry for the purpose of insuring steadiness.

The method of observing transits is as follows :—The observer, being comfortably seated (the telescope having been previously directed to the collimating star), notes carefully the minute, second, and fractional part of a second at which a star transits each wire. The hour is afterwards noted, and the counting of the clock verified when the transit is completed. This is done for several objects, the mean of the wires is taken, and thus, the differences of their right ascensions, subject to the rate of the clock, can be found. The fractional part is estimated by carefully noting the position of an object before its passage over the wire, and after its passage over the same wire. By a little practice, the instant when it was exactly behind the wire can be very accurately proportioned. In good observations the mean of wires is seldom liable to an error greater than one-tenth part of a second.

Recently, a new method of recording transit observations, by the agency of galvanism, has been brought into use at the Royal Observatory, Greenwich, which promises to supersede the old systems of observing. Its first introduction appears to have been in the coast survey of the United States; and in the hands of Mr. Walker, Dr. Locke, and Professor Mitchell, it has been considerably improved. The form of the invention, as described by the Astronomer Royal, is as follows :—From the principal instruments of the observatory, galvanic wires are connected with a recording surface placed in another part of the building. The transit clock, at each beat, completes a galvanic circuit, which is registered by proper apparatus on the recording surface, consisting of a cylindrical barrel, covered with prepared paper. Above the barrel (which is driven by clockwork regulated by a conical pendulum), a system of prickers is placed, carried by a travelling frame, moving slowly in the direction of the barrel axis. Thus, the pricker, which is connected with the transit clock, will register seconds on this barrel, and will form a series of spiral lines as it revolves. The method of arrangement is as follows :—A wheel of 60 teeth is fixed on the escape-wheel axis, and the teeth of this wheel, in succession, make momentary contacts of the galvanic springs. The position of the springs is so adjusted, that the effect of the wheel-tooth upon them occurs only when an escape-tooth has passed the sloping surface of the pallet, and the other escape-tooth is dropping upon its bearing; and thus the resistance of the springs does in no way affect the legitimate action of the train upon the pendulum.

Another pricker, carried by the same travelling frame, is connected, by arbitrary touch, with an index at the eye end of the transit circle. At the instant of a star's passage behind the wire, the observer touches this index, which will, therefore, register on the barrel a series of punctures equivalent to a transit observation. An advantage is gained by this method, insomuch that the equatorial intervals of the wires may be reduced to three seconds of time—the duty of the observer merely consisting in writing down, in addition to the preceding signals, the name of the object observed. For the purpose of registering on the barrel the beginnings of some minutes, and hours and minutes, from which the rest may be inferred, a provision is made by certain prearranged signals at known instants of the transit clock. In this manner the paper, when taken off the barrel, may be easily translated. This system has so far succeeded admirably at Greenwich, requiring only the use of the nerves of sight and sensations of touch, of which there is a more intimate connection than those of the eye and the ear. It will, therefore, most probably reduce the amount of "personal equation."

It frequently happens that two observers will not give the same time of the occurrence of the same phenomenon; as, for instance, the passage of a star over the wires of a transit instrument. The amount of this difference, which is termed "personal equation," varies from two-tenths to half a second, though instances have been known of this quantity exceeding one second of time. Dr. Maskelyne, and Kinnebrook his assistant, differed in this manner seven-tenths of a second. In modern times, Bessel and Argelander have differed upwards of a second. The method of determining it is to compare the "clock error" of one observer with that of another independently obtained (at a short interval of time). Or it can be deduced by taking transits of the same star over some wires of a transit instrument, by one observer, compared with the transits over other wires by another observer. Reducing each separately to the middle wire, the difference of their methods of observing may be at once deduced. We refer to the annual volumes of the Greenwich observations for examples of the first of these methods.

It can also be obtained by a binocular eye-piece, an instrument which permits two observers to see the star in its passage over the wires at the same time, and thus to observe the whole transit. This instrument is the invention of the late Mr. J. Jones.

In order to determine the relative accuracy of transit observations at the separate wires, the following method, first introduced by Bessel, and recently used by Struve and Dr. Oudemans, may be applied. Let x be the mean error of one observed wire, arising from a defect of hearing, y the mean error produced by an imperfection in the sight, which may be caused by a wrong estimation of the time at which the star passes behind the wire (varying with the thickness of the wires); then the mean error of an observed transit at one wire will be

$$M = \sqrt{(x^2 + y^2 \sec.^2 \delta)}.$$

The error of hearing, or x, will arise from the estimation of the precise instant of the origin of second, and will, therefore, be the same for all stars. The other will vary as the secant of the declination.

Then, if the transits of several stars are reduced to the middle wire by the known intervals of the wires, and the difference of each result from the mean is taken, the squares of these differences will be $= (n - m) M^2$, where n = the number of wires, m = the number of observed culminations. The probable error of M, determined by this equation, will be $M \frac{0{\cdot}4769}{\sqrt{n}}$, the probable error of the value M^2 will be $M^2 \frac{0{\cdot}9538}{\sqrt{n}}$.

Forming for each culmination $\Sigma(\epsilon^2)$, and their sums for all the culminations of the same star, the equation will become

$$(n - m)\, x^2 + (n - m)\, y^2 \sec.^2 \delta = \Sigma(\epsilon^2).$$

Proceeding in this manner, Dr. Oudemans has found, from 228 culminations, observed from October, 1847, to October, 1848, the mean error of a single wire =

$$\text{or } M = \sqrt{(\overset{s.}{0}{\cdot}1242^2 + \overset{s.}{0}{\cdot}0603^2 \sec.^2 \delta)}.$$

But the probable error

$$w = \sqrt{(\overset{s.}{0}{\cdot}838^2 + \overset{s.}{0}{\cdot}0407^2 \sec.^2 \delta)}.$$

A similar investigation from October, 1848, to October, 1849, gave a mean error, or,

$$M = \sqrt{(\overset{s.}{0}{\cdot}0062^2 + \overset{s.}{0}{\cdot}0602^2 \sec.^2 \delta)};$$

and the probable error

$$w = \sqrt{(\overset{s.}{0}{\cdot}649^2 + \overset{s.}{0}406 \sec.^2 \delta)}.$$

It would, therefore, appear that his hearing had improved, whilst his sight had remained the same as before. This determination rests on 360 culminations.

Dr. Robinson has recently investigated this subject, and has introduced another error arising from atmospheric tremor, which he considers to vary as the secant of the zenith distance. From his observations in 1830, he deduces the following probable errors for a star whose declination is δ :—

$x = \pm \overset{s.}{0}{\cdot}0445$ $y = \pm \overset{s.}{0}{\cdot}0619$, Z, or the atmospheric tremor $= \pm \overset{s.}{0}{\cdot}0331$.

Several years afterwards, he found the following values :—

$$x = \pm \overset{s.}{0}{\cdot}0732 \qquad y = \pm \overset{s.}{0}{\cdot}0554 \qquad Z = \pm \overset{s.}{0}{\cdot}049.$$

But between the periods of the two observations, new and more numerous wires had been inserted in the transit instrument.

Astronomers are very careful that the three adjustments of the transit instrument, before mentioned, are satisfied. And, firstly, with regard to the line of collimation. This adjustment is generally made by the observation of a well-defined terrestrial mark in one position of the axis, measuring its distance from the central vertical wire (in terms of the micrometer) with which the telescope is furnished. If, on reversal of the axis, the mark be again seen at the same distance from the central wire, the collimation of the instrument is correct; but, if not, the wire frame must be moved to one-half the difference of the two bisections. In the practice of modern observatories, the complete correction of this error is seldom attempted; this adjustment, though probably in large instruments the most permanent, being nearly corrected, and then left for occasional verification.

The following extract from the *Greenwich Observations*, 1850 (Introduction, page xvi.), will show the method of determining the error of collimation :—

"The value of this error, which is given in seconds of space, is supposed positive when it implies an additive correction to the transits of stars above the pole. For its measurement the following method has been used :—

"A small transit instrument is fixed on temporary wooden piers in the north opening of the transit room, and its object-glass is turned towards the principal transit instrument. In this position, when the principal transit instrument is turned towards the small one, the wires of the latter are seen as well-defined marks at an infinite distance, and the error of collimation of the principal transit may be determined by repeatedly reversing it, and viewing these wires.

"In November, 1846, a new determination of the value of the micrometer-screw (of the transit telescope) was made by means of six transits of Polaris over the two wires moved by the micrometer. The mean of the intervals of the times of transit was found to be 3m. 1s. ·17; and the north polar distance of Polaris being 1° 30′ 9″·3, this corresponds to an interval of space = 71″·188. But, by bringing each micrometer wire several times into contact with the fixed central wire, this interval was found to correspond also to 4r. ·368 of the micrometer. Hence, one revolution = 16″·297.

"April, 29d. 22h. The St. Helena transit instrument was used in the manner stated above. The wire appeared as a broad white line, there being no reflector; and the edges of this line were observed alternately by placing upon them the micrometer wire of the transit instrument.

Hence apparent error of collimation for D .	0·017

"The illuminated end of the axis was left east, which was also the position of the micrometer head; and, as the readings of the micrometer increase as the wire moves from the head, D (or central vertical wire) was therefore east of the line of collimation, and stars pass it too late, or the error of collimation of D is —0r. ·017, or — 0″·277. Also, with the illuminated end of axis east, Polaris passes the mean of wires earlier than it passes D by 0s. ·07, which in arc is equivalent to 0″·03; and the correction for diurnal observation is — 0″·19. Hence the corrected error of collimation is — 0″·44."

The second method of determining the error of collimation is by observations of the transit of Polaris, or any other close circumpolar star, in one position of the axis, compared with its transit in a reversed position of the axis. By proper apparatus, this reversal of the instrument can be effected during the time of transit. If, therefore, three wires of Polaris, or λ Ursæ Minoris, be observed in one position of the axis, and the remainder of the transit in a reversed position, and if each set of wires be separately reduced to the central wire, half the difference of the two results will be the error of collimation for the object observed, which can be reduced to the error of collimation (in arc) for an equatorial star (dividing by the proper factor). It is necessary, however, in the use of this method, that the reversal be very carefully made, and that the mean of several results of separate stars be taken.

The following example of this method is extracted from the *Georgetown Observations* :—

Transit of λ Ursæ Minoris on August 7th, 1845.

$$\frac{t' - t'o}{2} = 1$$

$$\text{Error of collimation or } C = \frac{(t - t\,o)\,15 \sin. p}{2} = 0''\cdot303$$

The third method was originally introduced by Professor Struve, at the Pulkowa Observatory. It consists in mounting firmly two telescopes in the direction of the meridian, the wires of which can be adjusted on each other. It is evident that by comparing the principal instrument (transit or meridian circle) with each successively, the true line of collimation may be obtained without reversal.

For the purpose of determining the line of collimation of the Greenwich transit circle (as the instrument is not capable of reversion), two collimating telescopes, the axes of which are as nearly as possible in the same line with the principal instrument, are firmly mounted on brick piers, a few feet north and south of it. These collimating telescopes are furnished with proper wires, which can be accurately adjusted to coincidence, and will, therefore, represent (when viewed with the telescope of the transit circle) two objects at an infinite distance, and exactly opposed to each other. When a series of bisections is taken of each collimator in terms of the micrometer of the transit circle telescope, the mean of these will give the geometrical line of collimation. The annexed form will show the work :—

The error of horizontality of the axis is generally determined by the application of a spirit level to the pivots. But it must be previously known whether the pivots are perfectly circular, and of equal diameter. For this purpose, careful series of levellings are taken in reversed positions of the axis of the transit instrument. If we assume the Y's to be perfectly horizontal, but that on application of the level, the same pivot shows a quantity too high in reversed positions of the axis, it is evident that this pivot is the larger of the two ; and it is equally evident that if the Y's are not perfectly horizontal, we can determine the difference of the pivots from level readings in reversed positions of the axis. The following example, from the *Oxford Observations*, 1840, page v., will illustrate the whole process. The sign + is used when the west end of the axis is highest ; — when the east end is highest :—

Day, 1840.	Position of Lamp.	Level Reading.	E.—W.
		″	″
Jan. 16	East	+ 2·31	+ 9·14

28	West	— 5·83	+ 6·31
29	East	+ 0·48	

"From these it results, that when the lamp is east the west end of the axis is highest, and when the lamp is west the east end is highest ; thus they show that the solid pivot is larger than the perforated one.

"The angle of the level's Y's is the same as that of the pivot's Y's, both being rectangular, or very nearly so : therefore the difference of the radii of the pivots

$$= \frac{\text{Difference of the Level Readings in Opposite Positions of the Axis.}}{4\sqrt{2}}$$

"The column E — W shows the difference of the level readings, the arithmetical mean of which = 5″·445 ; therefore $\frac{5''{\cdot}445}{5{\cdot}660} = 0''{\cdot}902$ is the mass of the radius of the solid above that of the perforated pivot, and 0″·962 $\times \sqrt{2} = 1''{\cdot}361$ is the correction to be applied to the level readings to obtain the inclination of the pivot centres. This correction is to be added *algebraically* to the level readings when the lamp is west, and subtracted when the lamp is *east.*"

A careful series of levellings at different elevations of the object-glass, showed that there was no appreciable difference in the circularity of the pivots, as the reader will observe by reference to the descriptions of the Altazimuth and Transit Circle in the *Greenwich Observations*, 1847 and 1852, for the method adopted by the Astronomer Royal to insure perfect circularity of the pivots.

Dr. Oudemans, in his essay on the Transit Instrument, gives the following formulæ for the correction of the level indication caused by unequal diameters of the pivots. The error of level being determined after frequent reversals of the transit instrument, this correction may be easily deduced.

Let 2 g be the angles between the planes of the Y's, on which the pivots are placed ; 2 f, the angles between the feet of the level, by which it is placed on the pivots ; u, the difference of inclinations observed in both positions of the axis ; r and r', the two radii of the pivots ; L, the distance between the points, where the two pivots rest on the planes of the Y's. Now g, f, u, and L being known, the difference of the radii r and r' is made known by the following formulæ :—

$$r - r' = \tfrac{1}{2}\, u \, L \sin. 1'' \cdot \frac{\sin. g \sin.}{\sin. g + \sin. f}$$

He then gives a determination of the values before and after reversal, and finds an arithmetical mean of the differences, or of $u = + 4''{\cdot}15$. Since this value of u found will depend on one unequal breadth of the extremities of the axis, the correction of any inclination can be obtained by the level.

$$s = \pm \tfrac{1}{2}\, u \cdot \frac{\sin. g}{\sin. g + \sin. f}$$

In his transit circle, $2f = 98° 40'$, $2g = 91° 25'$; therefore

$$s = \pm \tfrac{1}{2} \times 0{\cdot}4854 \times 4''{\cdot}15 = \pm 1''{\cdot}01 = \pm \overset{s.}{0{\cdot}067}.$$

In order to eliminate any errors in the level itself, it is the practice to reverse it several times, or to take a series of readings in one position, and then to turn it, end for end, and to take a set of readings in an opposite position. The following is an example :—

The value of one division of the level scale may be determined by the application of the level to a vertical circle, moving it so as to produce changes in the circle reading, and in the position of the bubble. Thus, in the *Greenwich Observations*, 1836, Introduction, pages xvi. and xvii., "on January 27, the level of the transit instrument was lashed to Troughton's circle, and the circle being moved till the bubble was alternately near the end of one and the other scale, the microscopes A and B were read. This operation was repeated sixteen times. The mean of the results gave 2′ 0″·03 = 112·18 parts at one end, = 108·93 parts at the other end of the scale ; the mean value of one part being, therefore, 1″·086."

It can also be determined by the comparison of the results of the transit of a star observed by reflection and direct vision. A slowly moving star is generally selected for this purpose, four or more wires being observed in each position. The difference of the two results (separately reduced) is equal to double the level error of the object observed, which can be converted into "error of inclination" for an equatorial star by the proper factor. By comparing this result with the level indication, the value of one division of the scale may be found.

Lastly, it can be obtained by elevating or depressing the Y's by the proper screw, and finding the effect of a change of level indicative of the transits of a close circumpolar star. The level error may also be obtained by a Bohneberger's eye-piece, an instrument consisting of an ordinary eye-piece, perforated at the side, and so arranged that, by means of a glass reflector, placed near the eye lens, inside the tube, the light of a lamp may be thrown into the instrument. In this manner the system of vertical and horizontal wires may be seen, by directing the telescope nearly to its nadir position, and placing underneath the object-glass a trough of mercury. By causing the two images to overlap, by means of the right ascension micrometer (noting its readings), and comparing these with the corresponding readings for the line of collimation of the instrument previously obtained, the level error may be easily deduced. This method is now practised in the use of the Greenwich transit circle. The following form shows the readings of the transit micrometer for coincidence of the central wire, for determination of error of level of the axis of the transit circle of 1851:—

The azimuthal error may be determined by the transits, above and below the pole, of any close circumpolar star. In observatories, where the adjustments of an instrument are sufficiently steady to be relied on, the successive passages of Polaris, or δ Ursæ Minoris, for several days, are used for this purpose. But, in small instruments, whose foundations are not so firm, it is usual to obtain an azimuth error by corresponding observations of high and low stars, or an observation of Polaris, or δ Ursæ Minoris, compared with the transit of a star south of the zenith. Thus, Polaris and θ Ceti can be used advantageously for this purpose, the difference of their right ascension being only thirteen minutes, and their tabular right ascensions being known with sufficient precision.

Mr. Johnson, in his *Oxford Observations*, uses certain pairs of stars for azimuthal errors, whose positions have been determined with considerable accuracy. These stars are distributed in such a manner, that the observer can have little trouble in finding one transiting above the pole, and another passing below the pole, within a short interval of time of each other. Thus, the result is entirely free from any doubt as to the rate of the clock, or other causes, and the principal error can only arise from the unavoidable uncertainty of observation.

It is frequently necessary, in the use of a small transit instrument, to have a fixed mark in the direction of the meridian, which can be easily referred to for the purpose of determining the error of collimation, and also its deviation from the meridian, in cases when, from cloudy weather, observations from circumpolar stars cannot be obtained.

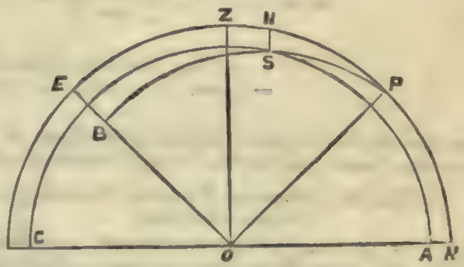
At the distance of 286 feet, a circle of two-tenths of an inch in diameter will subtend an angle of 12″ of azimuth. By noting the positions of the central wire of the transit in reversed positions of the axis, an approximation may be made at once to the error of collimation, from its relative positions in this circle. This meridian mark may be frequently verified by observations of circumpolar stars.

If the instrument be furnished with a micrometer, this method of determining the collimation will not be necessary.

We will now proceed with the investigation of the formulæ for the three preceding errors, and will show the method of application to the results of observations.

Error of Collimation.—The error of collimation is the distance of the middle line from the true line of collimation, east or west. When the middle wire is east of the true line of collimation, the transit is observed too soon, and consequently the correction for collimation is additive for stars above the pole, and subtractive for those below the pole. The contrary takes place when the middle wire is west of the line of collimation. According to this, the transit telescope may be supposed to describe a circle parallel to the meridian. Thus, let C S A (Fig. 206) be the circle described by the telescope, or the circle in whose plane the middle wire is. Then A N, or S N, is the error of collimation, which is generally expressed in seconds of arc. Let S be the place of a star, P S B a great circle passing through it. We have now to find B E, the corresponding part of the equator; but

Fig. 206.



$$\frac{S N}{\sin. P S} = B E \text{ in arc, or } \frac{S N}{15 \sin. P S} = B E \text{ in time,}$$

which is the correction to be applied to the observed transit. In that investigation, stars, however, near the pole, are supposed to transit the middle wire; that is, their distance from the pole is supposed to be greater than the error of collimation. If this were not the case, such stars could not pass the middle wire.

The correction for the error of collimation is written thus:—

$$\text{Correction} = \text{error} \times \frac{1}{15 \times \sin. \text{ star's } N P D}.$$

Correction for Level.—The error of level is considered positive when the western pivot is too high. In that position the great circle, passing through the north and south points of the horizon, and which is the circle on which observations are made, lies to the east of the meridian, and the observed time of passage is less than the true time for stars above the pole.

Thus (Fig. 207), O Z = the error of level.

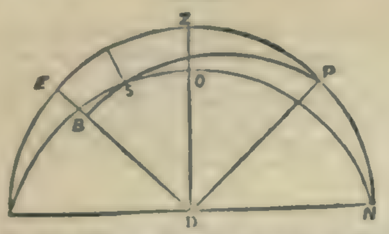
$$Z O \times \cos. S O = S x, \text{ and}$$

$$B E = \frac{S x}{15 \sin. N P D} = \frac{S x}{15 \sin. P S}$$

$$\therefore B E = \frac{Z O \times \cos. \text{ zenith distance south}}{15 \sin. N P D}.$$

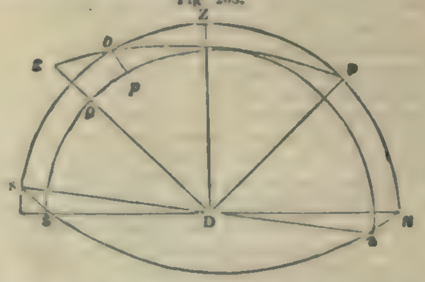
Azimuthal Error.—This error is considered positive when the eastern pivot is too far north. In this position, stars to the south of the zenith are observed before they come to the true meridian, and those north of the zenith after they pass the true meridian.

Fig. 207.



Let N *n* or S *s* (Fig. 208) be the azimuthal error, O the observed place of the star, then S *s* × sin. Z *o* = *o p*, draw the great circle P O E from the pole to the equator, passing through the star O, then E Q is the correction in R. Asc. in arc, which, being divided by 15, will give the correction in time; but E Q = O *p* × $\frac{1}{\text{sin. P O}}$; therefore, E Q *s* = S *s* × $\frac{\text{sin. Z } o}{15 \text{ sin. P } o}$ = azimuthal error × $\frac{\text{sin. Z D south}}{15 \text{ sin. N P D}}$. Since the sign of the correction to the north of the zenith is contrary to that of the south, if zenith distances *south* have the sign *plus*, and those to the north the sign *minus*, the above expression will give the correction in either case.

Fig. 208.



The preceding corrections for errors of level, azimuth, and collimation being all supposed positive, may be represented by

$$\frac{l \text{ cos. Z D}}{\text{sin. N P D}} + \frac{a \text{ sin. Z D}}{\text{sin. N P D}} + \frac{c}{\text{sin. N P D}}$$

where *l* represents the error of level, *a* that of azimuth, and *c* the error of collimation. By introducing the latitude L, the expression for the sum of these corrections may be written thus (δ being the declination),

$$\text{or} = \frac{l \text{ cos. } (\text{L} - \delta) + a \text{ sin. } (\text{L} \overset{*}{\mp} \delta) + c}{\text{cos. } \delta} \left\} \begin{array}{l} \dfrac{l\,(\text{cos. L cos. } \delta \overset{*}{\mp} \text{sin. L sin. } \delta)}{\text{cos. } \delta} \\ + \dfrac{a\,(\text{sin. L cos. } \delta \pm \text{cos. L sin. } \delta)}{\text{cos. } \delta} \end{array} \right.$$

$$= l \text{ cos. L} + l \text{ sin. L tan. } \delta + a \text{ sin. L} - a \text{ cos. L tan. } \delta + c \text{ sec. } \delta.$$

$$= (l \text{ cos. L} + a \text{ sin. L}) + (- a \text{ cos. L} + a \text{ cos. L}) \text{ tan. } \delta + c \text{ sec. } \delta.$$

= *m* + *n* sin. δ + *c* sec. δ, which is the form of these corrections Bessel gives in the *Tabulæ Regiomontanæ.*

To Find the Azimuthal Errors by Transits of a Circumpolar Star.

Let T = the time of superior transit, supposed too late; *t* = the time of an inferior transit, which will be too early; then, since the difference between these transits corrected for motion in R. A. should be 12h., all the other corrections being made, we shall have—

$$\text{T} - \frac{a \text{ sin. Z D}}{15 \text{ sin. N P D}} = 12\text{h.} + t + \frac{a \text{ sin. Z D}'}{15 \text{ sin. N P D}}$$

Let T − *t* = 12h. + *b*, then—

$$b = \frac{a\,(\text{sin. Z D} + \text{sin. Z D}')}{15 \text{ sin. N P D}}$$

$$= \frac{a\,(\text{sin. (colat. − N P D)} + \text{sin. (colat. + N P D)})}{15 \text{ sin. N P D}}$$

$$\text{or } b = \frac{2\,a \text{ sin. colat. cos. N P D}}{15 \text{ sin. N P D}} \therefore a = \frac{15\,b \times \text{tan. N P D}}{2 \text{ sin. colatitude}}$$

In a future page we shall afford numerical examples of the determination of azimuthal errors.

The preceding factors for collimation, level, and azimuth, viz.—

$$\text{Error of collimation} \times \frac{1}{15 \text{ sin. star's N P D}}$$

$$\text{Error of level} \times \frac{\text{cos. Z D south}}{15 \text{ sin. N P D}}$$

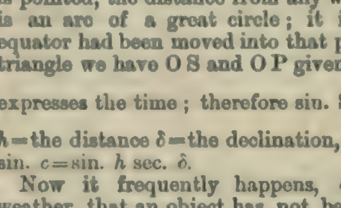
$$\text{Error of azimuth} \times \frac{\text{sin. Z D south}}{15 \text{ sin. N P D}}$$

are tabulated for different north polar distances at the principal observatories, the multiplication being easily made by means of a sliding ruler. Several other contrivances have been invented for forming these corrections by mechanical methods, by the Astronomer Royal, Professor Challis, and Mr. Carrington, for which we beg to refer to the Memoirs of the Royal Astronomical Society.

Having thus explained the formulæ and methods of determining the three preceding errors, we shall now proceed with the investigation for a determination of the equatorial intervals of the wires, which are immediately necessary for the reduction of imperfect transits.

When a heavenly body is observed with a transit instrument at a distance from the meridian, if this distance be known, and also the distance of the object from the equator, the time to be added to or subtracted from the sidereal time of observation can be computed thus:—Let P be the pole, Q E a portion of the equator, O the object at the distance O S measured on a great circle. (It may be well to remark that to whatever part of the heavens a transit instrument is pointed, the distance from any wire to the middle wire is an arc of a great circle; it is the same as if the equator had been moved into that position). Now in the triangle we have O S and O P given to find S P O, which expresses the time; therefore sin. S P O = $\frac{\text{sin. S O}}{\text{sin. O P}}$, or if h = the distance δ = the declination, c = angle S P O; then sin. c = sin. h sec. δ.

Fig. 209.



Now it frequently happens, especially in cloudy weather, that an object has not been, or cannot be, observed at all the wires of the transit instrument; but if the intervals of the wires be known—that is, the times employed by an equatorial star in passing from the first to the second, from the second to the third, &c.—the true time at which an object, which has been observed on any wire or wires, would transit the meridian, can be found. The manner in which the equatorial intervals are given, is the distance of the first wire from the mean of wires, which is called the first interval; the distances of the second and third from the same point are the second and third intervals—that is, the distance of the mean of all the wires from each wire is the interval: the intervals before the meridian point having the sign *plus*, and those after it the sign *minus*, for stars above the pole—the signs to be changed for stars below the pole. If the instrument be reversed, the signs are to be changed. For the determination of these intervals, Polaris, or some other star near the pole, is observed; then for each transit, the difference between each wire and the mean of all the wires is taken; and the mean of all these differences for the same wire for all the observations; then, if we call this mean for any wire$=c$, we have

$$\text{Sin. } h = \text{sin. } c \text{ cos. } \delta = \text{sin. } c \text{ sin. star's N P D}$$

$$\text{therefore } h = \frac{\text{sin. } c \times \text{sin. star's N P D}}{15 \text{ sin. } 1''}$$

This gives the equatorial distance in seconds of time from the wire under consideration to the mean of all the wires.

Now let $+a, +b, +c, +d, -e, -f, -g$, be the equatorial intervals for a telescope having seven wires, and suppose the times of transit of a star to have been observed on two of these wires; if the mean of these two observed times of transit be taken, it will be the time at which a star passed a point equally distant from both wires. We shall suppose the two wires to be the first and second; to find the distance of this point from the mean of wires, or from what we consider to be the meridian point. The distance between the first and second wires is $a-b$; hence the distance of the first wire from the required point is $\frac{a-b}{2}$, the distance of the first wire from the meridian point is a, therefore $a-\frac{a-b}{2}$ $=\frac{a+b}{2}$ is the distance of the point, for which we have the time of transit to the meridian point. This shows that we have only to take the sum of the equatorial intervals for the wires observed; this sum, divided by the number of wires, will be the distance of the point for which we have the time of transit from the meridional point. This distance being called h, and c representing the correction required, we have—

$$(1)\ \text{sin. } c = \text{sin. } h \text{ sec. } \delta, \text{ or}$$

$$(2)\ c \text{ sec.} = h' \text{ sec. } \delta.$$

For the pole star and others near it (1) must be used.

Determination of Intervals of the Greenwich Transit Instrument by the following Transits of Polaris:—

Another method of reducing imperfect transits is to form a table of intervals from the middle wire for different north polar distances, by multiplying the equatorial intervals by the secant of the declination (see preceding formulæ). When the wires observed of any object have been separately reduced to the middle wire by this table, the mean of all the results will be the correct number. For a planet, the change of right ascension in the interval, may be applied in the formation of the results for each wire.

The following is an example of Polaris by this method:
1848, October 2. Wires observed—A, B, C, D, E.
Declination of Polaris 88° 29′ 65″·7.

	h.	m.	s.		Reduction to Mean of Wires.	m. s.

The intervals of the transit wires may also be determined by directing the telescope of a theodolite to the object-glass of a transit instrument. In this manner the wires may be distinctly seen; but it is also necessary that the axes of the two instruments should be exactly in the same parallel. Gauss first introduced this method at Gottingen. The following is an example:—It is to be premised that the axis of the theodolite was higher than that of the centre of the circle, and therefore that the measured readings must be diminished by multiplying by the cosine of the inclination, or 23° 58′ 53″.

1823, October 23.

	Horizontal Distance. ′ ″	′ ″	True Distance. ′ ″	′ ″
Wire I.	11 25·050	11 23·000	10 25·93	10 24·06
" II.	7 45·900	7 46·275	7 5·69	7 6·03
" III.	3 58·225	3 57·750	3 37·66	3 37·23
" V.	3 58·850	3 59·375	3 38·24	3 83·71
" VI.	7 53·625	7 53·875	7 12·74	7 12·98
" VII.	11 17·600	11 17·775	10 19·11	10 19·28

At the Royal Observatory, Greenwich, the Astronomer Royal has made use of the south collimator for the determination of the wires of the transit circle. "The eye-piece of the transit circle was turned round 90°, so as to bring the wires into a sensibly horizontal position, and with the head of the micrometer upwards when the telescope was directed to the south. Each of the wires, in succession, was then brought upon a determinate point of the image of one of the nearly horizontal wires of the south collimator, partly by turning the instrument, and partly by the right ascension micrometer, and the instrument being clamped, the six microscopes of the zenith distance circle were read as well as the right ascension micrometer."

In this manner, the following concluded circle readings for each wire were obtained:—

	′ ″
Wire I.	59 33·696
" II.	56 6·746
" III.	52 39·290
" IV.	49 12·018
" V.	45 44·880
" VI.	42 17·242
" VII.	38 50·482

The mean of these numbers is 49′ 12″·051; and, comparing this with each number separately, we finally get for the distance in arc of each wire from the mean of all :—

	′ ″	s.
For Wire I.	+ 10 21·645	or + 41·443
,, II.	+ 6 54·659	+ 27·646
,, III.	+ 3 27·239	+ 13·816
,, IV.	− 0·033	− 0·002
,, V.	− 3 27·171	− 13 811
,, VI.	− 6 54·809	− 27·654
,, VII.	− 10 21·569	− 41·438

Dr. Drew has usefully applied a wire micrometer, attached to a five feet telescope, for the determination of the intervals of his transit circle—an instrument of forty-two inches focal distance. The value of one revolution of the micrometer being known, he was able to measure easily the distances of the wires, by directing the two object glasses towards each other. The result agreed closely with that deduced from a transit of δ Ursæ Minoris.

To find the correction to an imperfect transit of the moon or a planet :—

Let h'' be the apparent distance from the middle wire.
,, μ = the right ascension of the zenith.
,, α' = the apparent right ascension of the interval.
,, δ' = the apparent declination.

Then we have—

$$\text{Sin. } h = \cos.\ \delta' \sin.\ \overline{\mu-\alpha'} = \frac{d}{d'}\cos.\ \delta \sin.\ (\mu-\alpha),$$

Put $\sin.\ h = h \sin.\ 1''$, and $\sin.\ \overline{\mu-\alpha} = \overline{\mu-\alpha} \sin.\ 1''$. Then we shall have—

$$h = \frac{d \cos.\ \delta}{d'}(\mu-\alpha)\ .\ .\ .\ \mu-\alpha = \frac{h \times d'}{d \cos.\ \delta}\ .\ .\ .\ (36).$$

This is the expression for all those bodies which do not change their right ascension. The fixed stars are the only ones which do not, and their distances are so immense, that a' and d may be regarded as equal, which is also the case with the planets, on account of their distance. Let λ^{s} be the moon's or planet's increase of R. A. in one second of time, then $(1-\lambda)^{s}$ is the equatorial space described by the moon or planet in one second of sidereal time ; consequently, the sidereal time of describing $\mu-\alpha$, will be represented by—

$$\frac{1}{1-\lambda}\left(\frac{d'\,h}{d \cos.\ \delta}\right) = (1+\lambda)\frac{d'\,h}{d \cos.\ \delta}$$

$$= (1+\lambda) \times \frac{\sin.\ \text{Geo. Z. D.}}{\sin.\ \text{app. Z. D.}} \times \frac{h}{\cos.\ \delta'}, \text{ nearly } (37).$$

This is the formula given in the *Greenwich Observations* for the same purpose. In the case of the planets d' is very nearly equal to d, and the formula is—

$(1+\lambda) \times \frac{h}{\cos.\ \delta'}$, where λ is the increase of the planet's right ascension in one second of sidereal time.

Formula for Determining Collimation.—In the operations of the Brussels Observatory, the following formula for the determination of the collimation, independently of the other errors of the instrument, is used. The investigation is to be found in M. Lingré's memoir, *Sur les Corrections de la Lunette Méridienne*—one of the prize essays of the Brussels Academy, vol. xviii., 1844—'45. The stars best suited for this method are, one near the pole, another near the zenith, and a third of south declination. The example and formula are as follows :—

Example.—Greenwich Observations, 1842, May 10th.

		h.	m.	s.		h.	m.	s.		°	′	″	
β Corvi . . .	H =	12	25	39·53	R A =	12	26	8·86	p =	112	31	39	Observer Henry.
γ Ursæ Majoris .	H° =	11	45	3·88	R A° =	11	45	33·11	p° =	55	22	39	
Polaris S.P. . .	H′ =	13	1	30·42	R A′ =	13	2	6·52	p′ =	1	31	59	

Calculation of the Collimation.

$$C = D^\circ \frac{\sin. p^\circ \cos. \frac{1}{2}(p - p')}{2 \sin. \frac{1}{2}(p - p^\circ) \sin. \frac{1}{2}(p^\circ - p')} + D' \frac{\sin. p' \cos. \frac{1}{2}(p - p^\circ)}{2 \sin. \frac{1}{2}(p - p') \sin. \frac{1}{2}(p' - p^\circ)}$$

$$D^\circ = 15\left[(H + R A^\circ) - (H^\circ + R A)\right] = -1''\cdot50.$$

$$D' = 15\left[(H + R A') - (H' + R A)\right] = +101''\cdot40.$$

$$\tfrac{1}{2}(p - p') = 57^\circ\ 1'\ 49'' : \tfrac{1}{2}(p - p^\circ) = 38^\circ\ 33'\ 0'' : \tfrac{1}{2}(p^\circ - p') = 18^\circ\ 28'\ 40''$$

	− 1·20
C =	+ 2·79

A similar calculation, made on May 13th, 1842, using β Corvi, γ Ursæ Majoris, and Polaris, gave C = + 2″·67. This agrees very satisfactorily with the preceding result.

The error determined (by reversal of the instrument in the usual way practised at Greenwich) was found to be, on April 6th, = + 1″·51, which is a very good agreement.

The Astronomer Royal, in the *Cambridge Observations*, 1828, proposed a method, nearly similar, for determining the clock errors, and the errors of collimation and azimuth, but was obliged to discontinue it on account of the imperfect places of the star catalogues, and the difficulty of making observations sufficiently accurate. The following is the investigation :—" Let x, y, z, be the clock error, and the errors of collimation and deviation (the clock being supposed slow). O, O′, O″, the observed times of transit corrected for the error of level and the clock rate; T, T′, T″, the true sidereal times at which they pass the meridian; Y, Y′, Y″, the respective multipliers of the error of collimation, which give results additive to the observed transits; Z, Z′, Z″, the same for the error of meridian. Then the following equations subsist :—

$$O + x + Yy + Zz = T$$
$$O' + x + Y'y + Z'z = T'$$
$$O'' + x + Y''y + Z''z = T''$$

And subtracting the 2nd from the 1st, and the 3rd from the 2nd—

$$(Y - Y')\,y + (Z - Z')\,z = (T - O) - (T' - O')$$
$$(Y' - Y'')\,y + (Z' - Z'')\,z = (T' - O') - (T'' - O'')$$

" The catalogued R. A. and the observation of the transit must be extremely accurate, in order that any result worthy of confidence may be obtained from these equations. The most favourable stars are Polaris, a star below the pole, and a star above the pole, whose N. P. D. is considerable."

Method of Finding the Time.—The method of finding the time given in the following pages is capable of so many useful applications to travelling astronomers, that, in a treatise on this subject, it would be unwise to neglect it.

Professor Hansteen, in *Schumacher's Astronomische Nachrichten*, vol. vi., p. 189, gives a simple and expeditious means of determining the time by a small transit instrument, which requires only the observed transit of Polaris in a certain parallel, and the transit of a known fundamental star in the same vertical. The formulæ of reduction are as follow :—

$$A = \frac{\tan.\ \phi - \tan.\ \delta}{\tan.\ \delta - \tan.\ \delta' \cos.\ P}$$

$$B = A^2 \frac{\tan.\ \phi + 2 \tan.\ \delta'}{\tan.\ \delta - \tan.\ \delta' \cos.\ P}$$

$$P = 15\ (\alpha - \alpha' + T)$$

$$O = \frac{A \sin.\ P}{\sin.\ 15''} + \frac{B \sin.\ P^2}{\sin.\ 90}$$

In which δ and α are respectively the declination and right ascension of the pole star; δ' and α' are the same co-ordinates of another fundamental star; ϕ is the latitude of the place, and T is the sidereal interval of the observations.

Example.—At Christiana, on the 8th of November, 1823, the following transits of stars were observed with a universal instrument of Reichenbach :—

Star.		Eye-piece towards the East. h.	m.	s.
Polaris	τ . .	13	36	31·5
η Ursæ Majoris . . .	τ . .	13	42	49·6

Star.		Eye-piece towards the West. h.	m.	s.
Polaris	τ' . .	14	0	28·50
Polaris	τ' . .	14	10	47·46

The apparent places of the stars are—

		h.	m.	s.		°	′	″
Polaris . .	α =	24	58	32·90	δ =	88	22	26·68
η Ursæ Majoris .	α' =	13	40	34·47	δ' =	50	11	34·79
α Bootis . .	α'' =	14	7	37·38	δ'' =	20	6	8·66

Therefore we have—

	h.	m.	s.
$\alpha - \alpha'$ =	11	17	58·43
τ =	+	5	33·46
$\alpha - \alpha' + \tau$ =	11	23	31·89

$P = 170°\ 52'\ 58''$

	h.	m.	s.
$\alpha - \alpha''$ =	10	50	55·52
τ' =	+	10	18·96
$\alpha - \alpha'' + \tau'$ =	11	1	14·48

$P' = 165°\ 18'\ 35''$

The latitude ϕ is assumed to be 59° 54′ 8″·4.

Log. tan. δ' . .	0·0791592
Log. cos. P . .	9·9944783
	— 0·0736375
Log. (tan. ϕ — tan. δ') .	9·7204185
Log. N . . —	1·5612716
Log. A . . .	8·1591469
Log. sin. 15″ . .	4·1383339
Log. sin. P . . .	9·1999056
	1·4973864
Log. A^2 . . .	6·31829
Log. (tan. ϕ + 2 tan. δ')	0·61543
Ar. co log. N . .	8·43873
Ar. co. log. sin. 90″ .	3·36018
Log. sin. P^2 . . .	7·59971
	6·33234

tan. δ' . . =	35·22949
	1·18478
N . .	36·41427
Log. tan. ϕ . . =	1·7752525
Log. tan. δ' . — =	1·1999391
(Tan. ϕ — tan. δ') .	0·5753134
Tan. ϕ + 2 tan. δ' .	4·1251307
. . . .	s. + 31·433
. . . =	0·000
	31·433

In the same manner, if a calculation be made for α Bootis, we shall have—

$$\theta' = \overset{s.}{133\cdot205} + \overset{s.}{0\cdot004} = +\overset{m.}{2}\ \overset{s.}{13\cdot21}$$

From these values of the quantities θ and θ' are found the binary angles t and t' for these two stars; and the zenith distance of the pole star by this formula—

Cos. ξ = cos. ϕ cos. δ cos. $(P - t)$ + sin. ϕ sin. δ.

Therefore, by calculation—

	°	′		°	′
$P - t$ =	170	45	$P' - t'$ =	164	45
ξ =	31	43	ξ' =	31	40
ϵ =	0	23	ϵ' =	0	25
$\delta - \phi + Z$ =	—9	42	$\delta' - \phi' + Z'$ =	— 9	48
C =	0·13754		C′ =	0·15755	

The daily gain of the clock was 2s.·5; therefore for the time $\tau' - \tau$ or 28m., a was = 0s.·047. Therefore, if ϵ and $\epsilon' = 0$, C + C′ will be equal to 0·29509.

	m.	s.
$\tau' - \tau$ =	28	42·50
$- a$ =	—	0·05
$-(\alpha'' - \alpha)$ =	— 27	2·91
$-\ \theta' - \theta)$ =	— 1	41·78
S =		— 2·24

$$\frac{S}{C + C'} = \gamma = \frac{-\ 2\cdot24}{0\cdot29509} = \overset{s.}{7\cdot59}$$

By this value of γ itself we find,

for η Ursæ Majoris $C\gamma$ = − 1·044 s.

α Bootis $C'\gamma$ = − 1·196

Wherefore the state of the clock is as follows :—

η Ursæ Majoris.

	h.	m.	s.
α =	13	40	34·47
θ =		+	31·43
$- C\gamma$ =		+	1·04
Sidereal time =	13	41	6·94
Clock time =	13	42	4·96
Error of Clock		+	58·02

Arcturus.	$\alpha' =$	14h.	7′	37·38″
	$\theta' =$		2	13·21
	$+ C' \gamma =$			— 1·20
	Sidereal time =	14	9	49·39
	Clock time =	14	10	47·46
	Error of Clock		+	58·07

This method is likely to be of considerable value to the astronomer travelling from place to place; and for this purpose we give it here.

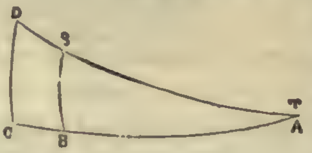
On the Determination of Right Ascension by the Transit Instrument.—The origin of right ascensions is the intersection of the ecliptic and equator at the vernal equinox. For the purpose of determining this origin, Dr. Maskelyne selected α Aquilæ, the place of which he arbitrarily assumed, and with which he compared thirty-five other principal stars, applying the clock error and rate; and, by these means, forming apparent right ascensions. These were afterwards converted into mean right ascensions, for the beginning of each year, by the application of precession, nutation, and aberration, from certain assumed constants. The places of all the others were, therefore, affected with the error of the assumed right ascension of α Aquilæ. To determine the amount of this error, he computed the sun's right ascension from the transit observations depending on the assumed place of α Aquilæ; and he also computed a right ascension of the sun, from observations of declination by the quadrant, by the formula,

Rad. × sin. R. A. = cotan. obliq. × tan. declination.

And comparing the two results for certain periods of time, on each side of the equinoxes, so as to eliminate any errors arising from refraction, parallax, obliquity of the ecliptic, and latitude of the place, he obtained a correction to his assumed place of α Aquilæ, which was common to the remaining stars of the catalogue.

When a number of stars have had their right ascensions determined by referring them to some fundamental star, they will all be charged with the error which may happen to belong to this star; and it is an object of the utmost importance to ascertain the existence and quantity of such error. The difficulty lies in the determining accurately the position of the first point of Aries, from which the right ascensions of all the stars are counted. The course pursued, therefore, by astronomers, is first to find the sun's right ascension, by comparing the transit of his centre with the transit of the fundamental star, or with the transits of several principal stars, related to it by known differences; and, secondly, to compute from his observed declination the right ascension belonging to the moment of the meridian passage. These operations should be performed on several days, near both the vernal and autumnal equinox. The right ascensions derived from a comparison with the stars, should agree with those derived from the observed declinations of the sun. If there be a constant difference, this will be the correction to be applied to the assumed right ascension of the fundamental star. The sun's right ascension is deduced from his declination in the following manner:—Let A C (Fig. 210) represent a part of the equator, A D a part of the ecliptic, and A be the first point of Aries. Suppose the sun to be at S, and draw S B perpendicular to A C; then A B will be the right ascension of the sun, and S B his declination. But, by Napier's rule, rad. × sin. A B = cotan. S A B × tan. S B; that is, sin. R. A. = cotan. obliquity × tan. dec.

Fig. 210.



Or, representing the sun's declination by δ, and the obliquity of the ecliptic by ω, we have

$$\text{sin. R. A.} = \frac{\text{tan. } \delta}{\text{tan. } \omega}$$

Example.—The following observations of the sun's centre were made at Greenwich in 1851 :—

Date.	Sun's R. A. Observed.	Sun's Dec. Observed.
	h. m. s.	° ′ ″
Sept. 15	11 34 16·15	2 47 0·18 N.
16	37 51·22	2 23 50·70 N.
21	55 48·55	0 27 15 35 N.
22	59 24·19	0 3 51·53 N.
23	12 3 0·32	0 19 33·76 S.

The following example, from the Appendix to the *Greenwich Observations*, 1851, will explain this process :—

Errors of the Assumed Position of the First Point of Aries, by Observations made near the Vernal and Autumnal Equinoxes of 1802. Assumed lat. of Observatory, 51° 28′ 38″·9. Assumed mean obliquity, 1802, Jan. 1, 23° 27′ 55″·58. Assumed mean R. A. of α Aquilæ, 1802, January 1, 19h. 41m. 7s. ·00.

		Mean	+ 16·72			Mean	— 15·58

[The correction applicable to the right ascensions of all stars observed in 1802, is (+ 16·72 — 15·58) ÷ 2 = + 0·57 = + 0·04s.]

Errors of collimation may be determined by a micrometer attached to the eye-piece of the telescope, by which the angular distance of the object from the central wire is first measured. The instrument is then reversed, and the distance of the same object from the central wire again measured. The azimuthal direction may be found by comparing any two stars, differing in declination, whose places are known, Polaris being generally one of these stars. At the present time, the places of certain fixed stars are used for these purposes, and a correction of the assumed equinox is obtained from all the right ascensions and north polar distances of the sun. (See the annual volumes of the *Greenwich* and *Cambridge Observations*).

When the preceding errors of collimation, level, and azimuth, have been applied to the results of observations, the transit instrument can be usefully employed in the determination of accurate time and the investigation of apparent right ascensions. The *Nautical Almanac* contains the apparent places, for every tenth day in the year, of certain fixed stars called clock stars, which can be immediately compared with the corrected instrumental results. A series of clock errors, for certain epochs of time, will thus be obtained (by taking the differences of the foregoing numbers); which, being grouped on successive days, will give at once a *rate* of the clock. In adopting the *rate* for use, due weight must be allowed for the interval of time on which each *deduced rate* depends, and also on its relative accuracy with regard to the number and distribution of the clock stars.

Having obtained the error of the clock at any certain period, and also the rate, by a simple interpolation we can find its error at any other time. When this is applied to the observed transit (properly corrected), the apparent right ascension is at once obtained. This can be converted into the mean right ascension for the beginning of each year by the day numbers, A, B, C, D, given in the *Nautical Almanac*, combined with the star constants, *a*, *b*, *c*, *d*, of the *British Association Catalogue*. This method of determining the corrections for precession, nutation, and aberration, is so lucidly explained in the latter work, that we shall content ourselves by simply referring to it; but we may mention that, for the purpose of avoiding *negative* signs in their computations, the Astronomer Royal has ingeniously transformed these formulæ. (See the Introduction to the *Greenwich Twelve Year Catalogue*). The two previous and following examples worked out, will illustrate all the preceding formulæ.

SPECIMEN OF THE GREENWICH METHOD OF RECORDING TRANSIT OBSERVATIONS.

Transits observed with the Transit Circle, and Computations of Apparent Right Ascension, at the Royal Observatory, Greenwich, in the year 1851.

The following examples will show the methods of determining azimuthal errors of the transit instrument at the Royal Observatory, Greenwich.

Approximate Solar Time. 1848.	Transits Corrected for Error of Collimation and Level Error, with the Corrections for Clock Rate and Change of R. A., and inferred Azimuthal Errors.	
d. h.		h. m. s.
April 28, 9	Transit of β Leonis corrected for two errors . . .	—. 11 40 45·45 + z × 0·041
	Tabular Right Ascension . .	11 41 19·74
	Clock Slow	34·29
	Rate [1·25 s.] for 1 h. 20 m. . . .	+·07
		34·36 — z × 0·041
		h. m. s.
April 28, 10½	Transit of Polaris S. P. . .	— 13 3 25·85 + z × 1·638
	Tabular Right Ascension . .	1 4 8·76
		42·91 — z × 1·638
	$\therefore Z = \frac{+8{\cdot}55}{1{\cdot}597} = +5'' 54$	
		h. m. s.
June 13, 8	Transit of Polaris S. P. —. .	13 4 5·46 + z × 1.638
20	Transit of Polaris	1 4 15·84 — z × 1·533
	Clock Rate [1·06 s.] for 12 h. . .	+ 0·53
	Subtract Increase of R. A. in 12h. . . .	— 0·40
		1 4 15·97 + z + 1·533
	$\therefore = + \frac{10{\cdot}51}{3{\cdot}171} = +3''{\cdot}314$	

The practical directions for using them, as given in the *Greenwich Observations*, are as follows (1848, p. xx.) :—

"If two consecutive transits of Polaris have been observed, the first transit (as corrected for error of collimation and level error) is altered by the change of the star's right ascension, and by the estimated clock error for 12h.; and the difference, in seconds of time, between the altered first transit and the second transit (rejecting 12h.) is divided by 3·171 to obtain the azimuthal error in seconds of space.

"If three transits have been observed, the difference between the first and second is taken (rejecting 12h.), and the difference between the second and third in like manner; and the mean between these is supposed to be independent of the change of right ascension and the clock's rate, and is then divided by 3·171.

"If several transits have been observed, the same process is used for every successive set of three, and the results are used separately, or the mean of the results is taken, according as there appears reason to think that the position of the instrument has or has not undergone change."

Example of the Determination of Azimuthal Error by Three Consecutive Transits of Polaris :—

Transit corrected for two errors.

			h. m. s.
1846.	Dec. 15.	Polaris . . .	1 4 49·39
			+ 14·09
	Dec. 15.	Polaris, S.P. .	13 4 35·30
			+ 11·78
	Dec. 16.	Polaris . . .	1 4 47·08
			25·87
			+ 12·94

$$\therefore Z = \frac{+12{\cdot}94}{3{\cdot}148} = +4''{\cdot}12.$$

On the Determination of Terrestrial Longitudes.—In this section we shall explain the principal methods used in the determination of terrestrial longitudes :—

Longitudes by transits of the moon and moon culminating stars.

The first introduction of this method appears to be entirely due to the German astronomers. About the year 1820, it was agreed on by Gauss, Bessel, Struve, Nicolai, and others, to observe transits of the moon, and certain prearranged stars lying in its parallel, for the purpose of determining longitudes. The celebrated Schumacher gave his zealous co-operation by the immediate publication of the results in the *Astronomisch Nachrichten*. In these kingdoms, the method was cultivated by Dr. Brinkley and the late Mr. Baily; the latter astronomer having contributed to its advancement by his memoir on the subject, in the *Transactions of the Royal Astronomical Society*, which led to the insertion of the requisite data in the pages of the *Nautical Almanac*.

The stars with which the moon is to be compared, are selected in the same parallel of declination, for the purpose of nullifying any small errors which may be left on the transit instrument; but, notwithstanding all the care which was taken by these refinements, there are still uncertainties produced by irradiation and a peculiar personal equation of the limbs of the moon, which tend to throw doubt on the results. The former quantity, or "irradiation," may be eliminated by the results of the moon's 1 L. and 2 L.; but the latter is a variable and unknown quantity, in some instances affecting the transits of the first and second limb in a different proportion. In the following pages we will show the method pursued by the Astronomer Royal in the longitudes of the North American boundary, and also those of MM. Rumker and Struve. The method of the Astronomer Royal is to be used in cases where there are no corresponding observations, and the results will consequently be affected with the tabular errors of the moon's right ascension in the *Nautical Almanac*, an approximation to which, however, may be made by observations on other days at any standard observatory. The methods of M. Rümker and Professor Struve are intended for corresponding observations; the former having been applied in the determination of the longitude of Port Stephens, New South Wales, and the latter in the longitudes of several places in Turkey, during the years 1828 to 1832 inclusive.

The first method of determining longitudes is by the absolute right ascensions of the moon's limb, and is only to be used when there are no corresponding observations of moon-culminating stars. It consists in making two assumptions of longitude, differing by any known quantity, and interpolating, for these times, the right ascensions of the moon's limb from the numbers given in the section of "Moon-Culminating Stars," in the *Nautical Almanac*. These tabular right ascensions are given for the time of transit of the upper and lower meridian at Greenwich. By comparing the interpolated data with the result of the meridian observation at the place, the exact difference of longitude may be found by a simple proportion. The true difference of longitude being supposed to lie between two assumptions 1′ different, the following will be the proportion:—

As the difference of the two interpolated R. A.'s : 60 sec. : : the difference between the R. A. of observation, and the computed R. A. : the correction of the first assumption.

The data from the *Nautical Almanac* are as follows:—

Moon's R. A. on preceding day.
R. A. at lower passage, preceding day.
R. A. of corresponding day.
Moon's R. A. at next lower passage.
Moon's R. A. at following day.

The following method of interpolation may be used, the fourth differences being considered constant:—

Suppose $a_h = a_0 + bh + ch^2 + dh^3 + eh^4$. In this, for h write $-2, -1, 0, +1, +2$, and take the differences. This gives—

	1st differences.	2nd differences.	3rd differences.	4th differences.
$a_{-2} = a_0 - 2b + 4c - 8d + 16e$	$+b - 3c + 7d - 15e$			
$a_{-1} = a_0 - b + c - d + e$		$2c - 6d + 14e$		
$a_0 = a_0$	$-b - c + d - e$	$2c + 2e$	$6d - 12e$	
$a_1 = a_0 + b + c - d + e$	$+b + c + d + e$			$24e$
$a_2 = a_0 + 2b + 4c + 8d + 16e$	$b + 3c + 7d + 15e$	$2c + 6d + 14e$	$6d + 12e$	$= \Delta''''$

Now take the differences of the terms a_{-2}, a_{-1}, a_0, a_1, a^2, thus—

$$\left.\begin{array}{lllll}
a_{-2} & & & & \\
 & +\Delta'_1 & & & \\
a_{-1} & & +\Delta''_{-1} & & \\
 & +\Delta'_0 & & +\Delta'''_{-1} & \\
a_{-0} & & +\Delta''_0 & & +\Delta'''' \\
 & +\Delta'_1 & & +\Delta'''_0 & \\
a_{-1} & & +\Delta''_1 & & \\
 & +\Delta'_2 & & & \\
a_{-2} & & & &
\end{array}\right\}$$

Comparing this with the foregoing difference, we shall have

$$24e = \Delta'''' \therefore e = \frac{\Delta''''}{24}$$

$$6d + 12e + 6d - 12e = \Delta'''_{-1} + \Delta'''_0 \therefore d = \frac{\Delta'''_{-1} + \Delta''_0}{12}$$

$$2c + 2e = \Delta''_0 \therefore c = \frac{\Delta''_0}{2}$$

$$b + c + d + e + b - c + d - e = \Delta_0' + \Delta'_1 \therefore b = \frac{\Delta'_0 + \Delta'_1}{2} - d.$$

$$\therefore a_h = a_0 + \left(\frac{\Delta'_0 + \Delta'_1}{2} - d\right)h^2 + \left(\frac{\Delta''_0}{2} - e\right)h^2 + \left(\frac{\Delta'''_{-1} + \Delta'''_0}{12}\right)h^3 + \frac{\Delta''''}{24}h^4$$

The interval between any two consecutive terms of the given quantities, as a_{-2}, a_{-1}, is supposed to be unity, and therefore h must be a fractional part of this unit. Thus, if this interval be 12h., and the time for interpolation 3h. 20m., then $h = \frac{3h.\ 20m.}{12h.}$. If the interval between the consecutive quantities be 24h., then we should have $h = \frac{3h.\ 20m.}{24h.}$; and so on for other intervals.

The following example will illustrate the whole process:—

Longitude of Port Essington, north-east coast of Australia, deduced from lunar transits observed there in 1839 by Captain Owen Stanley, R.N.

The following meridian right ascensions of the moon's 1 L. at Port Essington are found by the usual means, applying carefully the error and rate of the chronometer:—

	R.A. h.	R.A. m.	R.A. s.
1839, June 20, ☽ 1 L. . .	12	50	14·38
,, June 22, ☽ 1 L. . .	14	20	57·01
,, June 24, ☽ 1 L. . .	16	2	59·99
,, June 25, ☽ 1 L. . .	16	59	11·11
&c.		&c.	

By assuming two longitudes, 8h. 49m. east, and 8h. 48m. east, and interpolating, with fourth differences, the right ascension of the moon's limb, from the data for upper and lower transit over the Greenwich meridian, we find for longitude 8h. 49m. east, right ascension of the moon's 1 L., 12h. 50m. 14s.·64; and for longitude 8h. 48m. east, right ascension of the moon's 1 L., 12h. 50m. 16s.·46. The correction to the tabular right ascension of the moon's 1 L. is — 0s.·27, from an observation made at the Royal Observatory, Edinburgh.

The observed right ascension of the moon's 1 L. is

12h. 50m. 14s.·38; therefore, by a proportion, the longitude from this observation is 8h. 48m. 59s.·67 east.

Proceeding in a similar manner, we find for the observation in 1839, June 25, for assumptions of longitude 8h. 49m. east and 8h. 48m. east, the right ascensions of the moon's 1 L. 16h. 59m. 9s.·95 and 16h. 59m. 12s.·36 respectively (a correction of + 0s.·09 being applied from the Hamburg meridian observation).

The result of the meridian observation at Port Essington is 16h. 59m. 11s.·11; therefore the resulting longitude is 8h. 48m. 31s.·12 east.

The second method will include the use of moon-culminating stars observed at other stations. The simplest way is to form differences at each observatory between the transits of the moon's limb and each moon-culminating star (properly corrected for the rate of the clock in the interval). Comparing these differences with the respective differences at other stations, the increase of the right ascension of the moon's limb will be obtained, which will, however, differ from the increase in the right ascension of the moon's centre, in consequence of the change of the moon's geocentric semi-diameter in the interval of the two passages. This correction may be computed as follows:—If the geocentric radius of the moon culminating in A be called r, and the true declination d; and for a culmination at another station, B, these quantities are called ρ and δ respectively, the correction will be

$$\pm \frac{1}{15}\left(\frac{r}{\cos.\ d} - \frac{\rho}{\cos.\ \delta}\right)$$

the true difference of the right ascension of the centre for both times of observation. The sign — applies to the western limb, and the sign + to the eastern limb.

But, if the apparent right ascensions of all the objects observed are given at the stations, the more direct way will be as follows (Struve's method):—

Example.—1846, March 10. The following corresponding observations of the moon 1 L. and moon culminators were observed at Greenwich, Oxford, Hamburg, and Georgetown (U.S.) Observatories. The differences of longitude of Greenwich, Oxford, and Hamburg are supposed to be accurately known; and it is proposed to determine the longitude of the Georgetown Observatory.

The longitude of Oxford is . . 5m. 2s.·6 W.
" " Hamburg . . 39m. 54s.·1 E.
" " Georgetown. 5h. 8m. 20s. ± West.

1846, March 10. Apparent Right Ascensions Observed:—

	Greenwich.	Oxford.	Hamburg.	Georgetown.
	h. m. s.	h. m. s.	h. m. s.	h. m. s.
ξ Leonis	9 23 40·73	9 23 40·94	9 23 40·773	
ο Leonis	9 32 57·99	9 32 58·08	9 32 57·996	9 32 57·995
☽ 1 L.	9 44 4·21	9 44 14·22	9 42 44·850	9 54 13·876
Regulus	10 0 12·39	10 0 12·42	10 0 12·327	10 0 12·380
ρ Leonis	10 24 44·47	10 24 44·46	10 24 44·358	

Then, comparing each star with the Greenwich Observation, we have the following corrections:—

Name of Star.	Oxford.	Hamburg.	Georgetown.
	s.	s.	s.
ξ Leonis	— 0·21	— 0·043	
ο Leonis	— 0·09	— 0·006	— 0·005
Regulus	— 0·03	+ 0·063	+ 0·010
ρ Leonis	+ 0·01	+ 0·112	
Mean	— 0·08	+ 0·032	+ 0·003

When the above corrections are applied to the right ascension of the moon's limb, we shall be enabled to give its place independent of any errors, either in the assumed equinox, or of any small residual instrumental correction. Thus, the following sidereal times of observation are formed:—

	Greenwich.	Oxford.	Hamburg.	Georgetown.
	h. m. s.	h. m. s.	h. m. s.	h. m. s.
Sidereal time of observation	9 44 4·210	9 44 14·140	9 42 44·882	9 54 13·879
Longitude . . .	0 0·000	+ 5 2·600	— 39 54·100	+ 5 8 20·000
Greenwich sidereal time .	9 44 4·210	9 49 16·740	9 2 50·782	15 2 33·879
Greenwich mean solar time	10 31 13·45	10 37 26·94	9 50 6·77	15 48 50·95

Interpolating for these times, from the *Nautical Almanac*, we find the following right ascensions, declinations, and semi-diameters of the moon:—

	☽'s R. A. of Centre.	☽'s Semid.	☽'s Geo. Decl.
	h. m. s.	″ ′	° ′ ″
For the Greenwich Meridian Passage	9 45 3·86	14 48 06	+ 8 22 53
" Oxford "	9 45 13·84	14 48·06	+ 8 21 48
" Hamburg "	9 43 44·87	14 47·95	+ 8 29 10
" Georgetown "	9 55 13·54	14 48·93	+ 7 33 40

Computing the moon's geocentric radius, by the formula $\frac{\text{☽'s semid.}}{\text{15 cos. decl.}}$, we have for the four observations :—

	Observed R. A. of ☽'s 1 L.	$\frac{\text{☽'s Semid.}}{\text{15 cos. Decl.}}$	Observed R. A. of Centre.	Seconds of N. A.	Corrections of N. A.	Means.
	h. m. s.	s.	h. m. s.	s.	s.	
Greenwich .	9 44 4·210	59·843	9 45 4·053	3·86	+0·193	D. A.
Oxford . .	9 44 14·140	59·843	9 45 13·983	13·84	+0.143	s. +0·067
Hamburg .	9 42 44·882	59·852	9 43 44·734	44·87	−0·136	
Georgetown .	9 54 13·879	59·782	9 55 13·661	13·54	+0·121	D. A.

The longitudes of the first three observatories are considered well known, and, by taking their means, we obtain + 0s.·067. The correction from the assumed longitude of Georgetown is + 0s.·121; therefore the difference, + 0s.·54, is to be converted into an error of longitude.

The motion of the moon in R. A. at the time of Georgetown transit, by the formula $d\,L = \frac{d\,A' - d\,A''}{\mu}$, where d is + 115s.·08 in 1m., or + 0s.·03197 in 1 second of sidereal time — hence the correction of the assumed longitude is $\frac{+\ 0s.\cdot054}{0s.\cdot03197}$ = 1s.·69, or the true longitude from this observation is 5h. 8m. 21s.·69 west.

The following additional example of the determination of longitude, by observation of the moon and moon-culminating stars, is from Struve's *Geographical Investigations in Turkey*.

1831, May 22, the following transits of the moon and moon-culminating stars were observed :—

APPARENT RIGHT ASCENSIONS.

Object.	Schurscha.	Dorpat.	Cracow.	Greenwich.
	h. m. s.	h. m. s.	h. m. s.	h. m. s.
θ Virginis .	13 1 14·16	13 1 13·83	13 1 13·90	
☽ L. . . .	13 46 60	13 40 93	14 34·05	13 17 10·37
ι^3 Virginis .	26 45 64	26 45·80	26 45·75	26 45·77
174 Virginis	35 8·90	35 8 61	35 8·87	35 8·81

Taking the mean of the apparent right ascension at Dorpat and Cracow, we obtain—

h. m. s.
θ Virginis . . 13 1 13·86
ι^3 . . . . . 26 45·77
174 . . . . . 35 8·74

The following table of reductions is formed :—

Object.	Schurscha.	Dorpat.	Cracow	Greenwich.
	s.	s.	s.	s.
θ Virginis .	− 0 30	+ 0·03	− 0 04	
ι^3 Virginis .	+ 0 13	− 0·03	+ 0 02	− 0 00
174 Virginis	− 0 16	+ 0 13	− 0 13	− 0·07
Means . .	− 0·41	+ 0·04	− 0·05	− 0·03

By applying which to the observed right ascension of the moon's 1 L., the right ascensions of the moon's 1 L. are obtained, viz.—

	h. m. s.
At Schurscha . . .	13 13 46·49
„ Dorpat . . .	13 13 40·97
„ Cracow . . .	13 14 34·00
„ Greenwich . . .	13 17 10·34

Proceeding, then, with an assumption of longitude of Schurscha = 4, we obtain a correction of the ephemeris $d\,A'$, which includes both the error of the ephemeris, and also the motion of the moon in R. A. produced by an error in the assumed longitude. The error of the ephemeris having been determined by the comparison of the observations at Dorpat, Cracow, and Greenwich, the residual error at Schurscha will be entirely due to the erroneous assumption of the longitude of the latter place. Thus, if $d\,A$ be the correction of the ephemeris determined at the three standard observatories; and, if the observed right ascension of the moon at Schurscha be a', and that from the ephemeris A', so that $a' - A' = d\,A'$, then the correction of the assumed west longitude—

$$d\,L = \frac{d\,A' - d\,A}{\mu}.$$

The longitude of the place deduced from the lunar culmination will be then $L = L + d\,L$.

μ is the increase in R. A. (in arc) for the time of observation at the required place.

Assuming L′ = − 1h. 34m. 0s.·0 from Paris, and computing the value of the geocentric radius of the moon, by the preceding method the following table is formed :

Place.	Mean Time at Berlin.	Observed R. A. of ☽'s 1 L.	r sec. δ.	R. A. of Moon's Centre. Observed.	R. A. of Moon's Centre. From the Berlin Ephemeris.	Corrections.
	h. m. s	° ′ ″	′ ″	° ′ ″	° ′ ″	″
Schurscha .	8 25 17·39	198 26 37·35	+ 14 54·49	198 41 31·84	198 41 53·57	d A = − 21·73
Dorpat .	8 21 38 48	198 25 14 55	14 54·50	198 40 9·05	198 40 9·46	d A = − 9·41
Cracow .	8 49 29·93	198 38 30·00	14 54·46	198 53 24·46	198 53 24·47	d A = − 0·01
Greenwich	10 11 45·25	199 17 35·10	+ 14 54·34	199 32 29·44	198 32 31·68	d A = − 2·24

The three observatories give an error of the ephemeris very accordant; the mean is $d\,A = -0''\cdot88$, with $\mu = 0''\cdot4744$.

$$d\,L = \frac{-21\,73 + 0\,88}{0\,4744} = \frac{-20''\cdot85}{0\,4744} = -44\cdot0 \text{ sec.}$$

or the longitude of Schurscha = − 1h. 34m. 44s.·0 from Paris.

The comparison with the individual observatories gives—

With Dorpat $d\,L = \frac{-21''\cdot32}{0\cdot4744} = -44^{s}\cdot9$ lon. = 1h. 34m. 44s.·9.

Cracow $= \frac{-21\cdot72}{0\cdot4744} = -45\cdot9$ . . = 45·9.

Greenwich $= \frac{-19\cdot49}{0\cdot4744} = -41\cdot1$ . . = 41·1.

The Mean is . . = − 1 34 44·0.

M. Struve then proceeds to investigate the differences of determinations of longitude by the moon's 1 L., and moon's 2 L., and finds it necessary, in order to reconcile the observations made at twelve stations, to increase determinations of longitude by the moon's 1 L. 7s.·2, and to diminish those of the moon's 2 L. by the like quantity.

The following additional examples of the determination of longitudes by moon culminators, are extracted from Rümker's *Langen Bestimmung durch den Mond*, Hamburg, 1849.

The longitude of Hamburg, in three examples, being supposed to be well known, let p be the sidereal time of the earlier, and π that of the later culmination; t the mean time of the earlier culmination, and τ that of the later, deduced from the known longitude. Then for these times, the moon's right ascensions, declinations, and semi-diameters (viz., a and α, d and δ, r and ρ respectively), are to be interpolated from the ephemeris. There will thus be obtained from the ephemeris, the difference of the moon's right ascension $\alpha - a$, and there will be deduced from the observations the difference $\pi - p \pm (\rho \sec. \delta - r \sec. d) = A$, the *upper* sign applying to the *first*, and the *lower* to the second limb of the moon. Hence there will be this proportion—

$$\alpha - a : A = \tau - t : \lambda - L ;$$

consequently $(A - (\alpha - a)) \dfrac{(\tau - t)}{\alpha - a} = c$, the correction of the assumed longitude. The westerly place in these examples being the first, the sign of c is to be changed.

The observations at Port Stephens were made by Captain King, R.N., and have been published in the monthly notices of the Royal Astronomical Society; those at Hamburg, by M. Rümker, are given in the twenty-second volume of the *Astronomische Nachrichten.*

1843, April 12, Hamburg, East.

	h.	m.	s.
Moon's 1 L. . . .	11	43	39·797

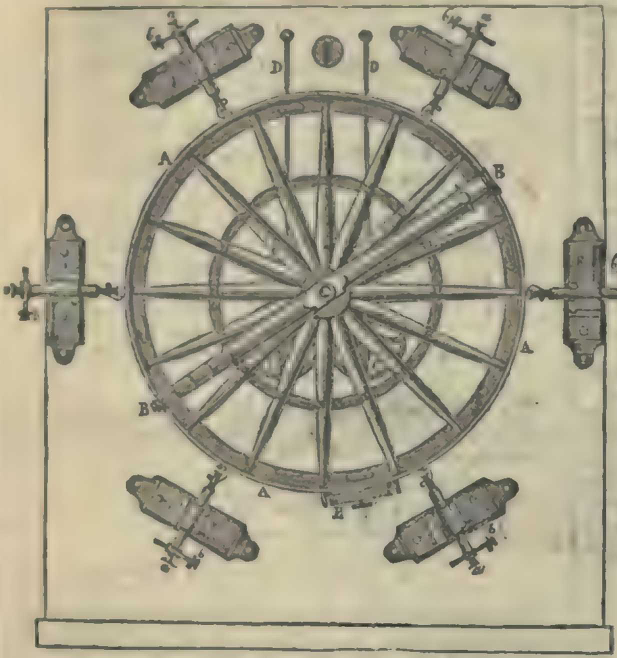
Meridian or Mural Circle.—The north polar distance of an object is determined by means of the meridian or mural circle. Previous to the introduction of the circle, the astronomical quadrant was used for this purpose; but it was discovered, about the beginning of the present century, that its results had been in a great measure vitiated by the expansion of the instrument, and consequent change of figure. The late Astronomer Royal (Mr. Pond), by aid of a circle only two feet in diameter, was enabled to detect and point out the errors of the Greenwich quadrant by a direct comparison of the results of the two instruments. Since that time, circular instruments have been very generally employed. The improved method of graduation, first introduced by Troughton, in 1806, and the previous invention of the micrometer-microscope by Ramsden, have allowed artists to give to this instrument the greatest degree of perfection. The first large instrument of this class appears to have been the Greenwich mural circle, which was completed by Troughton in 1811, and which, in several details, may almost be considered as a new instrument.

Fig. 211.



Some years previously, the celebrated Ramsden made a circle of five feet in diameter, with which Piazzi framed his great catalogue. The idea, however, is an old one, as Roëmer, although better known as the inventor of the transit instrument, used a meridian circle for several years, similar in construction to the modern form. In his letter to Leibnitz, December 15th, 1700, he mentions that he preferred an entire circle of four feet in diameter to a quadrant of eight feet radius. Of his observations with the meridian circle, extending from December, 1704, to December, 1710, only three days remain, the others having been destroyed by the fire which occurred at Hafnia, October 2nd, 1728. These three days' observations, from October 20th to October 23rd, 1706, have been carefully reduced by Dr. Galle, and contained in his *Inaugural Dissertation*, printed at Berlin, in 1845. The diameter of this meridian circle and the length of the axis was five feet and a quarter; the length of the telescope fixed to the axis was five feet. The circle was "read off" by two microscopes placed at an interval of 10°.

The mural circle consists of the graduated circle (Fig. 211) fixed in the meridian, and supported by a long axis, on which it revolves. This axis passes through a block of stone, or solid masonry, the weight of the instrument being taken off the pivots by means of counterpoises placed at the back of the pier. The circle is generally graduated on its rim from 0° to 360°, and also into smaller subdivisions of 5′ of arc.

The instrument is furnished with a telescope, B B, firmly fixed to the axis, and perpendicular to its plane, with which it revolves. The divisions are read by micrometer-microscopes, F, generally six in number, placed at equal distances around its circumference, their object being to eliminate, by readings of opposite diameters, errors arising from eccentricity, flexure of the axis, and expansion. The size of the instrument, at the principal observatories, varies from four to eight feet in diameter. The Greenwich circles were six feet; that at Cambridge is eight feet in diameter. The number of microscopes made use of at Oxford and Edinburgh is four; at Greenwich and Cambridge six are constantly *read off*. It was formerly thought necessary to have two instruments at Greenwich for determining a star's place—namely, a transit instrument and Troughton's mural circle; but a larger transit circle has been constructed for the Observatory, under the direction of the present Astronomer Royal, which has been in use since 1851. The telescope of this instrument has an aperture of eight inches, and a focal length of eleven feet and a-half; a length of axis between the extremities of the pivots of six feet, the diameter of each pivot being six inches. The circle is six feet in diameter, and of cast iron.

The axis of the circle is made horizontal by the aid of a plumb-line suspended in front of the circle, and viewed by two microscopes—one near the top, the other near the bottom of the circle; or, as this instrument is supposed to be used in conjunction with a transit instrument, the axis may be made horizontal by moving the adjusting screw, so as to make a zenith star pass the middle wire at the instant the star is passing the middle wire of the transit instrument.

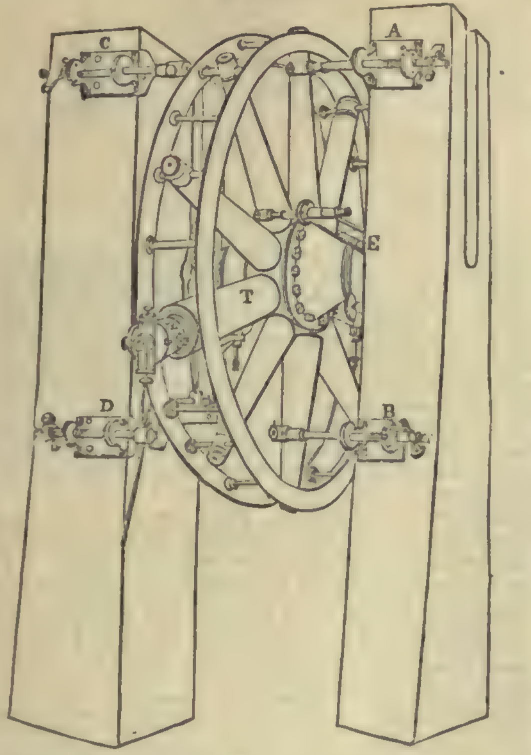
The adjustments of the meridional position of the mural circle are made by the observations of certain stars in conjunction with the transit instrument. The reading microscopes should accurately describe 300″, or five revolutions between each graduated space on the limb of the circle. This can be approximated to by proper adjusting-screws, which regulate the distance of the microscope from the limb; but, notwithstanding the accuracy with which the adjustment may be made, it is found that unequal temperature will alter these numbers considerably. The error arising from this circumstance is called the "correction for runs." It is the practice in observatories to determine the amount of this quantity frequently—which applies to a microscope reading of 5′—and to form corrections proportional for other circle readings. The following is an example (*Cambridge Observations*, May 3rd, 1834):—

	A	B	C	D	E	F	Sums of Excesses.
Negative side .	23·5	18·7	19·2	24·7	19·0	27·3	
Positive . .	25·1	19·4	20·3	26·5	20·3	26·1	
	+1·6	+0·7	+1·1	+1·8	+1·3	−1·2	+5″·3

The telescope is furnished with a system of vertical wires similar to the transit instrument, and a fixed horizontal wire placed at right angles to the others. This wire is generally adjusted so that an equatorial star will continue bisected during its transit; but it is sometimes left with a small inclination, which can be easily observed by comparison with the movable horizontal wire. Several stars being bisected at the first and seventh vertical wires, the effect of inclination can be readily determined for the whole, by comparison with the micrometer of the movable horizontal wire. To determine the value of one revolution of this micrometer, any distinct terrestrial object may be bisected at one position of the micrometer, and the circle carefully "read off." The same mark is again to be bisected at another position of the micrometer, and the circle is again to be "read off." When the two circle readings have been properly reduced, and the runs of the microscope having been applied, their difference will be a value of circle reading, in minutes and seconds, equal to a certain number of revolutions of the micrometer. This operation being repeated at different micrometer readings, a current value of one revolution of the telescope micrometer can be obtained. The more distant and distinct the terrestrial object selected is, the better.

A very convenient transit circle has been erected for the Observatory at Cambridge, Massachusetts, of which the accompanying engraving is a representation. With this instrument one observer can, at the same time, determine the right ascension and declination of a star with great precision. The telescope T (Fig. 212) has an object-glass of four and one-eighth inches of an aperture, and of four feet focal length. The length of the axes between the shoulders of the pivot is ninety-six inches; the pivots are of steel, and two-and-a-half inches in diameter, and the same in length. The eye-piece is provided with two micrometers, one having a vertical, and the other a horizontal movement. Besides the usual mode of illuminating the field through the axis, there are also facilities for illuminating the circus in a dark field. The circles are four feet in diameter, and cast in one piece, and both circles are graduated on silver from 0° to 360°, divided into five minute spaces. There are eight micrometer-reading microscopes attached to the granite piers, being four for each circle. Four of these are seen at A B C D, the other four being on the opposite side of the pier. These micrometers bisect diametrically both piers. The arm E, attached to the pier, supports an additional microscope, which serves as a pointer to indicate approximately the degrees and minutes. For levelling the axis a striding level is employed; and this, combined with a method of reflecting from quicksilver at the nadir point, affords means of ascertaining the amount of collimation of the middle wire without reversal of the pivots. There is, however, an apparatus for reversing the instrument when required. The object-glass of this circle is by Merz of Munich; the fitting by Simms of London.

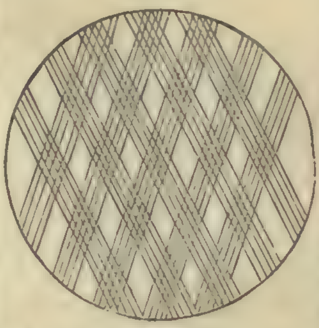
Fig. 212.



The mode of observation with the mural circle is as follows:—The telescope having been set approximately to the culminating star, the observer bisects the object by the movable horizontal wire as it passes the meridional vertical fibre. He then "reads off" the points and the six microscopes, as well as the telescope micrometer, by a combination of which a concluded circle reading may be obtained. It may be necessary to mention that the instrument is furnished with a clamp and a slow motion screw, by which the horizontal wire may be brought on the star, after the telescope has been approximately directed to it. If, by inadvertence, or other causes, the object is not observed at the meridian wire, it will involve a "correction of curvature," which is thus investigated.

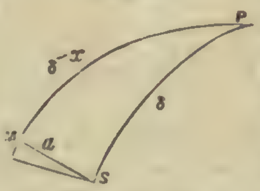
For the purpose of recording the position of every star within range by means of electro-magnetism, the telescope is firmly clamped to remain in its position, while the observer, sitting with his eye at the telescope, has but to press his finger upon a key at the instant a star is seen to pass the wires, which, for this purpose, are divided into two systems (Fig. 213). Those for right ascension are thirty-five in number, divided into groups of five each, the intervals between the wires being from two to three seconds. The wires for difference of declination are also thirty-five, and arranged in similar groups. In order to prevent confusion between observations for right ascension and declination, the rule is, to observe for right ascension on one set of wires first, and denote the magnitude of the star by telegraphic symbol; and afterwards to observe for declination on the inclined wires.

Fig. 213.



When an object is observed by the mural circle off the meridian, the north polar distance found from the circle reading is the N. P. distance of a point of the meridian, which is intersected by a great circle passing through the place of the object at the time of observation. If the object moved in a great circle, this would be its north polar distance when on the meridian; but as it moves in a parallel to the equator, a correction is required, which, as it is evident, will be positive for stars north of the equator, and negative for those south of it. It is thus computed:—

Fig. 214.



Let P be the pole (Fig. 214); S the place of the object; δ = its north polar distance; a = its distance from the meridian; $\delta - x$ = the observed N. P. D.; then we have

$$\cos.\ \delta = \cos.\ a \cos.\ (\delta - x) = (1 - 2 \sin.^2 \tfrac{1}{2} a)\ (\cos.\ \delta \cos.\ x + \sin.\ \delta \sin.\ x)$$

$$\cos.\ \delta = (1 - 2 \sin^2 \tfrac{1}{2} a)\ (\cos.\ \delta \times \sin.\ \delta \times x \sin\ 1'')$$
$$= \cos.\ \delta + \sin.\ \delta \times x \sin.\ 1'' - 2 \sin.^2 \tfrac{1}{2} a \cos.\ \delta$$
$$- 2 \sin.\ \delta \sin.^2 \tfrac{1}{2} a \times x \sin.\ 1''$$

If a be small, the last term will vanish, and by making $\sin.\ \tfrac{1}{2} a = \tfrac{1}{2} a \sin.\ 1''$, we have $2 \sin.^2 \tfrac{1}{2} a = \tfrac{1}{2} a^2 \sin.^2 1''$

$$\therefore \sin.\ \delta \times x \sin.\ 1'' = \cos.\ \delta \times \tfrac{1}{2} a^2 \sin.^2 1''.$$

$$x = \cos.\ \delta,\ \frac{\sin.\ 1''}{2}\ a^2.$$

The distance between the wires is supposed to be 20s. = one interval; and if n be the number of intervals, $a = n \times 20$;

$$\therefore a^2 = n^2 \times 400, \text{ consequently } x = \cot.\ \delta \frac{\sin.\ 1'' \times 400}{2} n.$$

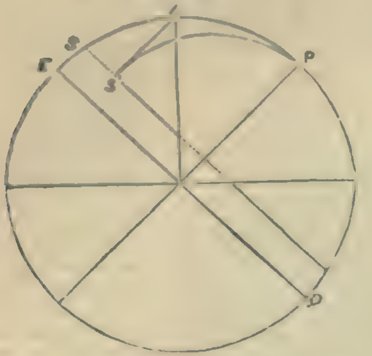
$$x = \tan.\ \text{declination} \times (\sin.\ 1'' \times 200)\ n^2.$$

In the case of a star near the pole, the following is the investigation for curvature of path (Fig. 215):—

Let Z S′ = Z = the observed zenith distance ; Z S — x = zenith distance on meridian; Z P S = p' the difference between the star's R. A. and the sidereal time of observation; d = star's declination; L = the latitude of the place of observation. Then in the triangle Z S′ P, we have

$$\cos. Z = \sin. L \sin. d + \cos. L \cos. d \cos. p$$
$$= \sin. L \sin. d + \cos. L \cos. d \left(1 - \frac{p^2}{2}\right)$$

Fig. 215.



But $\cos. Z - x = \sin. L \sin. d + \cos. L \cos. d$;

or since x is small,

$$\cos. Z + \sin. Z \times x = \sin. L \sin. d + \cos. L \cos. d;$$

therefore $x \sin. Z = \cos. L \cos. d \times \frac{p^2}{2}$

$$\sin. Z \times x \sin. 1'' = \cos. L \cos. d \times \frac{(15\,p)^2}{2} \sin.^2 1''$$

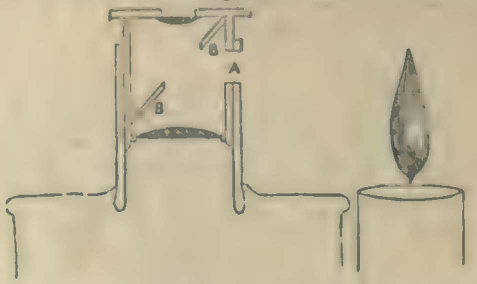
$$\therefore x'' = \frac{\cos. L \cos. d}{\sin. Z} p^2 \times \text{number whose log.} = 6{\cdot}73673$$

$$\text{or } \log. x'' = \log. \cos. L + \log. \cos. d - \log. \sin. Z + 6{\cdot}73673 + 2 \log. p$$
$$= \log. \cos. L + \log. \cos. d + \text{ar. co. } \log. \sin. Z + 6{\cdot}73673 + 2 \log. p.$$

For the purpose of obtaining a zero point of the mural circle, we make use of two different methods, of which the first consists in the observations of stars by reflection from a surface of mercury. The mode of operating is as follows:—Point the telescope to any known star when it crosses the meridian, and record the reading of the circle; on the next night observe the same star as it crosses the meridian, by pointing the telescope upon the image of the star reflected from the surface of the mercury. As the surface of a fluid at rest must be horizontal, and as the angle of reflection is equal to the angle of incidence, this image will be just as much depressed below the horizon as the star itself is above it. The arc intercepted on the limb of the circle, between the star and its reflected image, is the double altitude of the star, and its middle point is the horizontal point of the circle, allowing for the difference of refraction at the moment of observation. It is evident that the image of a star seen by reflection will be as much depressed below the horizon, as the object is really above it; and by combining the two readings of the circle for the same star, observed by reflection and direct vision, the horizontal point of the instrument may be readily determined. This method of obtaining a reflection and direct observation of a star, at the same transit, is daily practised at our principal observatories.

The second method is by the use of a Bohnenberger's eye-piece, previously explained. By causing the two images of the wire of the declination micrometer to coincide, and noting its readings, the *nadir*, and consequently the *zenith*, points of the circle may be determined by directing the telescope vertically downward upon a basin of mercury, the reflected image of the horizontal wire being made to coincide with its direct image. The telescope is directed towards the *nadir*, which is distant 90° from the horizontal point, or 180° from the zenith point. As this observation can be made at any time, independently of the weather, it is a most valuable method, and in many observatories is the one exclusively employed. The horizontal point determined by direct and reflected observations, should differ exactly 90° from the zenith point, as determined by the collimating eye-piece. This eye-piece, first suggested by Bohnenberger, consists of an ordinary eye-piece with an aperture A (Fig. 216), cut in its side, and a plane perforated speculum B B inserted between the two lenses, at an angle of 45°, with the optical axis, having a lamp held so as to throw a strong light on the speculum. The reflected images of the wires may be seen with great distinctness. Instead of a perforated opaque speculum, a piece of plane glass with parallel faces, and without any perforation, is sometimes used. The observer looks through the plane glass without difficulty, while sufficient light is reflected from the lower surface to render the lines visible. If the axis of the telescope be not horizontal, half the distance between the middle wire and its image, corrected for error of level, will give the error of collimation of the middle wire.

Fig. 216.



The tables of refraction, made use of at the Royal Observatory, Greenwich, are those of Bessel, modified and expanded from the *Tabulæ Regiomontanæ*. A numerical example of their application is given further on.

Example of a zenith point determination from the Greenwich Observatory, 1849. (See, also, page 1008).

183° 32″
Horizontal Point = Mean 50″·14
or Zenith Point = 93° 32′ 50″·14

The adopted Zenith Point is 93° 32′ 49″·89.

The printed form given as follows, will show fully the method of reducing observations of zenith distance. It is arranged for the reduction of the zenith distance observations with the transit circle, which differs from the above specimens, principally in the valuation of the micrometer-microscopes. The manner in which the revolutions and parts of revolutions of the microscope-micrometer are converted into arc, are explained as follows in the *Greenwich Observations*, 1852, page iv.:—

"I must premise that, as one revolution of each microscope-micrometer does not differ extravagantly from 1′ on the limb of the circle, we may consider each revolution as a nominal minute. Next, supposing the number of integral revolutions, as shown by each microscope, to be the same for all, we ought, in order to obtain the mean of the fractions of a revolution, to add together the subdivisions as shown by the different micrometer-heads, and divide the sum by 6. Thirdly, as the subdivisions are in the decimal scale, we should then multiply this mean by 60 to reduce it to seconds. It is evident thus that the number of nominal seconds to be attached to the nominal minute will be found by simply adding together the subdivisions on the micrometer-heads, and shifting the decimal point.

"The following were found by trial to be the *runs* of the six microscopes :—

"NUMBER OF REVOLUTIONS CORRESPONDING TO 5′ FOR MICROSCOPES.

	A	B	C	D	E	F
Means . . .	r 4·912	r 4·882	r 4·882	r 4·879	r 4·886	r 4·878

"The results given above show that the screws of the micrometers are so sensibly equal that, in the reduction of the observations, it is sufficient to take the mean of the six readings, and to apply to it the mean correction for runs. To do this, the following process is employed :— The sum of the runs for the six microscopes above given is 29r·320. Now, if the correction by which each revolution of a micrometer may be converted into a minute of arc were exactly $\frac{1}{50}$ part of the reading, then the sum of the runs would be $\frac{50}{51} + 30^{r}{\cdot}000$, or $29^{r}{\cdot}4118$. It is not

likely that the sum of the runs will, in ordinary cases, amount to this quantity; and the variable correction, after adding $\frac{1}{50}$ part to the mean of the readings of the microscopes, will therefore always be additive. To determine this quantity, let the sum of the runs be $29'\cdot412 - x$. Then the true reading, in seconds of space, corresponding to a nominal reading of r'' (including the value in seconds of the nominal minutes), will be

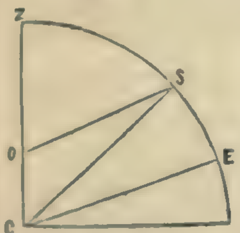
$$r'' \times \frac{30\cdot000}{29\cdot412 - x}$$

Or $$r'' \left\{ 1 + \frac{1}{50} + 0\cdot03468 \times x \right\}$$

Hence the correction, after adding $\frac{1}{50}$ part of the mean of readings, will be $+ r x \times 0''\cdot03468$. For the purpose of calculating this quantity easily, by the ordinary proportioned scale, it is convenient, in the first place, to compute its value, where $r = 100''$. This value, which is evidently $+ 3''\cdot468 \times x$, is tabulated for different values of x. Let X be the number taken from this table; then, for any actual reading r, the correction will be $\frac{r\text{X}}{100}$; a quantity which can easily be taken from the ordinary sliding rule.

PARALLAX.—The change which takes place in the position of a heavenly body on account of its having been observed from a point which is not the centre of motion, is called its parallax. All the heavenly bodies appear to move in the concave surface of a sphere concentric with the earth; hence the centre of the earth is considered to be the centre of motion. We shall now inquire into the change which would take place in the position of a body which has been observed at the surface of the earth, and its position as seen from the centre. Or, in other words, to find the correction which should be applied to an observation made at the earth's surface to reduce it to what it would be if made at the centre. Let C (Fig. 217) be the centre of the earth, O the place of observation on its surface, Z the geocentric zenith, S the object observed; then Z O S is the observed zenith distance, Z C S the zenith distance as seen from the centre, which is called the true zenith distance, because astronomers reduce all their observations to this point. The difference of these angles is the parallax; it is, therefore, the angle subtended by the earth's semi-diameter at the object observed.

Fig. 217.



Put Z C S the true zenith distance = Z.
Z O S the apparent zenith distance = Z′.
C O the earth's semi-diameter = r.
C S the distance of the object from the earth's centre = D.
The parallax O S C = p.

Then $$Z + p = Z', \text{ or } Z = Z' - p.$$

This shows that the observed zenith distance is greater than the true zenith distance by the quantity p. Hence the true zenith distance is found by subtracting the parallax from the observed zenith distance.

It is evident that parallax exerts its influence in a vertical plane passing through the object; consequently it has no effect on the right ascension of an object when observed on the meridian; but if the observation be made on either side of the meridian, the right ascension will be affected by it, as it raises the object to an hour circle nearer to the meridian. Hence, if the object lay east of the meridian, the apparent right ascension is diminished; but, if west, it is increased by parallax. Refraction has a contrary effect.

Now we have $\frac{\sin. Z'}{\sin. p} = \frac{D}{r}$ $\therefore \sin. p = \frac{r}{D} \sin. Z' = \frac{r}{D} \sin. (Z + p) \quad . \quad . \quad . \quad (1)$

The equation $\sin. p = \frac{r}{D} \sin. Z'$, gives $p = 0$ when $Z' = 0$, and $\sin. p = \frac{r}{D}$ when $Z' = 90°$. As this is the greatest value of Z', $\frac{r}{D}$ is the greatest value of $\sin. p$.

Therefore, in the geocentric zenith the parallax is nothing, whereas in the horizon it is the greatest possible.

Put $\frac{r}{D} = \sin. \pi$, then $\sin. p = \sin. \pi \sin. Z'$. This equation may be put under the form

$$p \left(\frac{\sin. p}{p} \right) = \pi \left(\frac{\sin. \pi}{\pi} \right) \sin. Z$$

$$\therefore p = \pi \left(\frac{\sin. \pi}{\pi} \right) \left(\frac{p}{\sin. p} \right) \sin. Z' \quad . \quad . \quad . \quad . \quad (2)$$

The horizontal parallax π, or rather the horizontal equatorial parallax (for the moon), given in the *Nautical Almanac*, is the angle subtended by the earth's equatorial semi-diameter.

Let r' be the semi-diameter of the place of observation, then $r' \sin. \pi$ will be the sine of the horizontal parallax at that place, and we shall have

$$p = r' \pi \left(\frac{\sin. \pi}{\pi} \right) \left(\frac{p}{\sin. p} \right) \sin. Z' \quad . \quad . \quad . \quad . \quad (3)$$

This is the formula given in the Introduction to the *Greenwich Observations* for computing the moon's parallax when observed on the meridian.

The equation $\sin. p'' = r' \sin. \pi \sin. Z$ may be written

$$p'' \sin. 1'' = r' \pi'' \sin. 1'' \sin. Z'$$

Or, $$p'' = r' \pi'' \sin. Z' \quad . \quad . \quad . \quad (4)$$

This will be sufficiently exact for the planets. In the

Example of the Reduction of an Observation with the Mural Circle. (See page 1027).

case of the moon, a correction will be necessary, which is found thus—

$$\sin. p'' = p'' \sin. 1'' - \frac{p''^3 \sin.^3 1''}{6} \text{ nearly ; hence}$$

$$p'' \sin. 1'' - \frac{p''^3 \sin.^3 1''}{6} = \left(\pi'' \sin. 1'' - \frac{\pi''^3 \sin.^3 1''}{6}\right) \sin. Z'$$

but $p''^3 \sin.^{1''} = \pi''^3 \sin.^3 1'' \sin.^3 Z'$, by neglecting powers higher than the third ; hence, by substitution,

$$p'' \sin. 1'' = \pi'' \sin. 1'' \sin. Z' - \frac{\pi''^3 \sin.^3 1''}{6} (\sin. Z' - \sin.^3 Z')$$

$$= \pi'' \sin. 1'' \sin. Z' - \frac{\pi''^3 \sin.^3 1''}{6} \sin. Z' \cos.^2 Z'$$

Consequently the correction is

$$-\frac{\pi''^3 \sin.^3 1''}{6} \sin. Z' \cos.^2 Z' \quad . \quad . \quad . \; (5)$$

This correction is applied in the Greenwich Lunar Reductions from 1750 to 1830.

Again, since $\sin. \pi = \frac{r}{D}$, for any other distance D′, we shall have $\sin. \pi' = \frac{r}{D}$; therefore,

$$\sin. \pi : \sin. \pi' \; \frac{1}{D} : \frac{1}{D}, \text{ or } \frac{\pi'}{D} = \frac{\pi}{D}.$$

If D′ be expressed in parts of D taken as unit, we have $\pi = \frac{\pi}{D}$; therefore, if π be the sun's horizontal parallax at the mean distance from the earth, and D′ the distance of any planet from the centre of the earth, expressed in terms of the sun's mean distance, the planet's horizontal parallax will be represented by $\pi \times \frac{1}{D'}$, and for a planet we shall have

$$p = \pi \times \frac{1}{D} \sin. Z' \quad . \quad . \quad . \quad . \; (6)$$

It is by this method the parallax of the planets has been computed in the Greenwich Planetary Reductions from 1750 to 1830.

Equation (1) gives the means of finding the parallax when the true zenith distance is given ; thus

$$\sin. p = \sin. \pi \sin. (Z + p) = \sin. \pi (\sin. Z \cos. p + \cos. Z \sin. p)$$

$$\tan. p = \sin. \pi \sin. Z + \tan. p \cos. Z \sin. \pi$$

$$\tan. p = \frac{\sin. \pi \sin. Z}{1 - \sin. \pi \cos. Z} \quad . \quad . \quad . \quad . \; (7)$$

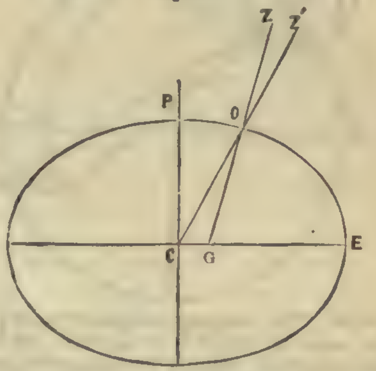
And by the usual method of development,

$$p = \frac{\sin. \pi \sin. Z}{\sin. 1''} + \frac{\sin.^2 \pi \sin. 2 Z}{2 \sin. 1''} + \frac{\sin.^3 \pi \sin. 3 Z}{3 \sin. 1''}, \text{ \&c. } (8)$$

We have seen that $\sin. \pi = \frac{r}{D}$; hence, if D be very great, π will be very small ; and, therefore, bodies at an extremely great distance, compared with the radius of the earth, have no sensible parallax.

Before proceeding any further, it may be well to remark that the value of sin. p depends on lines drawn from the centre of the earth, or from what is called the geocentric zenith, which differs from the astronomical zenith for this reason :—All astronomical instruments used for determining the north polar distance of an object depend on a zenith point, or something equivalent to one ; and this is nothing more than the instrumental reading corresponding to a vertical position of the telescope, and is determined by observing the same star by direct vision and reflection. The zenith point is therefore the reading for a point perpendicular to the horizon ; or, which is the same, a line drawn from the point thus determined in the heavens to the place of observation, is a normal to the curve by which the earth is generated, supposing it to be a surface of revolution. The earth is supposed to be a surface of revolution, generated by an ellipse revolving round its shorter axis ; the ratio of the axis being 300 : 299. Now, it is well known that normals to an ellipse do not pass through its centre ; hence the lines drawn from the centre of the earth to the place of observation, which determines the geocentric zenith, will make a small angle with the normal to the earth's surface at the same place, which determines the astronomical zenith ; and this angle is called the angle of the vertical. The geocentric zenith is nearer to the equator than the astronomical zenith by the value of this angle ; and as all the bodies (some comets excepted) for which we have to compute parallax, lie to the south of the zenith, the angle of the vertical is subtracted from the astronomical zenith distance, in order to have the geocentric zenith distance. This angle is easily determined, for it is the difference between the astronomical and geocentric latitude of the place of observation, and is thus formed : —Let P (Fig. 218) be the pole of the earth ; E a point of the equator ; O the place of observation ; Z′ the geocentric zenith ; Z the astronomical zenith ; then Z′ C E is the geocentric latitude = L g, and Z G E is the astronomical latitude = L a, and Z′ O Z = C O G is the angle of the vertical. Let a and b be the axis of the ellipse, the equation of the normal Z G is

Fig. 218.



$$y - y' = \frac{a^2}{b^2} \cdot \frac{y'}{x'} (x - x') = \frac{a^2}{b^2} \tan. L g (x - x') ;$$

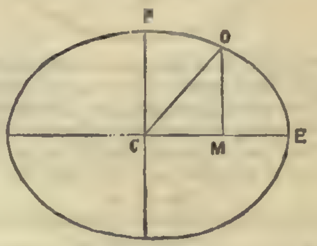
therefore,

$$\tan. L a = \frac{a^2}{b^2} \tan. L g, \text{ or } \tan. L g = \frac{b^2}{a^2} \tan. L a \; . \; . \; . \; . \; (9) ;$$

hence, L g becomes known. For an ellipticity of $\frac{\ }{300}$, and the astronomical latitude of Greenwich, viz., 51° 28′ 39″, we find the geocentric latitude, 51° 17′ 29″, and consequently the angle of the vertical = 11′ 12″.

The value of r', by which the moon's horizontal parallax must be multiplied, to have the horizontal parallax at the place of observation, is thus computed (Fig. 219) :

Fig. 219.



C O = r', O C E = L g ; then by the property of the ellipse $b^2 x^2 + a^2 y^2 = a^2 b^2$, we easily find

$$r^2 = \frac{a^2 b^2}{a^2 \sin.^2 L g + b^2 \cos.^2 L g}$$

$$= \frac{a^2 b^2}{a^2 - (a^2 - b^2) \cos.^2 L g}$$

$$r^2 = \frac{b^2}{1 - \frac{a^2 - b^2}{a^2} \cos^2. L g} \; \therefore r = b \sec. \theta$$

$$\text{where } \sin.^2 \theta = \frac{a^2 - b^2}{a^2} \cos.^2 L g.$$

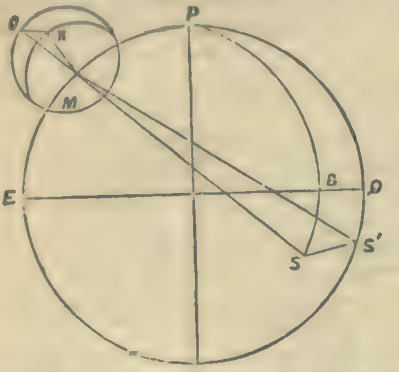
The reductions from the apparent to the mean places are performed in a manner similar to that previously explained for right ascension.

The other corrections for circle observations, viz., defective illumination of Moon and Venus, &c., are so fully explained in the Introduction to the *Greenwich Observations*, that a short investigation will only be necessary.*

Correction for Defective Illumination.—The following is the investigation of the correction for the defective illumination of the moon in the right ascension :—

Let S (Fig. 220) be the place of the sun, M that of the moon ; if the sun were at S′ both limbs of the moon would be full 12h. ∽ apparent time of moon's transit = B P Q = arc B Q, but B Q × cos. S B = S S = S M S′ = O M *n* = arc O *n*. This is the arc on the moon's disc, which is not illuminated, and its versed sin. is the part of the surface not enlightened.

Fig. 220.

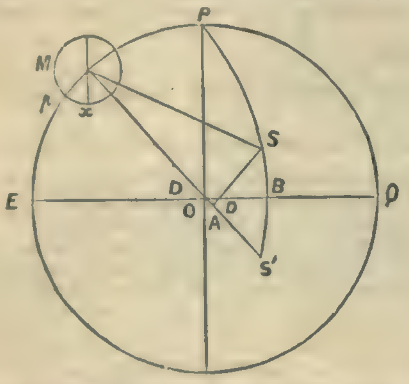


Moon's semi-diameter × versed sine S S′ = correction.

Defective Illumination in N. P. D.—Moon gibbous.

Let E Q (Fig. 221) be the equator, P the pole, E M = E O M = S′O B = D = the moon's declination. If the sun were at S′ both limbs of the moon would be enlightened. E P S = sun's hour angle = the difference between the times of passage of the sun and moon without regard to sign. Then in O B = cot. B O S′ × tan. B S′.

Fig. 221.



∴ tan. B S = sin. O B tan. D = sin. (E P S − 90°) tan. D =

— cos. sun's hour angle × tan. moon's apparent declination.

B S′ is called the new declination.

New declination — sun's declination = angle required. When this angle is positive, the north limb is full.

From S′ let fall the perpendicular arc S A, then cos. B O S′ = cos. B S′ sin. B S′ O. ∴ sin. B S′ O = $\frac{\text{cos. B O S}'}{\text{cos. B S}'}$ sin. S A = sin. S S′ sin. AS′S = sin. SS′; sin. AS′ S = sin. S S′ × $\frac{\text{cos. B O S}'}{\text{cos. B S}'}$ = sin. S S′ cos. B O S′ sec. B S′. S A s called the new angle, therefore sine new angle = cos. app. decl. × sec. new decl. × sine angle required.

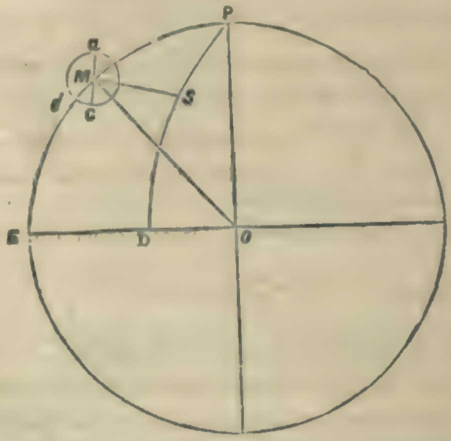
The new angle, or S A, is taken for the measure of S M A or *p* M *x*, the angle of defective illumination.

Defective Illumination in N. P. D.—Moon horned.

Mean time of passage 3h. to 6h.

Let S (Fig. 222) be the sun, M the moon on the meridian, *a c* perpendicular to S M. Join M O, D = E M = the moon's apparent declination, *d* = the sun's apparent declination. The angle M P S = T = the difference between the mean times of passage of the sun and moon ; the angle S M O is the angle of defective illumination = 90° — P M S.

Fig. 222.

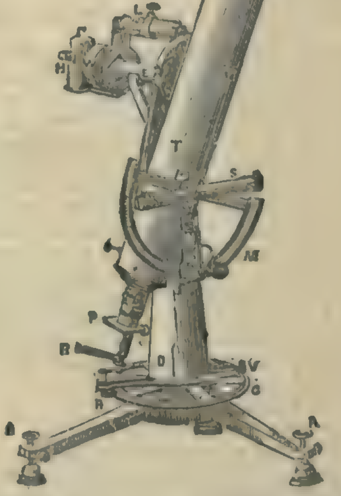


$$\text{tan. P M S} = \frac{\text{sin. T}}{\text{cos. D tan. } d - \text{sin. D cos. T}}$$

$$\text{tan. S M O} = \text{cot. P M S} = \frac{\text{cos. D tan. } d}{\text{sin. T}} - \frac{\text{sin. D cos. T}}{\text{sin. T}}$$

The Zenith Telescope.—The instrument employed in measuring the difference of the zenith distance and hour, called the zenith telescope, may be described here, although it is scarcely the proper place for it. A A (Fig.

Fig. 223.



---

* The subject of parallax has already been examined, in reference to the sun, moon, &c., at page 926: to which the reader is referred for the practical application of the preceding remarks and formulæ.

223) are the screws which support the entire instrument, and by which the column carrying the telescope-screw is rendered truly vertical; C is the horizontal circle twelve inches in diameter, graduated to 10′, and reading to 10″, by means of its Vernier and microscope, V. B is the tangent-screw for slow motion.

This circle serves to mark the position of the meridian when it has once been determined. It likewise enables the observer to turn the telescope promptly through 180° of azimuth. D is the vertical column which supports the telescope, and about which the telescope turns in azimuth. E is a horizontal axis, to one end of which is attached the telescope T T, which is counterpoised by the weight, W, at the other end; this axis is hollow, and through it passes the light of the lamp, H, to illumine the wires of the telescope. The telescope has a focal length of about forty inches, and an aperture of three inches. L is the level by means of which the column D is rendered truly vertical, riding on the horizontal axis. M is a graduated semicircle attached to the telescope, and having a Vernier, N, with a microscope. This semicircle serves as a finder for setting the telescope to the altitude of the stars to be observed. S S is a very delicate level attached to the semicircle. P is the parallel wire micrometer for measuring small differences of altitude; and R is the diagonal eye-piece, so constructed that the micrometer may not interfere with the field of observation.

The stars selected for observation by this instrument should be within a convenient range of the micrometer—say 10′—one culminating to the north, and the other south of the zenith. Having levelled the instrument, set the telescope to an altitude midway between the two stars, and bring the bubble of the level S to the middle of its scale.

Bring the telescope into the plane of the meridian by setting the Vernier of the horizontal circle to the point previously determined.

As the first star enters the field of view, follow its image with one of the horizontal wires, and bisect it at the instant it crosses the middle wire. Record the position of the level S, noting the divisions corresponding to each extremity of the bubble. Turn the telescope 180° in azimuth, taking care to preserve the same inclination to the horizon, and make a similar observation on the second star, bisecting it with the horizontal wire. A comparison of the readings of the two micrometers will give the zenith distance of the two stars after correction by readings of the level, and also for the difference of refraction of the two stars.

We here subjoin a table of calculated orbits of comets, from the best authorities.

SECTION XI.

NAVIGATION AND NAUTICAL ASTRONOMY.

CHAPTER I.

INTRODUCTION.

The principles of Navigation rest almost entirely upon that part of Plane Trigonometry which is limited to the doctrine of plane triangles. A person unacquainted with the mathematical theory upon which the practical rules followed by the navigator are based, would naturally imagine, as the track of a ship is a path marked out on the surface of a *sphere*, that to calculate, from the necessary data, the length of this track, the aid of *Spherical* Trigonometry would be required. But, in general, such is not the case; and for this reason:—spherical trigonometry is wholly concerned with the arcs of great circles of the sphere, and with the angles formed by such arcs; whereas, the course of a ship at sea, unless it sail on the equator, or on a meridian, is never a great circle;—it is either a small circle, a parallel to the equator, or else a line cutting the successive meridians over which it sails, obliquely, and at the same invariable angle, so long as its *course* remains unchanged. A ship, continuing on this unchanged course, would trace out, on the surface of the sphere, a winding or spiral curve, called in navigation a *rhumb line*, and which is widely different in figure from a circle. If a vessel were to start from any point between the equator and either pole, and on a course inclined ever so little towards that pole, it would wind round the globe in this spiral path, approaching nearer and nearer to the pole, but actually arriving at it only after it had circulated round it an infinite number of times.

It is the length of a portion of such a spiral line that is one of the objects of navigation to calculate; and it is pretty obvious that rules and formulæ, supplied by *spherical* trigonometry, can give no aid in such a calculation; since the latter science has nothing to do with the spiral curves, which vessels at sea trace out.

It would seem, however, that these spirals on a *sphere*, are equally external to the proper objects of *plane* trigonometry, which recognises only *straight* lines, drawn on a flat surface. But it must be observed that navigators are not interested in any investigations respecting the form or shape of the spiral path of a ship; but only in its *length*, and in the angle it makes with the meridians crossed by it. *Lengths*, and the angles formed by them, are, of course, the proper objects of consideration in plane trigonometry; and some notion may, therefore, be formed as to how it happens that a ship's course and distance sailed, are matters for investigation by plane, and not by spherical trigonometry. In the latter subject, the *form* of the lines concerned cannot possibly be disregarded, any more than their lengths; it would not be spherical trigonometry unless the lines of which it treats were all of them portions of great circles of the same sphere. Plane trigonometry regards lengths and angles only; and these alone are all that navigators require to be calculated.

It is obvious, therefore, that, in order to understand the *science* of navigation, the theory and practice of plane trigonometry—as far, at least, as the triangle is concerned—must be previously acquired; but modern books on Trigonometry, with but few exceptions, are very deficient in this needful preparatory instruction; so that it becomes almost imperative upon a writer on navigation, who wishes to be clear and intelligible, to conduct his reader through some amount of preliminary matter before formally entering upon the special object of his work. We shall, therefore, introduce the subject by an article on the calculation of plane triangles; referring to the chapters on Trigonometry, in the Section of MATHEMATICS, for the necessary theoretical principles; except in a few cases where it may be thought expedient to use rules of operation not expressly provided for in that part of this work: in such cases the theoretical investigation will precede the practical rule.

Most persons who read this Section, will very likely do so for the sole purpose of becoming acquainted with the general principles of a most valuable part of practical mathematics; and more especially for learning in what way a few elementary theories, in pure mathematics, are made available for objects of such commercial and national importance, as the conducting a ship across the ocean from one port to another; the daily registry of its position on the globe; the determination of its direct distance from any preceding position, however irregular its actual course between the two positions may have been; of its distance from the equator at any time, and from the meridian of Greenwich, &c., &c. These things are well worth inquiring into even by the non-professional student of science; as they give a practical value, of the highest kind, to what might otherwise seem to be but barren speculations.

Nothing can more forcibly illustrate the importance of the theoretical principles developed in the Mathematical Section above referred to, than the application of those principles to Navigation and Nautical Astronomy; for, aided by the Compass and the Log, and by a simple optical instrument—the construction of which those principles have suggested—they instruct the mariner to read aright the intelligence of the stars—those faithful finger-posts of heaven, which direct him unerringly on his course across a vast and dreary expanse, where no human skill can erect a signal to guide, or a beacon to warn; and where even the busy traffic of ages has left no beaten pathway behind it.

Our object is to describe, in simple language, but in a strictly scientific manner, how all this is brought about; and while we shall explain everything that can be reasonably desired by the mathematical student, we shall also furnish, to the practical seaman, the reasons on which his rules of calculation are founded, and the principles on which his tables are constructed; and will thus, we hope, afford a useful accompaniment to whatever book of rules and tables he may choose to consult in the ordinary exercise of his profession. It is in the highest degree desirable that persons engaged in a calling so responsible, should be enabled to judge for themselves of the soundness and accuracy of the directions which guide them, and not deliver themselves blindly up to authoritative rules. The amount of mathematical knowledge necessary to convert their art into a science is really very small; and the satisfaction arising from knowing a thing as an ascertained truth, instead of receiving it upon trust, is alone sufficient to compensate for the time expended on the study of it. Besides, mere printed directions can never suffice for unforeseen emergencies; and in no occupation are these more likely to arise than amidst the hazardous duties of the sailor's life. In such circumstances a little science may often be of more avail than volumes of prescribed directions; and even in the ordinary calculations, which form part of the every-day routine on shipboard, time and figures are often both thrown away by the unscientific mariner, under the impression that he is increasing the accuracy of his work, when he is, in reality, only encumbering it with errors. A very meritorious writer, Lieut. Raper, justly remarks, that "very indistinct and erroneous notions prevail among practical persons on the subject of accuracy of computation, and much time is, in consequence, often lost in computing to a degree of precision wholly inconsistent with that of the elements themselves. The mere habit of working invariably to a useless precision, while it can never advance the computer's knowledge of the subject, has the unfavourable tendency of deceiving those who are not aware of the true nature of such questions, into the persuasion that a result is always as correct as the computer chooses to make it; and thus leads them to place the same confidence in all observations, provided only they are *worked* to the same degree of accuracy."* These are very judicious observations; and Lieut. Raper is, as far as we know, the only person who has drawn attention, in print, to this customary waste of calculation.

The tables which accompany books on navigation are, in general, computed to an extent of decimals—usually six or seven places—much beyond what the ordinary calculations of navigation require; and the unscientific seaman uses them *all*, when half the number would, in most cases, be amply sufficient: his fault is analogous to that of the ill-taught school-boy, who, having to multiply together two numbers of five decimals—the final decimal of each number being confessedly inaccurate—is at the trouble of computing ten decimals in his product, and fancies, if there be no error in his operation, that they are all correct, whereas five of them at least are wrong, and, therefore, worse than useless.

We shall now proceed to those preliminary matters which furnish the suitable introduction to the different sailings—plane sailing, parallel sailing, middle latitude sailing, and Mercator's sailing.

ON LOGARITHMS.—Logarithms are a peculiar kind of numbers, invented by Lord Napier, for the purpose of shortening the calculations by common figures, whenever these calculations require the operations of multiplication or division, the raising of powers, or the extracting of roots.

Logarithms are of great importance in the computations of Navigation and Nautical Astronomy; and it was mainly for the purpose of reducing the labour of such computations, that Napier was led to construct a *table of logarithms.*

The peculiar character, and the practical use of these important numbers may be briefly explained as follows, the principles of Algebra, as given in our mathematical section, being previously understood.

It is therein shown (see Algebra, page 465) that, a being any *base*, and x and y any exponents,

$$a^x \times a^y = a^{x+y}, \text{ and } a^x \div a^y = a^{x-y};$$

and, moreover, that whatever exponents m and n may be, $(a^m)^n = a^{mn}$.

Now let us suppose that any number N could be written in the form a^x, a being some chosen number fixed upon as a *base*, and x the suitable exponent to justify the equation $a^x = \text{N}$; thus, the base a might be the number 2, or 3, or 4, or any other positive number different from unity; and it is plain that, whether we can find it or not, *some* value exists for x which would satisfy the equation just written, whatever be the positive number N. There is no doubt, for instance, that a numerical value for x exists such that $2^x = 12$: the value of x must evidently lie between 3 and 4. Again, the value of x, which satisfies the condition $2^x = 6$, must evidently lie between 2 and 3. Now imagine two numbers thus represented, one of them N by a^x, and the other N′ by a^y; then, from the principles stated above, we should have, by multiplication and division,

$$a^x \times a^y, \text{ that is, } a^{x+y} = \text{N N}'; \text{ and } a^x \div a^y, \text{ that is, } a^{x-y} = \text{N} \div \text{N}'.$$

where we see that the *multiplication* of the two numbers N, N′ is replaced by the simple *addition* of the two exponents x and y, in the proposed notation for those numbers, and that the *division* of N by N′ is replaced by the simple *subtraction* of the exponent y from the exponent x. The proper exponent s, to be placed over the base a, so that a^s may replace the number N N′, is therefore $s = x + y$; and the proper exponent, for the number $\frac{\text{N}}{\text{N}'}$, is $s = x - y$. It appears from this, that if a table were constructed in which the numbers 1, 2, 3, &c., up to the highest number likely to occur in calculation, were inserted, and against each number n were placed the proper exponent x—that is, such a value of x that the equation $a^x = n$ should, in each case, be satisfied—the operations of multiplication and division might, by aid of the table, be converted into the simpler operations of addition and subtraction.

Such a table was actually constructed by Napier; it was afterwards improved by Briggs, who found that 10 was the most convenient number to choose for the base a; and the tables constructed to this base, and in which are inserted against each number n the value of x proper to satisfy the equation $10^x = n$, are the modern *tables of logarithms*:—the exponent x, adapted to any proposed number n, being called the *logarithm* of n; so that a table of logarithms is nothing more than a table of exponents—the base-number, to which each exponent is conceived to be attached, being 10.

For example, suppose we want the logarithm of 67:—in other words, that we require the value of the exponent x, fitted to satisfy the condition $10^x = 67$, we turn to the tables, and find the value to be $x = 1{\cdot}826075$.

In like manner, if we want the logarithm of 58, or to solve the equation $10^x = 58$, we find, from the table, that $x = 1{\cdot}763428$. We therefore say that log. 67 = 1·826075, and log. 58 = 1·763428; which is only another way of expressing that

$$67 = 10^{1\cdot826075}, \text{ and } 58 = 10^{1\cdot763428}.$$

The product of these numbers is $67 \times 58 = 10^{1\cdot826075+1\cdot763428}$; that is $10^{3\cdot589503}$. The quotient of the first by the second is $67 \div 58 = 10^{1\cdot826075-1\cdot763428}$; that is $10^{\cdot062647}$. In other words, log. $(67 \times 58) = 3{\cdot}589503$, and log. $(67 \div 58) = {\cdot}062647$. Turning now to the table, we find, against the logarithm 3·589503, the number 3886, and against the logarithm ·362647, the number 1·155 . . . : we conclude, therefore, without actually performing the operation of multiplication or division, that

$$67 \times 58 = 3886, \text{ and } 67 \div 58 = 1{\cdot}155 \ldots.$$

And in a similar way may the product or quotient of any two numbers, within the limits of the table, be found: for the *product*, we *add* the logs. of the factors; for the *quotient*, we *subtract* log. of divisor from log. of dividend. The result, in each case, is a log., against which, in the table, is the product or quotient sought; and in this way addition and subtraction is made to replace the more lengthy operations of multiplication and division.

It must be noticed, however, that the *integral* part of the logarithm or exponent is not inserted in the table—only the *decimal* part: the insertion of the integral part, or *index*, as it is called, is unnecessary, because this index is at once known from inspection of the number to which the logarithm belongs: thus, since

$$10^0 = 1,\ 10^1 = 10,\ 10^2 = 100,\ 10^3 = 1000,\ 10^4 = 10000, \text{ \&c.},$$

we know that the log. of a number between 1 and 10 must lie between 0 and 1; we know, therefore, that the index of a positive number, anywhere between these limits, is 0. We see, also, that the log. of a number between 10 and 100 must lie between 1 and 2; the index of such a number must therefore be 1. In like manner, since the log. of a number between 100 and 1000 must lie between 2 and 3, we know that the index of such a number must be 2; and so on.

Hence the index of the log of a number consisting of but one integer—however many decimals may follow that integer—is 0; the index of a log. of a number consisting of two integers, however many decimals may follow, is 1; of a number consisting of three integers, the index of the log. is 2; of a number consisting of four integers, the index is 3; and, generally, of a number consisting of n integers, the index of the log. is $n-1$.

---

* *The Practice of Navigation and Nautical Astronomy.* By H. Raper, Esq., Secretary to the Royal Astronomical Society.

We have, therefore, only to count the figures in the integral part of a number, disregarding the decimals, and then to write down, for the index of the log. of that number, the figure denoting what was counted, diminished by 1: to this index the proper decimal part of the log., called the *mantissa*, which is furnished by the table, is to be united, when the complete log. will be exhibited. Thus, for the numbers 43, 58, 32·47, 67·813, &c., the index, in each case, is 1; for each of the numbers 246, 835, 647·29, 158·72, &c., the index is 2; and so on.

If, however, the number proposed have no integral figures—that is, if it consist wholly of decimals—then the index of the log. will be *negative*. For instance, suppose the number is ·3247, we may write it thus $\frac{3{\cdot}247}{10}$; and, from the principles already explained, the log. of the quotient thus indicated is log. 3·247 — log. 10; that is, log. 3·247 — 1. Consequently, the index of the log. of ·3247 is the index of log. 3·247 diminished by 1: but as there is only one integer in the number 3·247, the index of its log. is 0; therefore the index of log. ·3247 is —1. Suppose the number is ·03247; this may be written $\frac{{\cdot}3247}{10}$: hence log. ·03247 = log. ·3247 — log. 10; that is, = log. ·3247 — 1: but the index of log. ·3247, as just shown, is —1; hence the index of log. ·03247 is —2. Similarly, the index of log. ·003247 is −3, that of log. ·0003247 is −4, and so on. Consequently, whatever be the number whose log. is required, we find the index of that log. thus:—

Count how many places the *leading figure* of the number is from the unit's place, and put down what is counted, for index: the figure thus put down will be *plus* if the counting is towards the right, and *minus* if towards the left; or the rule is expressed otherwise, thus:—"Place your pen between the first and second FIGURE (NOT CIPHER), and count *one* for each figure or cipher, until you come to the decimal point; the number this gives will be the index. If you count to the right the index is positive, if to the left it is negative." (See page 522).

The decimal part of the log. of a number is always found against that number in the table, which is to be referred to so soon as the index is written down. Because of this ready way of ascertaining what the index of the log. of a number is, it is not necessary to insert more than the mantissa, or decimal part of the log., in the table: but it is to be observed that this decimal part is always *plus*. For instance, having first written down the proper index, we find, on referring to the table, that

$$\text{log. } {\cdot}3247 = -1 + {\cdot}511482,\ \text{log. } {\cdot}03247 = -2 + {\cdot}511482,$$
$$\text{log. } {\cdot}003247 = -3 + {\cdot}511482,\ \&c.$$

But a more compact and convenient way of writing these logs. is this, namely:

$$\text{log. } {\cdot}3247 = \bar{1}{\cdot}511482,\ \text{log. } {\cdot}03247 = \bar{2}{\cdot}511482,\ \text{log.}$$
$${\cdot}003247 = 3{\cdot}511482,\ \&c.$$

And in this form the logarithms of numbers less than unity—that is, of numbers of which all the figures are decimals—are always used in practice.

The logarithmic operation for finding a product from its factors suggests that for finding any power of a known root, or any root of a known power: thus, since n^p merely denotes the product of p factors, each equal to the number n, we have log. $n^p = p$ log. n; and since if $n^{\frac{1}{p}} = r$, we must have $n = r^p$, it follows that log. $n = p$ log. r, and consequently that log. $r = \frac{\text{log. } n}{p}$. We thus derive the following practical rules for performing the more troublesome operations of arithmetic in a short and easy manner by help of a table of logarithms.

1. *Multiplication.*—From the table take the log. of each factor; add these logs. together: the *sum* will be the log. of the *product* of the factors; and against this log. in the tables, will be found the product sought.

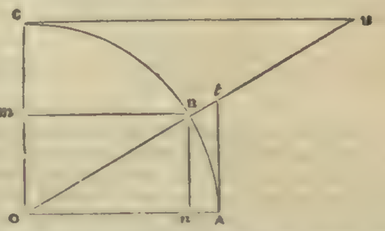
2. *Division.*—Subtract the log. of the divisor from the log. of the dividend: the remainder is the log. of the *quotient.*

3. *Powers, and Roots.*—Multiply the log. of the number to which the exponent is attached, by that exponent, whether it be integral or fractional: the result will be the log. of the power or root.

As to the means which algebraists have devised for constructing such a table as that here referred to, the student may consult the Chapter on Logarithms and Series in the Section on Mathematics: it has been thought sufficient, in this introductory article, to show the general principles on which tables of logs. are based, without entering into details as to their actual formation. These tables are given at page 525, *et seq.*

ON THE SINES, COSINES, TANGENTS, &c., OF ANGLES.—In the Section on Mathematics (p. 613) the trigonometrical terms, sine, cosine, tangent, &c., are defined in two different ways. For the purposes of navigation, the first of these ways will be found to be the more convenient, as well as the more intelligible to the learner. Taking the diagram at page 613, we may explain the lines there figured as follows (Fig. 1):—

Fig. 1.



Sine.—The sine of an angle A O B, or of the arc A B, which measures that angle, is the straight line B*n* drawn from the extremity B of the arc, at right angles to, and terminating in, the radius O A, drawn to the commencement of the arc.

Cosine.—And the cosine of the same angle is the portion O*n* of the radius between the centre O and the foot *n* of the sine.

Tangent.—The tangent of the same angle is the line A*t*, touching the measuring arc A B at its commencement A, and terminating in the prolonged radius drawn through the extremity B.

Secant.—And this prolonged radius, that is, the line O*t*, is the secant of the angle A O B.

As A is regarded as the origin or commencement of the arc which measures the angle A O B, so C is regarded as the commencement of the *complement* of that arc; that is, of the arc which, united to the former, makes up a quadrant or 90°. The sine, cosine, &c., of *this* arc (or of the angle which it measures) are the cosine, sine, &c., of the former, as is obvious; and the tangent and secant of the latter are called the cotangent and cosecant of the former; thus:—

Cotangent.—The cotangent of the angle A O B, or of the arc A B which measures it, is the line C*u*, drawn to touch the complement of that arc at C, and terminating in the secant O*t*, or in that secant prolonged.

Cosecant.—And O*u*, drawn from the centre through B, up to the cotangent, is the cosecant of the angle A O B, or of the arc A B.

The lines here defined refer to circular arcs and the angles which they measure. The sides O A, O B of the angle at O, are each equal to the radius of the circle here considered: if these sides or radii had been of any other length, no change would have taken place in the angle at O; neither would any change have taken place in the *number of degrees* contained in the measuring arc; but the actual length of that arc would have varied, being longer than A B in a circle of longer radius, and shorter than A B in a circle of shorter radius. On this account the sine, cosine, &c., of an *arc* are not lines of fixed lengths for a fixed number of degrees: a degree of one circle is double the length of a degree of another of only half the radius of the former. Now, in trigonometry, angles alone, independently of all connection with their measuring arcs, are almost exclusively the subjects of consideration; and it is therefore necessary that an invariable angle should have an invariable sine and cosine, &c. It is agreed, therefore, that the trigonometrical sine, cosine, &c., should be estimated according to the scale O A = 1: in other words, that the abstract number 1, being the numerical representative of the radius O A, the abstract numbers, which, conformably to this scale, are the numerical expressions for B*n*, O*n*, &c., should be called the *trigonometrical* sine, cosine, &c., of the angle A O B. The lines in the preceding diagram, considered *as* lines, are the *geometrical* sine, cosine, tangent, &c., of the arc A B, or of the angle A O B *to radius* O A; but viewed as merely linear representations of abstract numbers, O A denoting the abstract unit, they are the trigonometrical sine, cosine, tangent, &c., of the angle A O B.

It is thus that the terms sine, cosine, tangent, &c., as employed in trigonometry, are regarded as *ratios;* for from what has just been said,

$$\text{O A} : \text{B}n :: 1 : \frac{\text{B}n}{\text{OA}}, \text{ the trigonometrical sine of O.}$$

$$\text{O A} : \text{O}n :: 1 : \frac{\text{O}n}{\text{OA}}, \ldots\ldots\ldots \text{ cosine } \ldots$$

$$\text{O A} : \text{A}t :: 1 : \frac{\text{A}t}{\text{OA}}, \ldots\ldots\ldots \text{ tangent } \ldots$$

&c. &c.

And generally any geometrical sine, cosine, &c., divided by the radius of the arc with which such sine, cosine, &c., is connected, is the trigonometrical sine, cosine, &c., of the angle measured by that arc: but in trigonometry, the terms sine of an angle, cosine of an angle, &c.—without any prefix—are sufficiently explicit, because when geometrical lines are meant, the fact is always stated.

The learner will find it an assistance to keep the diagram at page 1037 before his mind in investigating the relations among the trigonometrical quantities now considered, regarding the lines defined above as merely the linear representatives of the abstract numbers, sine, cosine, &c., the radius being the representative of the abstract number 1; for he will have the aid of geometry to assist him in establishing the fundamental principles of trigonometry. Thus, from Euclid, Prop. 47, Book I., we know that

$$\text{B}n^2 + \text{O}n^2 = \text{O B}^2,\ \text{O A}^2 + \text{A}t^2 = \text{O}t^2,\ \text{O C}^2 + \text{C}u^2 = \text{O}u^2,$$

so that we have from the first of these,

$$\text{sin.}^2\text{O} + \text{cos.}^2\text{O} = 1 \quad \ldots \ (1)$$

from the second,
$$1 + \text{tan.}^2\text{O} = \text{sec.}^2\text{O} \quad \ldots \ (2)$$

and from the third,
$$1 + \text{cot.}^2\text{O} = \text{cosec.}^2\text{O} \quad \ldots \ (3)$$

Also from the property that the sides about the equal angles of equiangular triangles are proportional (Euc., Prop. 4, B. VI.), we find, upon comparing together the equiangular right-angled triangles B O*n*, *t*O A, as also the equiangular right-angled triangles B O*m*, *u*O C, that

$$\frac{\text{sin. O}}{\text{cos. O}} = \frac{\text{tan. O}}{1}, \text{ that is, tan. O} = \frac{\text{sin. O}}{\text{cos. O}} \quad \ldots \ (4)$$

$$\frac{\text{cos. O}}{\text{sin. O}} = \frac{\text{cot O}}{1}, \ \ldots\ldots \text{ cot. O} = \frac{\text{cos. O}}{\text{sin. O}} \quad \ldots \ (5)$$

$$\frac{\text{sin. O}}{1} = \frac{1}{\text{cosec. O}}, \ \ldots \text{ sin. O} = \frac{1}{\text{cosec. O}}; \quad \ldots \ (6)$$

$$\frac{\text{cos O}}{1} = \frac{1}{\text{sec. O}}, \ \ldots\ldots \text{ cos. O} = \frac{1}{\text{sec. O}} \quad \ldots \ (7)$$

These fundamental relations will suffice for our present purpose. We learn—

From (1), that sin. O $= \sqrt{(1 - \text{cos.}^2\text{O})}$; and cos. O $= \sqrt{(1 - \text{sin.}^2\text{O})}$.

From (2), that sec. O $= \sqrt{(1 + \text{tan.}^2\text{O})}$; and tan. O $= \sqrt{(\text{sec.}^2\text{O} - 1)}$.

From (3), that cosec. O $= \sqrt{(1 + \text{cot.}^2\text{O})}$; and cot. O $= \sqrt{(\text{cosec.}^2\text{O} - 1)}$.

From (4) (5), that tan. O $= \frac{1}{\text{cot. O}}$; and cot. O $= \frac{1}{\text{tan. O}}$.

And from (6) (7), that cosec. O $= \frac{1}{\text{sin. O}}$; and sec. O $= \frac{1}{\text{cos. O}}$.

For the more general theory of the trigonometrical ratios, the student is referred to the Chapters on Trigonometry.

ON THE TABLES OF SINES, COSINES, TANGENTS, &c.—The numerical values of the trigonometrical lines considered above are computed according to the scale radius = 1. and are arranged in tables called tables of *natural sines, cosines,* &c. As tangents, cotangents, secants, and cosecants, may be deduced with but little trouble from sines and cosines, as shown above, and as, moreover, the *natural* sines, cosines, &c., are seldom employed in navigation, the tables of these, which accompany books on that subject, usually give only the sines and cosines. But the tables which furnish the logarithms of these, being indispensable in most of the calculations performed by the mariner, are always given in a complete form, and contain the logarithmic sines, cosines, tangents. cotangents, and cosecants of all angles from 0° up to 90°. In the former tables the numerical values of the sine and cosine of every angle between 0° and 90° is less than 1, because the radius itself is only 1: the logarithms of all these sines and cosines would, therefore, have negative indices (p. 1037), which is an inconvenience in practice. To remedy this, the logarithmic tables are computed, not to the scale rad. = 1, but to the scale rad. = 10^{10}, which is so large as to preclude the possibility of any logarithm in the tables requiring a negative index: in these tables, the index, or integral part of the log., is always inserted before the decimal part; while in the logs. of numbers, as already stated, the index is omitted.*

Now, in investigating the rules and formulæ of trigonometry, the argument always proceeds on the supposition that the numerical value of the radius is 1; and consequently, in the practical application of those rules and formulæ, it must be borne in remembrance, when logs. are used, that the radius is taken 10^{10} times as great—that is, instead of the log. of a natural sine, cosine, &c., we employ in reality the log. of 10^{10} times that natural sine, cosine, &c. For instance, if we call any natural sine, cosine, &c., p, the logarithmic tables will give us, not log. p, but log. $10^{10}p$—that is, log. 10^{10} + log. p; or since log. 10^{10} is 10 log. $10 = 10 \times 1$, the tables will give us 10 + log. p, so that the log. of every natural sine, cosine, &c., is increased by 10. In order, therefore, that our practical results may agree with our theoretical formulæ, these superfluous 10's—introduced merely to avoid negative logs.—must be suppressed at the close of our operation. If, in our work, as many of these logarithmic trigonometrical quantities are used subtractively as are used additively, then, of course, as the superfluous 10's destroy one another, no correction of the final result becomes necessary; but if more of these logs. are additive than subtractive, as many 10's as mark the excess of additive over subtractive logs. must be suppressed in the result; and if the excess be in favour of the subtractive logs., so many 10's must be introduced. The suppression or the introduction of a 10, in any amount, is so easy a matter, that the trouble attending it is not worth consideration, in comparison with the advantages gained by the avoidance of logs. with negative indices.

What has now been said being understood, let us suppose that, by aid of the algebraic series and formulæ in our Section on Mathematical Science, the two sets of trigonometrical tables have been constructed—namely, tables of natural sines, cosines, &c., and tables of logarithmic sines, cosines, &c.; and let us endeavour to see a little into the use and advantages of what is thus supplied, in the calculations of plane triangles.

---

* For tables of logarithmic sines, cosines, &c., see p. 666, *et seq.*

And first as to the table of natural sines, cosines, &c. By referring to the diagram at p. 1037, we see that this table supplies, already computed for us, the numerical lengths of the sides of two similar right-angled triangles O B*n*, O*t*A, whatever be the angle O, from O = 0°, up to O = 90°. We may be quite sure, therefore, whatever be the magnitude or shape of any right-angled triangle met with in practice, that *two* triangles, *equiangular to it*, will always be found in the table; the sides of the one, O B*n*, being computed to the scale O B, the hypotenuse, = 1, and the sides of the other to the same scale, the base O A, = 1. The table thus furnishes us with the perpendicular and base of every possible right-angled triangle whose hypotenuse is 1, and also with the perpendicular and hypotenuse of every possible right-angled triangle whose base is 1.

Now the sides about the equal angles of equiangular triangles are proportional (Euc., Prop. 4, Book VI.), so that if *one* side only of a triangle be known, and *all* the sides of another, equiangular to it, be given, we can compute the unknown sides of the former by simple proportion. It follows, therefore, that if one side only, of any right-angled triangle, with which we may be engaged in practice, be measured, we shall be able to calculate each of the other sides, in this manner, provided only we know where to look for the triangle, equiangular to the proposed triangle, in the table.

As already observed, there are always *two* such equiangular triangles in every complete table of natural sines, cosines, &c., so that we have a choice as to which shall be compared with the triangle to be calculated; but we must, of course—take which ever we may—be careful to compare base with base, perpendicular with perpendicular, and hypotenuse with hypotenuse. The sides of the two triangles O B*n*, O*t*A, computed in the table, do not, however, go by these names: the base of the triangle O B*n* is called *cosine* of the angle O, the perpendicular is called *sine* of the angle O, and the hypotenuse is called *radius*, or 1. Also the base of the similar triangle O*t*A is *radius* or 1, the perpendicular is *tangent* of the angle O, and the hypotenuse is *secant* of the angle O: the angle O, expressed in degrees and minutes, is thus a sufficient guide to direct us to that part of the table where the equiangular triangle we are in search of is to be found.

It is always best to fix upon that one of the two tabular triangles in which the unit-length, or radius, corresponds to the given side of the triangle proposed for calculation. Thus, if the given side be the hypotenuse, we should compare our triangle with the tabular triangle O B*n*, because in this the hypotenuse is 1; we should then have to compare the perpendicular of the proposed triangle with B*n*, that is, with sin. O, and the base with O*n*, that is, with cos. O. For example, if the angle equivalent to O, and the hypotenuse were given to find the perpendicular and the base, then, referring to the necessary particulars, on the page of the table headed by the degrees and minutes in the given angle, we should be supplied with the first three terms of the proportion.

1 : sin. O : : given hyp. : required perp.,

Consequently the required perp. $= \dfrac{\text{hyp.} \times \text{sin. O}}{1}$ = hyp. × sin. O.

Also, 1 : cos. O : : given hyp. : required base,

Consequently the required base $= \dfrac{\text{hyp.} \times \text{cos. O}}{1}$ = hyp. × cos. O.

As the first term of each proportion is 1, all division is thus avoided; and the operation reduced merely to the multiplication together of two factors.

On the other hand, if the base were given to find the perpendicular and hypotenuse, the other tabular triangle, O*t*A, would be the better to compare with the proposed one, because the radius or unit-line here is O A, the *base*, corresponding to the side given, and the proportions would be 1 : tan. O : : given base : required perp.,

and 1 : sec. O : : given base : required hyp.,

∴ required perp. = base × tan. O, and required hyp. = base × sec. O.

As to the tables of logarithmic sines, cosines, &c., little need be said in addition to what has already been stated; they furnish the logarithms of the tabular numbers in the table of natural sines, cosines, &c., with the addition of 10 to each logarithm, as before explained. By using the logarithmic tables, we convert the multiplication of the two factors adverted to above, into the addition of the corresponding logarithms. Sufficient practical details of these operations will be given in the next article.

It may be noticed here, however, that in what is said above, as to the assistance afforded by trigonometrical tables, our observations have had exclusive reference to *right-angled* triangles; we shall shortly see that they are equally available for oblique-angled triangles; but, it will strike the learner as a remarkable fact, that, notwithstanding the complicated character of the curve, traced on the surface of the globe by the course of a ship, all the calculations in reference to the different sailings, involve only *right-angled triangles*—the simplest kind of triangles with which trigonometry has to deal; we shall, therefore, give a distinct article on the calculation of the sides and angles of right-angled triangles.

TO CALCULATE THE SIDES AND ANGLES OF RIGHT-ANGLED TRIANGLES.—The sides and angles of any triangle make up what are called the six *parts* of the triangle; and if any three of these six parts, provided they are not the three angles, be given, the remaining three can be found by calculation. In a *right-angled* triangle, one of the six parts is always known—namely, the right angle; so that a side and one of the acute angles, or two sides, being measured, we can always calculate the remaining parts.

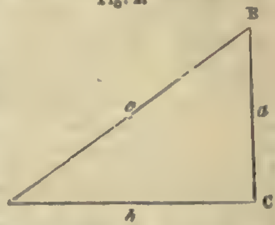
The reason that the three angles alone will not suffice for the determination of the other three parts—the three sides—is obvious from the simplest principles of geometry; for all *equiangular* triangles are alike, as respects the equality of the angles; so that, from the angles alone, we could not conclude to which one, out of an infinite variety of similar triangles, the proposed angles are considered to belong, for they belong, in reality, equally to all.

In a right-angled triangle the given parts must therefore be either :—

1. A side and one of the acute angles, or,
2. Two of the sides, to find the remaining parts.

I. *When the Hypotenuse and one of the Acute Angles are given.*

Fig. 2.



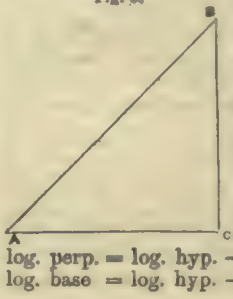
Let the hypotenuse A B (Fig. 2), and the angle A be given; then turning to the diagram at page 1037, we should compare the given side A B, with the radius O B, as directed above; so that O B *n* would be the tabular triangle equiangular to the triangle A B C. And, therefore, if *c* denote the numerical length of A B, since the numerical length of O B is 1, A B = O B × *c*; consequently, *a* and *b* being the numerical lengths of B C, and A C, we have, since the like sides are proportional,

B C = B *n* × *c*, and A C = O *n* × *c*, that is,

a = *c* sin. A, and *b* = *c* cos. A.

Hence the following rule :—

Fig. 3.



RULE.—Multiply the given hypotenuse by the sine of the angle at the base; the product is the perpendicular. Multiply the given hypotenuse by the cosine of the angle at the base: the product is the base.

Or work by the following formula,

perp. = hyp. × sin., ang. at base; base = hyp. × cos., ang. at base,

which by logarithms will be,

log. perp. = log. hyp. + log. sin., ang. at base − 10;
log. base = log. hyp. + log. cos., ang. at base − 10.

Example 1.—In the right-angled triangle A B C (Fig. 3), are given A B = 480 feet, and the angle A = 53° 5′; required the perpendicular B C, and the base A C.

1. *To find the perpendicular* B C.

Without logarithms.

B C = A B sin. A.

Sin. A, 53° 5′, = ·7995

A B = 480

639600

31980

∴ B C = 383·7600

With logarithms.

Log. B C = log. A B + log. sin. A − 10.

−10

Log. A B = log. 480 = 2·6812

Log. sin. A, 53° 5′, = 9·9028

Log. B C log. = 383·8 = 2·5840

Hence B C is 383·8 feet.

2. *To find the base* A C.

Without logarithms.

A C = A B cos. A.

Cos. A, 53° 5′, = ·6006

A B = 480

480480

24024

∴ A C = 288·2880

With logarithms.

Log. A C = log. A B + log. cos. A − 10.

−10

Log. A B = log. 480 = 2·6812

Log. cos. A, 53° 5′, = 9·7786

Log. A C = log. 288 3 = 2·4598

Hence A C is 288·3 feet.

In solving the preceding example we have taken only *four* places of decimals from the tables; this is a number quite sufficient for all the ordinary purposes of navigation, and it will be remembered that the present introductory article is only preparatory to the discussion of that subject.

If, instead of the angle A at the base, the angle B at the vertex had been given, the operation would have been much the same as that above; for, since A = 90° — B, sin. A = cos. B; and cos. A = sin. B, because the sine and cosine of an angle are respectively the same as the cosine and sine of the *complement* of that angle; so that where we have used above sin. A, we should have used its equal cos. B; and where we have used cos. A we should have substituted its equal sin. B. This must be observed in solving the last three of the following examples.

2. In the triangle A B C (last figure) are given A B = 291, angle A = 47° 55′, to find A C, B C.
Ans. A C = 195, B C = 216.

3. Given A B = 480, angle A = 53° 8′, to find A C, B C.
Ans. A C = 288, B C = 384.

4. Given A B = 521, angle B = 36° 6′, to find A C, B C.
Ans. A C = 307, B C = 421.

5. Given A B = 645, angle B = 50° 50′ to find A C, B C.
Ans. A C = 500, B C = 407·4.

6. Given A B = 98, angle B = 33° 12′, to find A C, B C.
Ans. A C = 53·66, B C = 82.01.

II.—*When the base or perpendicular, and one of the acute angles are given.*

Let the base A C, and the angle A be given; then, referring to the diagram at p. 1037, Fig. 1, we are to compare the given side A C with the radius, or unit-line, O A; so that O*t*A is the tabular triangle now to be referred to. As A C is *b* times O A, therefore, because the proposed and tabular triangles are equiangular, B C must be *b* times A*t*, and A B *b* times O*t*; that is,

$$a = b \text{ tan. A, and } c = b \text{ sec. A.}$$

Hence the following rule:—

RULE.—Multiply the given base by the tangent of the angle at the base: the product will be the perpendicular. Multiply the given base by the secant of the angle at the base: the product will be the hypotenuse.

In a right-angled triangle either of the two perpendicular sides may be regarded as the base, and the other as the perpendicular; so that two distinct rules would be unnecessary. And as in the former case, when the vertical angle B is given instead of the base angle A, the former may take the place of the latter in the operation, provided only that we write cotan. for tan., and cosec. for sec.

But, as already observed at page 1038, the tables of *natural* sines and cosines, which accompany books on navigation, do not, in general, furnish the natural tangents and secants; so that, if this table be employed in the work, we must make use of the relations established at page 1038, namely,

$$\text{tan. A} = \frac{\text{sin. A}}{\text{cos. A}},\ \text{sec. A} = \frac{1}{\text{cos. A}};\ \text{cotan. B} = \frac{\text{cos. B}}{\text{sin. B}},$$

$$\text{cosec. B} = \frac{1}{\text{sin. B}}.$$

The working formulæ for the present case are as follows:—

perp. = base × tan. ang. at base; hyp. = base × sec. ang. at base.

Or, by logarithms,

log. perp. = log. base + log. tan. ang. at base — 10;

log. hyp. = log. base + log. sec. ang. at base — 10.

The first of these formulæ, if the table referred to be limited to natural sines and cosines only, must be replaced by

$$\text{perp.} = \frac{\text{base} \times \text{sin. ang. at base}}{\text{cos. ang. at base}};\ \text{hyp.} = \frac{\text{base}}{\text{cos. ang. at base}},$$

agreeably to the relations given above.

EXAMPLES.

1. In the right-angled triangle A B C, Fig. 3, are given the base A C = 327, and the angle A = 54° 17′: required the perpendicular B C, and the hypotenuse A B.

1. *To find the perpendicular* B C.

Without logarithms.

$$\text{B C} = \frac{\text{A C sin. A}}{\text{cos. A}}$$

sin. A 54° 17′, = ·8119

A C = 327

56833 (See the remarks at page 1042.)

16238

24357

cos. 54° 17′ = ·5838)265·4913(454·8 = B C.

With logarithms.

log. B C = log. A C + log. tan. A — 10.

— 10

A C = 327 . . . . . . 2·5145

tan. A, 54° 17′ . . . . . 10·1433

log. B C, 454·8 . . . . . 2·6578

Hence B C = 454·8

2. *To find the hypotenuse* A B.

$$\text{A B} = \frac{\text{A C}}{\text{cos. A}}$$

·58,3,8) 327 (560 = A B

2919

351

350

1

$$\text{log. A B} = \text{log. A C} + \text{log. sec. A} - 10.$$

$$\begin{array}{lr}
 & -10 \\
\text{A C} = 327 \;\ldots\ldots & 2.5145 \\
\text{sec. A, } 54^\circ\, 17' \;\ldots\ldots & 10{\cdot}2338 \\
\hline
\text{A B, } 560 \;\ldots\ldots & 2{\cdot}7483 \\
\hline
\end{array}$$

The logarithmic operation might have been performed as readily by using the formula for A B, as before, which gives

$$\text{log. A B} = \text{log. A C} - \text{log. cos. A} + 10.$$

The work by this formula will be as follows :—

$$\begin{array}{lr}
 & 10 \\
\text{A C} = 327 \;\ldots\ldots & 2\,5145 \\
\text{cos. A, } 54^\circ\, 17' \;\ldots\ldots & -9{\cdot}7662 \\
\hline
\text{A B} = 560 \;\ldots\ldots & 2{\cdot}7483 \\
\hline
\end{array}$$

2. In the triangle A B C (Fig. 3), are given A C = 195, and the angle A = 47° 55′, to find B C and A B.
Ans. B C = 216, A B = 291.

3. Given A C = 288, and the angle A = 53° 8′, to find B C and A B. Ans. B C = 384, A B = 480.

4. Given A C = 421, and the angle A = 36° 6′, to find B C and A B. Ans. B C = 307, A B = 521.

5. Given A C = 625, and the angle B = 41° 15′, to find B C and A B. Ans. B C = 713, A B = 948.

6. Given the base of a right-angled triangle 346½, and the opposite angle 54° 36′ : required the perpendicular and hypotenuse. Ans. Perp. 246·2, Hyp. 425·1.

III. *When the hypotenuse and one of the other sides are given.*

Let the hypotenuse A B (Fig. 3), and the perpendicular B C be given ; then comparing A B with the radius or unit line O B in the diagram at page 1037 (Fig. 1), the tabular triangle O B*n* will be that to which the proposed triangle is to be compared : and since A B is *c* times O B, therefore B C is *c* times B*n* ; that is to say,

$$a = \text{B C} = c \text{ sin. A, therefore sin. A} = \frac{a}{c}.$$

If the base were given instead of the perpendicular, then we should have

$$b = \text{A C} = c \text{ cos. A, therefore cos. A} = \frac{b}{c}.$$

The rule is therefore as follows :—

RULE.—Divide the perpendicular by the hypotenuse : the quotient will be the sine of the angle at the base. Divide the base by the hypotenuse : the quotient will be the cosine of the angle at the base.

An angle being thus determined, the remaining side of the triangle may be found by either of the preceding rules. Or, without first finding an angle, the third side of any right-angled triangle may be determined from the other two, by the 47th of Book I. of *Euclid ;* for since $c^2 = a^2 + b^2$; $\therefore a^2 = c^2 - b^2$, and $b^2 = c^2 - a^2$; the working formulæ for finding the angles, when the hypotenuse and a side are given, are

$$\text{sin. ang. at base} = \frac{\text{perp.}}{\text{hyp.}} : \text{cos. ang. at base} = \frac{\text{base}}{\text{hyp.}}.$$

Or, by logarithms,

log. sin. ang. at base = log. perp. − log. hyp. + 10 ;
log. cos. ang. at base = log. base − log. hyp. + 10.

EXAMPLES.

1. In the right-angled triangle A B C (Fig. 3), are given the hypotenuse A B = 480, and the perpendicular B C = 384, to find the angles A, B, and the base A C.

1. *To find the angles* A, B.

Without logarithms.

$$\text{sin. A} = \frac{\text{BC}}{\text{AB}}.$$

$$\begin{array}{l}
480)384({\cdot}8 = \text{sin. } 53^\circ\, 8' \\
384 \\
\hline
\end{array}$$

With logarithms.

$$\text{log. sin. A} = \text{log. B C} - \text{log. A B} + 10$$

$$\begin{array}{lr}
 & 10 \\
\text{B C, } 384 \;\ldots\ldots & 2{\cdot}5843 \\
\text{A B, } 480 \;\ldots\ldots & -2{\cdot}6812 \\
\hline
\text{sin. A, } 53^\circ\, 8' \;\ldots & 9{\cdot}9031 \\
\hline
\end{array}$$

Consequently A = 53° 8′, ∴ B = 90° − 53° 8′ = 36° 52′.

2. *To find the base* A C.

A C = A B cos. A
cos. A, 53° 8′, = ·6
∴ 480 × ·6 = 288 = A C

A C is thus determined with very little troublo.

$$\text{log. A C} = \text{log. A B} + \text{log. cos. A} - 10$$

$$\begin{array}{lr}
 & -10 \\
\text{A B, } 480 \;\ldots\ldots & 2{\cdot}6812 \\
\text{cos. A, } 53^\circ\, 8' \;\ldots\ldots & 9{\cdot}7781 \\
\hline
\text{A C, } 288 \;\ldots\ldots & 2{\cdot}4593 \\
\hline
\end{array}$$

To find the base without the aid of the angle, we have $\text{A C}^2 = \text{A B}^2 - \text{B C}^2 = (\text{A B} + \text{B C})(\text{A B} - \text{B C}) = 864 \times 96 = 82944$

$$\begin{array}{lr}
\dot{8}2\dot{9}4\dot{4}\,(288 \text{ ; or by logs., log. } 864 = & 2{\cdot}9365 \\
4 \quad \ldots\ldots \quad \text{log. } 96 = & 1{\cdot}9823 \\
\hline
48)429 & 2)4{\cdot}9188 \\
384 & \\
\hline
568)4544 & \text{log. } 288 = 2{\cdot}4594 \\
4544 & \\
\hline
\end{array}$$

Consequently A C = 288. The sum of the two logs. on the right is divided by 2, because the half of the log. of a number is the log. of the square root of that number.

2. Given the hypotenuse A B = 237, and the perpendicular B C = 197, to find the angles and the base.
Ans. A = 56° 13′, B = 33° 47′, Base = 132.

3. Given the hypotenuse A B = 645, and the perpendicular B C = 407·4 to find the angles and the base.
Ans. A = 39° 10′, B = 50° 50′, Base = 500.

3. Given the hypotenuse A B = 400, and the base A C = 236, to find the angles and the perpendicular.
Ans. A = 53° 51′, B = 36° 9′, Perp. = 323.

4. Given the hypotenuse A B = 54·68, and the base A C = 35·5, to find the angles and the perpendicular.
Ans. = 49° 31′, B = 40° 29′, Perp. = 41·6.

5. Given the hypotenuse of a right-angled triangle = 779·8, and the perpendicular = 725, to find the vertical angle and the base. Ans. 21° 36′, and 287.1.

6. Given the hypotenuse = 780·6, and the base = 607·6, to find the angle at the base, and the perpendicular. Ans. 38° 53′, and 490.

IV. *When the base and perpendicular are given.*

The base A C = *b*, and the perpendicular B C = *a* being given, we are to compare the triangle with the tabular triangle O A*t*, of which the base O A = 1 : we thus have B C = *b* times A*t*, that is

$$a = b \text{ tan. A } \therefore \text{tan. A} = \frac{a}{b}.$$

Consequently the rule for finding the angle A at the base is as follows :—

RULE.—Divide the perpendicular by the base : the quotient will be the tangent of the angle at the base. Or, divide the base by the perpendicular : the quotient will be the tangent of the angle at the vertex. The hypotenuse may be found without first finding the angles by *Euclid*, 47th of Book I. : thus $c^2 = a^2 + b^2$. The formulæ for finding either angle is therefore

$$\text{tan. ang. at base} = \frac{\text{perp.}}{\text{base}} \text{ ; tan. ang. at vertex} = \frac{\text{base}}{\text{perp.}}$$

Or, by logarithms,

log. tan. ang. at base = log. perp. — log. base + 10;
log. tan. ang. at vertex = log. base — log. perp. + 10.

EXAMPLES.

1. In the right-angled triangle A B C (Fig. 3), page 1039, are given the base A C = 288, and the perpendicular B C = 384, to find the angles and the hypotenuse.

1. *To find the angles* A, B.

Without logarithms.

$$\text{tan. A} = \frac{\text{BC}}{\text{AC}}$$

$$\begin{array}{l} 288)384(1{\cdot}3333\ \ldots = \text{tan. A, } 53^\circ\,8'. \\ 288 \\ \hline 96 \\ 864 \\ \hline 96 \end{array}$$

With logarithms.

$$\text{log. tan. A} = \text{log. B C} - \text{log. A C} + 10.$$

$$\begin{array}{lr} & 10 \\ \text{B C, } 384\ \ldots\ldots\ldots & 2{\cdot}5843 \\ \text{A C, } 288\ \ldots\ldots\ldots & -\ 2{\cdot}4594 \\ \hline \text{tan. A, } 53^\circ\,8'\ \ldots\ldots & 10{\cdot}1249 \end{array}$$

$\therefore$ A = 53° 8′, and B = 90° − A = 36° 52′.

2. *To find the hypotenuse* A B.

$$\text{A B} = \sqrt{(\text{A C}^2 + \text{B C}^2)}$$

$$\begin{array}{rl} 288^2 = & 82944 \\ 384^2 = & 147456 \\ \hline & 230400(480 = \text{A B} \\ & 16 \\ \hline 88) & 704 \\ & 704 \\ \hline & 00 \end{array}$$

$$\text{A B} = \text{A C sec. A}.$$

$$\therefore \text{log. A B} = \text{log. A C} + \text{log. sec. A} - 10.$$

$$\begin{array}{lr} & -10 \\ \text{A C, } 288\ \ldots\ldots\ldots & 2{\cdot}4594 \\ \text{sec. A, } 53^\circ\,8'\ \ldots\ldots & 10{\cdot}2219 \\ \hline \text{A B, } 480\ \ldots\ldots\ldots & 2{\cdot}6813 \end{array}$$

In the foregoing example, a table of natural tangents and secants is necessary to enable us to find the required parts without logarithms, and in the shortest manner; tan. A being determined as above, and then A B from the formula A C sec. A.

In all works on Navigation, as also in most books on Trigonometry, the calculation of the several cases of right-angled triangles is performed exclusively by logarithms. The learner will perceive, from the illustrations furnished above, that, in general, the work is more expeditious without logarithms than with them; and that it would be of advantage to the practical navigator if tables more comprehensive than those generally given—that is, tables including the natural tangents and secants—were bound up with books on navigation. As the preceding examples show, a single reference to such a table suffices for the discovery of the unknown part; whereas *three* references to the logarithmic tables are necessary. In the latter mode of working, fewer figures may appear on the paper, but the time occupied in two searchings in the table, out of three, is saved; and, in operations of this kind, referring to tables, and transcribing the figures, constitute the principal part of the trouble.

The greatest amount of arithmetical work involved in any of the preceding solutions occurs in the example at p. 1040; but the multiplication and division operations there indicated, according to the common beaten track, may be pruned of many superfluous figures by using the *contracted* methods: thus to multiply ·8119 by 327, in the shortest way, without sacrificing accuracy in the result, write the figures of the multiplier in reverse order thus, 723; and multiply as in the margin, rejecting from the multiplicand a figure at every step, after the first, but attending to the *carryings* from the rejected figures. And similarly for contracted division, as exemplified at the page referred to, and again here in the margin. It will be observed, however, that the whole of the division part of this work would have been saved if tan. 54° 17′ had been supplied by the tables: the entire work would then have stood as here annexed.

$$\begin{array}{rr} \text{sin. } 54^\circ\,17' = & {\cdot}8119 \\ & {\cdot}723 \\ \hline & 24357 \\ & 1624 \\ & 568 \\ \hline \text{cos. } 54^\circ\,17' = {\cdot}5838) & 265{\cdot}49(454{\cdot}8 \\ & 23352 \\ \hline & 3197 \\ & 2919 \\ \hline & 278 \\ & 233 \\ \hline & 45 \\ & 46 \end{array}$$

A person but moderately expert in the simple operations of arithmetic could execute the work in the margin in less time than it would take to refer to the logarithmic tables, and to transcribe therefrom a single number. And then the numerical process, being placed permanently before the eye, is very easily revised if error be suspected. These obvious advantages are of sufficient importance to justify the entire abandonment of logarithms in those calculations of Navigation—and they include nearly all—in which right-angled triangles only are concerned. When oblique-angled triangles are the subjects of computation, the case is different; as the logarithmic operation has then, with few exceptions, the advantage over that with the natural numbers, as will be sufficiently seen in the next article.

$$\begin{array}{rr} \text{tan. } 54^\circ\,17' = & 1{\cdot}3908 \\ & 723 \\ \hline & 41724 \\ & 2782 \\ & 974 \\ \hline \text{B C} = & 451{\cdot}80 \\ \hline \end{array}$$

2. In the right-angled triangle A B C (Fig. 3), are given the base A C = 101·9, and the perpendicular B C = 195·4, to find the angles and the hypotenuse.
   Ans. A = 62° 27′, B = 27° 33′, A B = 220·3.

3. Given the base A C = 659·8, and the perpendicular B C = 520·5, to find the other parts.
   Ans. A = 38° 16′, B = 51° 44′, A B = 840·4.

4. Given the base A C = 35·5, and the perpendicular B C = 41·6, to find the other parts.
   Ans. A = 49° 31′, B = 40° 29′, A B = 54·68.

5. Given the base A C = 32·76, and the perpendicular B C = 46·58, to find the vertical angle B.
   Ans. B = 35° 7′.

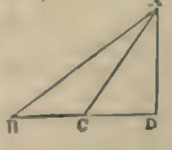
6. Given the base A C = 53·66, and the perpendicular B C = 82·01, to find the angles and the hypotenuse.
   Ans. A = 56° 48′, B = 33° 12′, A C = 98.

Miscellaneous Examples in the Calculation of Right-angled Triangles.

1. The angle of elevation A C D (Fig. 4), of the top A, of a tower, was found to be 55° 54′; and from the station B, 100 feet from C in the same straight line D B, the angle of elevation A B D was found to be 33° 20′: what was the height of the tower?

Solution without Logarithms.

Fig. 4.



By right-angled triangles,

D C = A D tan. C A D, D B = A D tan. B A D,

$\therefore$ D B — D C = B C = A D (tan. B A D — tan. C A D).

But B A D = 90° — 33° 20′ = 56° 40′, and C A D = 90° − 55° 54′ = 34° 6′,

$\therefore$ B C = 100 = A D (tan. 56° 40′ — tan. 34° 6′).

By referring to a table of natural tangents, we find

Tan. 56° 40′ = 1·5204
Tan. 34° 6′ = ·6771

The difference = 8,4,3,3) 100 (118·6 = A D.
8433
1567
843
724
675
49
51

The division here is by the contracted method, recommended before.

Hence the height of the tower is 118·6 feet, very nearly; it is accurately between 118·5 feet and 118·6 feet: but nearer the latter than the former.

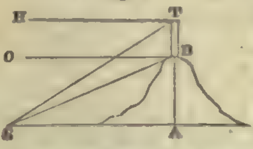
To solve such examples as this by logarithms, as is done in the books, the computation of an oblique-angled triangle—namely, of the triangle A B C—is necessary; and there will be five references to the logarithmic tables. In the above operation two references to a table suffice; and the subsequent arithmetical work, whatever number the dividend in the division may be, will always be trifling, if the contracted method of dividing be employed.

2. From the top of a castle (Fig. 5), 60 feet high, standing upon a hill near the sea-shore, the angle of depression H T S of a ship at anchor was observed to be 4° 52′; and the angle of depression O B S, taken from the bottom of the castle, was found to be 4° 2′. What was the distance A S of the ship?

Solution without Logarithms.

Since T H (Fig. 5) is parallel to A S, the angle A S T is equal to the angle H T S (Euc. 29, I.) For a like reason the angle A S B is equal to the angle O B S. Consequently, the angles of elevation A S T, A S B are known—namely, A S T = 4° 52′, and A S B = 4° 2′.

Fig. 5.



By right-angled triangles,

A T = S A tan. A S T, A B = S A tan. A S B,
∴ A T − A B = 60 = S A (tan. A S T − tan. A S B).

By the table of natural tangents, we find

Tan. A S T = tan. 4° 52′ = ·0851
Tan. A S B = tan. 4° 2′ = ·0705

The difference = ·01,4,6)60 (4100 = S A,
584
16
15
1

Consequently, the horizontal distance of the ship is 4100 feet, or 1367 yards, very nearly. By multiplying S A by tan. A S B, we shall get the height of the hill—namely,

·0705 × 4100 = 289 = A B.

3. The angle of elevation of the top of a tower was found to be 46° 30′, the place of observation from the bottom being 220 feet distant in a horizontal line: required the height of the tower. Ans. 232 feet.

4. At a horizontal distance of 45 yards from the bottom of a steeple, the angle of elevation of the top was found to be 48° 12′; the height of the observer's eye was 5 feet: required the height of the steeple. Ans. 52 yards.

5. In order to find the height of a castle surrounded by a moat, the angle of elevation of its top was taken from a convenient station, and found to be 46° 10′; then at a station 110 yards further off, but in the same horizontal line as the former station and the bottom of the castle, the angle of elevation was again taken, and found to be 29° 56′: required the height of the castle. Ans. 141·6 yards.

6. The height of an inaccessible object being required, the angle of elevation was taken at some distance from it, and found to be 51° 30′; and then a further distance of 75 feet being measured in the same horizontal line, the angle of elevation was again taken, and found to be 26° 30′. What was the height of the object, and at what horizontal distance was it from the first place of observation? Ans. Height, 61·97 feet; distance, 49·29 feet.

7. From the top of a ship's mast, 80 feet above the water, the angle of depression of another ship's hull was taken, and found to be 20°. What was the distance between the ships? Ans. 220 feet.

8. From the top of a lighthouse, 85 feet high, reckoning from the summit of the rock on which it stands, the angle of depression of a ship at anchor was found to be 3° 38′, and the angle at the bottom of the lighthouse, or top of the rock, was found to be 2° 43′: required the horizontal distance of the ship and the height of the rock above the level of the sea.

Ans. Distance, 5296 feet; height of rock, 251 feet.

9. From the edge of a ditch, 36 feet wide, surrounding a fort, the angle of elevation of the top of the wall was found to be 62° 40′: required the height of the wall, and the length of a scaling-ladder to reach from the edge of the ditch to the top.

Ans. Wall, 69·6 feet; ladder, 78·4 feet.

10. In the year 1784, two observers on Blackheath, at the distance of exactly a mile one behind the other, observed the angle of elevation of Lunardi's balloon, at the same instant of time; these angles were 36° 52′ and 30° 58′ respectively: required the perpendicular height of the balloon. Ans. 3 miles.

To Calculate the Sides and Angles of Oblique-angled Triangles.—In an oblique triangle the given parts must be either

1. Two angles and a side;
2. Two sides and an angle; or
3. The three sides, to find the remaining three parts.

I. *When the given parts are either two angles and an opposite side, or two sides and an opposite angle.*

Investigation of the Rule.

Let the triangle be A B C, and let it be either acute-angled or obtuse-angled, as in Figs. 6 and 7; and let the perpendicular A D be drawn, meeting the base or the base produced in D.

Fig. 6.

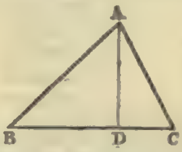


Fig. 7.

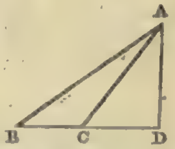


As in the former investigations, let the sides of the triangle, or rather their numerical measures, be represented by a, b, c, these letters applying to the sides opposite to the angles A, B, C, respectively. Each triangle presents now two right-angled triangles—namely, the triangles A B D, A C D; and from each we get a distinct expression for the perpendicular A D common to both; namely,

$$AD = AB \sin. B, \text{ and } AD = AC \sin. C;$$

so that A B sin. B = A C sin. C, that is,

$$c \sin. B = b \sin. C, \therefore \frac{c}{b} = \frac{\sin. C}{\sin. B}$$

which shows that *any one side of a triangle is to any other, as the sine of the angle opposite to the former, is to the sine of the angle opposite to the latter.* The angle C, in the preceding equations, belongs to the right-angled triangle A C D, which, in the second diagram, is not the angle C of the proposed triangle A B C, but the supplement of that angle; yet, as the sine of an angle is the same as the sine of its supplement, we may regard the C, in sin. C above, as the angle of the proposed triangle in each diagram.

The property enounced in italics above, supplies the following rule, when of the three given parts two are opposite to one another :—

RULE.—*To find an angle.* As one of the given sides is to the other, so is the sine of the angle opposite to the former, to the sine of the angle opposite to the latter.

To find a side. The sines of the given angles are to each other as the sides opposite to those angles.

If a, b, be any two sides, and A, B, their opposite angles,

$$\therefore a : b :: \text{sin. A} : \text{sin. B} = \frac{b \text{ sin. A}}{a},$$

$$\text{Or, sin. A} : \text{sin. B} :: a : b = \frac{a \text{ sin. B}}{\text{sin. A}},$$

$$\therefore \text{log. sin. B} = \text{log. } b + \text{log. sin. A} - \text{log. } a\text{; log. } b = \text{log. } a + \text{log. sin. B} - \text{log. sin. A.}$$

When an *angle* is to be determined by this rule, there is sometimes a choice of *two* angles ; and the case is then called the *ambiguous case.* The ambiguity arises from the circumstance that the sought angle is to be inferred from its *sine ;* and in the absence of all overruling restrictions, *two* angles have each equal claim to the *same sine :* an angle and its supplement. But if it happen that one of the given sides which is opposite to the given angle, is *greater* than the other given side, the angle opposite to the latter must be *acute*, otherwise the triangle would have two obtuse angles, which is impossible. Also, if either of two angles are known to be obtuse, the others must, of course, each be acute. Except under these conditions, the angle sought, may be either acute or obtuse ; so that there are two distinct triangles determinable from the proposed given parts, these parts belonging equally to both triangles.

EXAMPLES.

1. In a triangle two of whose sides are a = 95·12, and b = 98, and of which the angle A opposite to the former is 32° 15′, it is required to find the angle B opposite to the latter, as also the third side c.

To find the angle B.

As a = 95·12	−1·9783
: b = 98	1·9912
: : sin. A, 32° 15′	9·7272
: sin. B, 33° 21′	9·7401

To find the side c.

As sin. A, 32° 15′	−9·7272
: sin. C, 114° 24′	9·9594
: : a = 95·12	1·9783
: c = 162·3	2·2105

This example comes under the ambiguous case noticed above, for the side b, opposite to the sought angle, being greater than the side a, opposite the given angle, the angle B may be either 33° 21′ or its supplement 146° 39′, as the sine determined above belongs equally to both ; and each of these angles is greater than 32° 15′. The side c is calculated here for the acute angle B = 33° 21′, for which C = 180° − (32° 15′ + 33° 21′) = 114° 24′. If it be calculated for the obtuse angle B = 146° 39′, then C will be C = 180° − (32° 15′ + 146° 39′) = 1° 6′.

It will be seen that there is an inconvenience in having a *subtractive* logarithm in each of the columns ; it may be replaced by an additive quantity as follows :—Instead of writing down 1·9783 from the table, write down what this number wants of 10, which is 8·0217 ; but instead of subtracting from 10, to get this remainder, in the ordinary way, commence with the leading figure 1 on the left, and proceed from figure to figure towards the right, subtracting each from 9, till the last, 3, is reached, which subtract from 10 : this is of course the same, in effect, as subtracting the 3 from 10, in the common way, and carrying 1 from every figure in proceeding from right to left ; but it is easier to write down the remainder by the former way than by the latter : thus, pointing to the 1 in the number 1·9783, we write down 8 ; to the 9 we write down 0 ; to the 7 we write down 2 ; to the 8 we write down 1 ; and, lastly, to the 3 we write down 7. The remainder thus written in place of the tabular logarithm, is called the *arithmetical complement* of that logarithm. The arithmetical complement should always be written instead of a subtractive log., and *added ;* and the error of 10, thus committed, is to be corrected by suppressing 10 in the result of the addition.

The foregoing work should, therefore, be modified thus :—

To find the angle B.

As a = 95·12, Arith. Comp.	8·0217
: b = 98	1·9912
: : sin. A, 32° 15′	9·7272
: sin B, 33° 21′	9·7401

To find the side c.

As sin. A, 32° 15′, Arith. Comp.	·2728
: sin. C, 114° 24′	9·9594
: : a = 95·12	1·9783
: c = 162·3	2·2105

2. Given A = 48° 3′, B = 40° 14′, and c = 376, to find a and b.

C = 180° − (48° 3′ + 40° 14′) = 91° 43′.

To find a.

As sin. C, 91° 43′, Arith. Comp.	·0002
: sin. A, 48° 3′	9·8714
: : c = 376	2·5752
: a = 279·8	2·4468

To find b.

As sin. C, 91° 43′, Arith. Comp.	·0002
: sin. B, 40° 14′	9·8102
: : c = 376	2·5752
: b = 243	2·3856

3. Given a = 355, c = 336, and A = 49° 26′, to find b and C.

Ans. b = 465·3, C = 45° 58′.

4. Given a = 310, B = 62° 9′, and C = 41° 13′.

b = 281·7, c = 210, A = 76° 38′.

5. Given a = 70, b = 104, and B = 44° 12′.

A = 27° 59′, C = 107° 49′, c = 142.

6. Given b = 104, c = 142, and B = 44° 12′.

There are *two* triangles having these parts in each; the remaining parts being as here annexed.

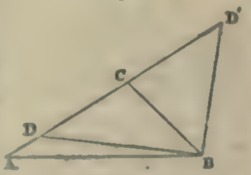
C = 72° 11′ or 107° 49′.
A = 63° 37′ or 27° 59′.
a = 134·8 or 70°.

II. *When the given parts are two sides and the included angle.*

Investigation of the Rule.

Let the two sides A C, B C (Fig. 8), and their included angle A C B, be given, to find the remaining angles A, B, of the triangle A B C.

Fig. 8.



From the greater C A, of the two given sides, cut off a part C D, equal to the less C B ; and also prolong A C, till C D′ = C B : then C B = C D = C D′, and consequently, with centre C, and radius C B, a circle may be circumscribed about D B D′, so that the angle D B D′ is a right angle (Euc. 31 of III.), and therefore C D B is the complement of D′.

Now C D B = A + A B D : add C B D = C D B to each ;

$$\left.\begin{array}{c} \text{then } 2\text{ C D B} = \text{B} + \text{A}, \therefore \text{C D B} = \tfrac{1}{2}(\text{B} + \text{A}), \\ \therefore \text{sin. A D B} = \text{sin. } \tfrac{1}{2}(\text{B} + \text{A}) \\ \text{And consequently, since D}' \text{ is the comp. of D,} \\ \text{sin. A D}'\text{B} = \text{cos. } \tfrac{1}{2}(\text{B} + \text{A}) \end{array}\right\} \cdots (1)$$

$$\left.\begin{array}{l}\text{But C B D, the half sum of A and B, added to}\\ \quad\text{A B D, gives B, the greater,}\\ \therefore \text{A B D} = \tfrac{1}{2}(\text{B}-\text{A}),\ \therefore \sin.\ \text{A B D}\\ \qquad = \sin.\ \tfrac{1}{2}(\text{B}-\text{A})\\ \text{But sin. A B D}', \text{ greater than } 90^\circ, \text{ is the same as}\\ \quad\text{the sine of an angle as much less than } 90^\circ\\ \therefore \sin.\ \text{A B D}' = \cos.\ \tfrac{1}{2}(\text{B}-\text{A})\end{array}\right\}\ldots(2)$$

These relations being established, let us refer to Case I., which gives

$$\frac{\text{AD}'}{\text{AB}} = \frac{\text{AC}+\text{CB}}{\text{AB}} = \frac{\sin.\ \text{ABD}'}{\sin.\ \text{AD}'\text{B}}\ldots(3)$$

$$\text{and}\quad \frac{\text{AD}}{\text{AB}} = \frac{\text{AC}-\text{CB}}{\text{AB}} = \frac{\sin.\ \text{ABD}}{\sin.\ \text{ADB}}\ldots(4)$$

Hence, dividing (3) by (4), we have

$$\frac{\text{AC}+\text{CB}}{\text{AC}-\text{CB}} = \frac{\sin.\ \text{ABD}'\ \sin.\ \text{ADB}}{\sin.\ \text{ABD}\ \sin.\ \text{AD}'\text{B}}\ldots(5)$$

that is, by substituting for these sines their values in (1) and (2),

$$\frac{\text{AC}+\text{CB}}{\text{AC}-\text{CB}} = \frac{\cos.\ \frac{1}{2}(\text{B}-\text{A})\ \sin.\ \frac{1}{2}(\text{B}+\text{A})}{\sin.\ \frac{1}{2}(\text{B}-\text{A})\ \cos.\ \frac{1}{2}(\text{B}+\text{A})}$$

$$= \frac{\tan.\ \frac{1}{2}(\text{B}+\text{A})}{\tan.\ \frac{1}{2}(\text{B}-\text{A})}\quad\text{(page 1038);}$$

so that in any plane triangle, *the sum of two sides is to their difference, as the tangent of half the sum of the opposite angles is to the tangent of half their difference.* The following, therefore, is the rule :—

RULE.—As the sum of the two given sides
Is to their difference,
So is the tangent of half the sum of the opposite angles
To the tangent of half their difference.

$$\text{or,}\quad a+b : a-b :: \tan.\ \frac{\text{A}+\text{B}}{2} : \tan.\ \frac{\text{A}-\text{B}}{2}.$$

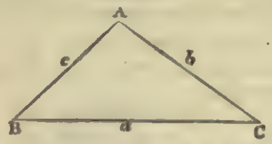
The half difference of the unknown angles thus becomes known; and as their half sum is also known—for the whole sum is 180° minus the given angle (Euc. 32 I.)—the two angles themselves are readily discovered; the greater of the two is the half sum increased by the half difference, and the less, the half sum diminished by the half difference.

NOTE.—Instead of using the tangent of half the sum of the opposite angles, we may use the cotangent of half the included angle, as is obvious.

EXAMPLES.

1. In the triangle A B C (Fig. 9), are given $b = 47$, $c = 85$, and the angle A = 52° 40′; required the remaining parts.

Fig. 9.



$\frac{1}{2}(\text{C}+\text{B}) = 90^\circ - 26^\circ\ 20' = 63^\circ\ 40'$, and the formula for finding $\frac{1}{2}(\text{C}-\text{B})$ is

$$c+b : c-b :: \tan.\ \tfrac{1}{2}(\text{C}+\text{B}) : \tan.\ \tfrac{1}{2}(\text{C}-\text{B})$$

As $c+b$ = 132 Arith. Comp.	7·8794
: $c-b$ = 38	1·5798
: : tan. $\frac{1}{2}$(C + B), 63° 40′	10·3054
: tan. $\frac{1}{2}$(C − B), 30° 11′	9·7646

∴ C = 93° 51′, the sum of $\frac{1}{2}$(C + B) and $\frac{1}{2}$(C − B)
B = 33° 29′, the difference.

As all the angles of the triangle are now known, the remaining side a may be found by Case I., thus :—

To find the side a,

As sin. B, 33° 29′ Arith. Comp.	·2583
: sin. A, 52° 40′	9·9004
: : b = 47	1·6721
: a = 67·74	1·8308

It may be observed here that the third side of the triangle may always be determined independently of Case I., and in a manner somewhat more easily, by employing a relation furnished by the foregoing investigation, thus : the equations (3) and (4), after putting for the sines the values previously deduced, are

$$\frac{\text{AC}+\text{CB}}{\text{AB}} = \frac{\cos.\ \frac{1}{2}(\text{B}-\text{A})}{\cos.\ \frac{1}{2}(\text{B}+\text{A})};\quad \frac{\text{AC}-\text{CB}}{\text{AB}} = \frac{\sin.\ \frac{1}{2}(\text{B}-\text{A})}{\sin.\ \frac{1}{2}(\text{B}+\text{A})}$$

which furnish the proportions

$$\cos.\ \tfrac{1}{2}(\text{B}-\text{A}) : \cos.\ \tfrac{1}{2}(\text{B}+\text{A}) :: b+a : c\ \ldots\ (6)$$
$$\sin.\ \tfrac{1}{2}(\text{B}-\text{A}) : \sin.\ \tfrac{1}{2}(\text{B}+\text{A}) :: b-a : c\ \ldots\ (7)$$

The advantage of using either of these proportions instead of the rule in Case I. is, that all the three logarithms employed occur at the same openings of the table as the logarithms in the process for finding the angles, and they may, therefore, be readily taken out at the same time : *one* of the three—that for the sum or difference of the sides—has only to be repeated.

For the particular triangle solved above, the second of these proportions is

$$\sin.\ \tfrac{1}{2}(\text{C}-\text{B}) : \sin.\ \tfrac{1}{2}(\text{C}+\text{B}) :: c-b : a;$$

and in order to show the facilities gained by employing it, we shall re-work the example just given by its aid.

As $c+b$ = 132 Arith. Comp.	7·8794	To find the side a.	
: $c-b$ = 38	1·5798		1·5798
: : tan. $\frac{1}{2}$(C + B), 63° 40′	10·3054	sin.	9·9524
: tan. $\frac{1}{2}$(C − B), 30° 11′	9·7646	Arith. Comp. sin.	·2986
∴ C = 93° 51′ B = 33° 29′		a = 67·74	1·8308

It may assist the memory in computing the side by this method, to observe that the three terms employed in the proportion for the side are merely those in the proportion for the angles *reversed*, with sine in the place of tangent.

Another use, too, may be made of the proportions (6) and (7)—namely, in the case where two angles and the interjacent side are given to find the remaining sides, as in the following example.

2. Given A = 41° 13′, B = 62° 9′, and $c = 310$, to find a and b.

Inverting the proportions (6) and (7), we have

$$\sin.\ \tfrac{1}{2}(\text{B}+\text{A}) : \sin.\ \tfrac{1}{2}(\text{B}-\text{A}) :: c : b-a$$
$$\cos.\ \tfrac{1}{2}(\text{B}+\text{A}) : \cos.\ \tfrac{1}{2}(\text{B}-\text{A}) :: c : b+a.$$

Hence the work will stand as follows :—

As sin. $\frac{1}{2}$(B + A), 51° 41′ Arith. Comp.	·1054	Arith. Comp. cos.	·2076
: sin. $\frac{1}{2}$(B − A), 10° 28′	9·2593	cos.	9·9927
: : c = 310	2·4914		2·4914
: $b-a$ = 71·8 or nearly 71·7	1·8561	$b+a$ = 491·7	2·6917
		$b-a$ = 71·7	
(See Example 4, page 1044.)		2 | 420 , 210 = a 563·4, 281·7 = b	

3. Given $a = 512$, $c = 907$, and B = 49° 10′, to find the remaining parts of the triangle.
Ans. A = 34° 6′, C = 96° 44′, b = 691.

4. Given $a = 95{\cdot}12$, $c = 98$, and B = 114° 24′, to find the remaining parts.
Ans. A = 32° 15′, C = 33° 21′, b = 162·34.

5. Given $a = 112$, $b = 120$, and C = 57° 57′, to find the remaining parts.
Ans. A = 57° 28′ B, = 64° 35′, c = 112 6.

6. Given $b = 154{\cdot}3$, $c = 365$, and A = 57° 12′, to find the remaining parts.
Ans. B = 24° 45′, C = 98° 3′, a = 310.

III.—*When the given parts are the three sides.*

Investigation of the Rules.

Returning to the diagrams of Case I., page 1043, we have by right-angled triangles,

$$\text{B D} = c\cos.\ \text{B, and C D} = b\cos.\ \text{C}.$$

If the angle C of the triangle be acute, the cosine of it will be positive; if it be obtuse, as in the second of the diagrams referred to, it will be negative. In the equation above, the angle C is A C D, which is acute in the second diagram; but if we replace it by the angle C of the triangle, thus making cos. C subtractive, we shall have, equally for both triangles, the condition

$$a = b \cos. C + c \cos. B$$

And similarly, $b = c \cos. A + a \cos. C$

$$c = a \cos B + b \cos A.$$

Let these be regarded as three algebraical equations, in which the unknown quantities (usually x, y, and z) are cos. A, cos. B, and cos. C; then, multiplying them by a, b, c respectively, we have—

$$a^2 = ab \cos. C + ac \cos B$$
$$b^2 = bc \cos. A + ab \cos. C$$
$$c^2 = ac \cos. B + bc \cos. A;$$

and subtracting each of these from the sum of the other two, there results—

$$\left.\begin{array}{l} b^2 + c^2 - a^2 = 2bc \cos. A \\ a^2 + c^2 - b^2 = 2ac \cos. B \\ a^2 + b^2 - c^2 = 2ab \cos. C \end{array}\right\} \therefore \left\{\begin{array}{l} \cos. A = \dfrac{b^2 + c^2 - a^2}{2bc} \\ \cos. B = \dfrac{a^2 + c^2 - b^2}{2ac} \\ \cos. C = \dfrac{a^2 + b^2 - c^2}{2ab} \end{array}\right.$$

The expressions on the right furnish a complete solution to the present problem; but when the given sides a, b, c, consist each of several places of figures, the calculation of the fractions involves a good deal of arithmetical work. On this account, means have been contrived to change the preceding forms into others, that shall consist exclusively of *factors* and *divisors*, without any addition or subtraction operations; so that the expressions may be fitted for computation by logarithms: how this is brought about we shall explain presently. But, as logarithms may be dispensed with whenever a, b, c are conveniently small numbers, we shall first show the best form of using the above expression for cos. A, in such a case.

Subtract 1 from the fraction for cos. A; it then becomes,

$$\frac{b^2 + c^2 - a^2}{2bc} - 1 = \frac{(b - c)^2 - a^2}{2bc}$$
$$= \frac{(b - c + a)(b - c - a)}{2bc}$$

and now adding the 1 subtracted, we have—

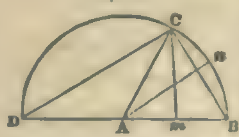
$$\cos. A = \frac{(b - c + a)(b - c - a)}{2bc} + 1$$
$$= 1 - \frac{(a + b - c)(a - b + c)}{2bc} \ldots (1)$$

which is tolerably convenient for calculation without logarithms: but a form somewhat preferable is given subsequently.

If the 1 were transposed and signs changed, the right-hand member of the last equation would be equally convenient for calculation *with* logarithms; but the left-hand member, which would then be $\overline{1 - \cos. A}$, has no corresponding logarithm in the ordinary tables;* the object is then to change $\overline{1 - \cos. A}$ into some equivalent trigonometrical quantity, the log. of which is to be found in the tables. A diagram will assist in showing how this is to be effected

Suppose A B, Fig. 10, to be the trigonometrical radius—namely, A B = 1, and let B C D be the arc of a semicircle to that radius, and B A C the angle A; then An bisecting the chord B C, also bisects the arc B C and the angle A, ∴ B C = 2 sin. ½ A.

Fig. 10.



Now D C B, in a semicircle, being a right angle, we have (Euc. 8 of VI.) B D. Bm = B C²; that is, since B D = 2, and Am = cos. A,

$$2(1 - \cos. A) = (2 \sin. \tfrac{1}{2} A)^2 \therefore \overline{1 - \cos. A} = 2 \sin.^2 \tfrac{1}{2} A,$$

$$\therefore (1),\ \sin.^2 \tfrac{1}{2} A = \frac{(a - b + c)(a + b - c)}{4bc}$$

$$\therefore \sin. \tfrac{1}{2} A = \sqrt{\frac{\frac{1}{2}(a - b + c)\frac{1}{2}(a + b - c)}{bc}}$$

a formula well adapted to computation by logarithms. If s be put to represent $\frac{1}{2}(a + b + c)$, then the two factors in the numerator will be respectively $s - b$ and $s - c$, and we shall have the expression for sin. ½ A in the more compact form,

$$\sin. \tfrac{1}{2} A = \sqrt{\frac{(s - b)(s - c)}{bc}} \quad . \quad . \quad . \quad . \quad (I)$$

Again: because as proved above $\frac{1}{2}(1 - \cos. A) = \sin.^2 \frac{1}{2} A$, if each be subtracted from 1, we shall have,

$$\tfrac{1}{2}(1 + \cos. A) = 1 - \sin.^2 \tfrac{1}{2} A = \cos.^2 \tfrac{1}{2} A,$$

$$\therefore 2 \cos.^2 \tfrac{1}{2} A = 1 + \cos. A = 1 + \frac{b^2 + c^2 - a^2}{2bc}$$

$$= \frac{(b + c)^2 - a^2}{2bc} = \frac{(a + b + c)(b + c - a)}{2bc}$$

$$\therefore \cos. \tfrac{1}{2} A = \sqrt{\frac{s(s - a)}{bc}} \quad . \quad . \quad . \quad . \quad (II)$$

and dividing (I) by (II), we have finally

$$\tan. \tfrac{1}{2} A = \sqrt{\frac{(s - b)(s - c)}{s(s - a)}} \quad . \quad . \quad . \quad . \quad (III)†$$

Either by the formulæ marked (I), (II), (III), will supply a rule for finding an angle from the sides being given; but it is better to work by the formula itself than to be guided by written directions. That marked (II) is a little the shortest; but when ½ A, that is, half the sought angle, is foreseen to be very small, it will be better to use the formula (I): the reason is that the sines of angles very near 90°, or, which is the same thing, the cosines of angles very near 0°, vary from each other by such slight differences, that several of such angles have equal claim to the same sine or cosine. For instance, suppose we were led to 9·9999998 for the logarithmic sine or cosine of an angle to be found. By tables calculated to seven places of decimals, this number is the log. sine of every angle, indifferently, between 89° 56′ 19″ and 80° 57′ 8″; and, consequently, the log. cosine of every angle between 2′ 52″ and 3′ 41″. In such extreme cases the formula (III) is to be preferred, although for a small angle (I) may be safely employed, and (II) for a large one. In practice, however, these ill-conditioned triangles, as they are called, are always avoided, if possible; and in Navigation they are but little likely to be met with. An error of a few seconds in *this* subject is, however, a matter of no moment; and we advert to the peculiarity here, merely to explain to the learner how it happens that, although the three formulæ above are all equally correct, yet in inquiries where the minutest accuracy is necessary, one of them may, in certain rare cases, be preferable to another. The defect is not in the formulæ, but in the tables, which being calculated to only six or seven places of decimals, cannot, of course, mark distinctions of value that affect only the decimals more remote.

EXAMPLES.

1. Given the sides a = 95·12, b = 162·34, and c = 98, to find the angle A.

By formula (I).

$$\sin. \tfrac{1}{2} A = \sqrt{\frac{(s - b)(s - c)}{bc}}$$

a = 95·12		
b = 162 34	Arith. Comp.	7·7896
c = 98	Arith. Comp.	8·0088
2)355·46		
s = 177·73		
$s - b$ = 15·39	. . . .	1·1872
$s - c$ = 79·73	. . . .	1·9016
		2)18 8872
sin. ½ A, 16° 7½	. . . .	9·4436
2		
∴ A = 32° 15′		

---

* The expression 1 – cos. A is called the *versed-sine* of the angle A. A table of *natural* versed-sines is given in Vol. II. of Dr. Mackay's valuable work on *The Theory and Practice of finding the Longitude.*

† The student may compare the above formulæ with similar expressions at page 624, in connection with the calculation of sines, &c., from derived formulæ.—ED.

By formula (II).

$$\cos.\ \tfrac{1}{2}A = \sqrt{\frac{s(s-a)}{bc}}$$

$a = 95{\cdot}12$
$b = 162{\cdot}34$ Arith. Comp. 7·7896
$c = 98$ Arith. Comp. 8·0088

2)355·46

$s = 177{\cdot}73$ . . . . 2·2498
$s - a = 82{\cdot}61$ . . . . 1·9170

2)19·9652

cos. ½ A, 16° 7½′ . . . . 9·9826
2

∴ A = 32° 15′

In the first of these logarithmic operations there enters a log. sine, and in the second a log. cosine: each, therefore, requires a correction, as noticed at page 1038; 10 should be added to the right-hand member of each of the formulæ (I), (II), when expressed logarithmically. Now *two* tens have been added to the sum of the four logs. above, on account of the two complements; so that, after dividing this sum by 2, for the square root, *one* ten, in excess, affects the result, which therefore supplies the 10 that ought to have been added, and thus the proper correction is provided for.

We shall now exhibit the work of the preceding example without logarithms. The most convenient formula for this purpose is, perhaps, that immediately derived from the expression for cos. A at page 1046, by first adding and then subtracting 1; we thus get

$$\cos.\ A = \frac{(b^2 + 2bc + c^2) - a^2}{2bc} - 1 = \frac{(b + c)^2 - a^2}{2bc} - 1$$
$$= \frac{(a + b + c)(b + c - a)}{2bc} - 1$$

$a = 95{\cdot}12$
$b = 162\ 34$
$c = 98$

$a + b + c = 355{\cdot}46$ . . . 355·46
$b + c - a = 165{\cdot}22$ reversed = 22561

$b = 162{\cdot}34$ 35546
$c = 98$ 21328
1777
129872 71
146106 7

15909·32 × 2 = 31818,64)58729(1·8457
31819

·8457 = cos. A, 32° 15′ 26910
25455

The contracted method, so often recommended in these pages, is used throughout this operation. 1455

22

It may be remarked here, that in computing, as in this specimen, the first figure in the quotient will always be 1, followed by decimals; so that there will be no occasion to take any notice of decimal points, either in the dividend or divisor: it is sufficient that we know that the first figure of the quotient is always an integer (unit), and the following figures decimals. But there is no question that, in general, the operation by logarithms would be preferred. It is worthy of notice, however, that whenever *a*, *b*, *c* are all divisible by the same number, we may divide accordingly, and use the quotients: thus, instead of the above values, we might have taken $a = 47{\cdot}56$, $b = 81{\cdot}17$, and $c = 49$; these being the halves of those values.

2. Given $a = 174{\cdot}1$, $b = 232$, and $c = 345$, to find the angle A. Ans. A = 27° 4′.

3. Given $a = 95{\cdot}12$, $b = 162{\cdot}34$, and $c = 98$, to find the angle B. Ans. B = 114° 24′.

4. Given $a = 3388$, $b = 2065$, and $c = 1637$, to find the angle A. Ans. 132° 7′.

5. Given $a = 112$, $b = 112{\cdot}6$, and $c = 120$, to find all the angles. Ans. A = 57° 28′, B = 57° 57′, C = 64° 35′.

6. Given $a = 698$, $b = 352$, and $c = 467$, to find all the angles. Ans. A = 116° 12′, B = 26° 54′, C = 36° 54′.

MISCELLANEOUS QUESTIONS REQUIRING THE SOLUTION OF PLANE TRIANGLES.—1. Being on one side of a river, and wishing to know the distance of a tree (C—Fig. 10, *ante*) on the other side, I measured a length of 500 yards along the side of the river, and set up a rod at each end (A and B): the angle at A, subtended by B C, was then measured, and found to be 74° 14′; and the angle at B, subtended by A C, was found to be 49° 23′: required the distance of the tree from each station.

Here the two angles at A and B are given, as also the interjacent side A B; the third angle at C is therefore known; namely, C = 180° — (74° 14′ + 49° 23′) = 56° 23′.

As sin. C, 56° 23′ Arith. Comp. . ·0795
: sin. B, 49° 23′ . . . 9·8803
: : A B = 500 . . . . 2·6990

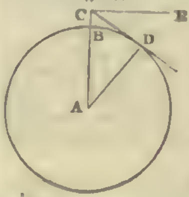
: A C = 455·8 . . . . 2·6588

As sin. C, 56° 23′ Arith. Comp. . ·0795
: sin. A, 74° 14′ . . . 9·9833
: : A B = 500 . . . . 2·6990

: B C = 577·8 . . . . 2·7618

2. From the top of a mountain 3 miles high, the angle of depression of the visible horizon—that is, of the circle where sky and sea appeared to meet—was found to be 2° 13′½: it is required from this to determine the diameter of the earth.

Fig. 11.



Let A (Fig. 11) be the centre of the earth, C the summit of the mountain B C, and E C D the angle of depression of the remotest visible point of the surface of the sea, below the horizontal line C E.

The angles A C D, D C E, make up a right angle; so do the angles A C D and A, because D is a right angle (Euc. 18 of III.); therefore the angle A = the angle E C D. Now by right-angled triangles A C = A D sec. A.

∴ A C − A B = B C = A D (sec. A − 1); that is,

$$AD\,(\sec.\ 2^\circ\ 13'\tfrac{1}{2} - 1) = 3,\ \therefore AD = \frac{3}{\sec.\ 2^\circ\ 13'\tfrac{1}{2} - 1}$$

By help of a table of natural secants this expression for the semi-diameter AD is very readily calculated. To convert it into a form adapted to logarithms, we have, by putting $\frac{1}{\cos.\ A}$ for sec. A,

$$AD = \frac{BC}{\sec.\ A - 1} = \frac{BC\cos.\ A}{1 - \cos.\ A}$$

But it was shown at page 1046 that $1 - \cos.\ A = 2\sin.^2 \tfrac{1}{2}A$,

$$\therefore AD = \frac{BC\cos.\ A}{2\sin.^2\tfrac{1}{2}A},\ \therefore 2\,AD = \frac{BC\cos.\ A}{\sin.^2\tfrac{1}{2}A}$$

∴ log. diameter = log. 3 + log. cos. 2° 13′½ − 2 log. sin. 1° 6′¾ + 10,

the 10 being added because there are two subtractive log. sines—namely, log. sin. 1° 6′¾ + log. sin. 1° 6′¾, and only one additive trigonometrical quantity—namely, log. cos. 2° 13′½.

log. 3 . . . . ·477121
log. cos. 2° 13′½ . . . . 9·999672
log. sin. 1° 6′¾ Arith. Comp. 1·711859
Repeated . . . . 1·711859

log. diam., 7952½ . . . . 3·900511

Hence the diameter of the earth, as deduced from these observations, is 7952½ miles.

Otherwise by a table of natural cosines.

Since, as shown above, $A\,D = \frac{BC \text{ cos. } A}{1 - \text{cos. } A}$, we may compute by the table of natural sines and cosines as follows:—

$$\begin{array}{lrl}
\text{nat. cos. } 2^\circ\,13'\,\tfrac{1}{2} = & \cdot 999246 & \\
 & 3 & \\
\hline
1 - \cdot 999246 = \cdot 000754\;) & 2\cdot 997738\,(& 3976 \\
 & 2262 & \quad\;\; 2 \\
\hline
 & 7357 & 7952 \text{ miles the diameter.} \\
 & 6786 & \\
\hline
 & 5713 & \\
 & 5278 & \\
\hline
 & 4358 & \\
 & 4524 &
\end{array}$$

3. Wanting to know the breadth of a river, I measured a base of 500 yards in a straight line close to its edge, and at each end of it I found the angles subtended by the other end, and a tree close to the opposite margin of the river to be 53° and 79° 12′: what was the breadth of the river? Ans. 529·5 yards.

4. Two ships of war intending to cannonade a fort separated from each other 500 yards, as near to the shore as possible: the angles subtended by each ship and the fort were observed from the other ship to be 38° 16′ and 37° 9′: required the distance of the fort from each place of observation. Ans. 312 yards and 320 yards.

5. The peak of Teneriffe is said to be 2½ miles above the surface of the sea: the angle formed at the top between a plumb-line, which, of course, hangs perpendicular to the horizon, and the line from the eye to touch the sea at the remotest visible point, is found to be 87° 58′: required the diameter of the earth. Ans. 7936 miles.

6. Three objects, A, B, C, whose distances apart were A C = 8 miles, B C = 7½ miles, and A B = 12 miles, were visible from a station D, in the line joining A and B; and the angle at that station, subtended by AC, was observed to be 107° 56′ 13″; required the distance of the three objects from D.

Ans. A D = 5 miles, D B = 7 miles, D C = 4·89 miles.

We here conclude the introductory chapter on the solution of plane triangles: it is intended solely to familiarise the learner with the business of practical calculation, and to illustrate the best and shortest methods of arranging his arithmetical operations. Many instances have been given, more especially in what concerns right-angled triangles, of the advantage of making more use of the table of natural sines and cosines than is at present customary. Valuable as logarithms unquestionably are, they do not always effect a saving of time or trouble, even in cases well fitted for their application; and we would, therefore, recommend that the example we have here set him be followed by the learner—that he would exercise his own deliberate judgment as to which kind of table will aid him in reaching his result in the readiest way, and not in all cases resort to logarithms, as is almost invariably done in works of this kind.

But whatever table he uses he should use with deliberation and care: tabular numbers should never be transcribed in a hurry, as everything depends on the accuracy with which they are written down. It should also be the habitual practice of the calculator to make all the use he can of his table when it is in his hand; and when it is not in use, he should advance his work as much as practicable before he refers to it. In order to this, as many as possible of the *arguments*, as they are called—that is, of the quantities with which the tabular numbers are to be connected—should be written down before the tables are touched: thus, in Example 1, for instance, page 1046, the entire skeleton of the operation should be formed before the table of logarithms is referred to, to fill it up. Again, in Example 2, page 1045, every item, in both columns of the work, should be written down while the tables are in hand, and they should be again referred to only after the amount of each column is found.

In the chapters on TRIGONOMETRY in the mathematical section, the main object has been to develop the analytical theory of angular magnitude, and not to enter at any length into arithmetical details; the present chapter, independently of the special purpose it is intended to serve in this section, may, therefore, be acceptable to the student as a praxis on certain theoretical principles there delivered. This collateral object has not been lost sight of in the preparation of the foregoing pages; and we have, accordingly, introduced examples in sufficient number and variety to supply the learner with all needful materials for exercise, in the ordinary calculations of Practical Trigonometry.

Before closing the introductory portion of our subject, it may be well to collect into one place the several formulæ for the solution of oblique triangles. By thus bringing them together, future reference to them will be facilitated; and the learner, by having the whole more frequently under his eye, will, at length, get them so impressed on his mind as eventually to dispense altogether with a formal reference to them. This amount of familiarity with his tools is a necessary qualification in a good workman.

Formulæ for the Solution of Plane Triangles.

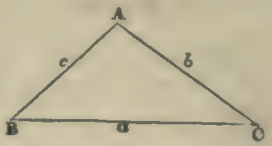
I. $a : b :: \text{sin. } A : \text{sin. } B$

II. $a + b : a \backsim b :: \text{tan. } \tfrac{1}{2}(A + B) : \text{tan. } \tfrac{1}{2}(A \backsim B)$

$\text{sin. } \tfrac{1}{2}(A \backsim B) : \text{sin. } \tfrac{1}{2}(A + B) :: a \backsim b : c$

$\text{cos. } \tfrac{1}{2}(A \backsim B) : \text{cos. } \tfrac{1}{2}(A + B) :: a + b : c$

Fig. 12.



$$\text{III. sin. } \tfrac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{bc}}, \quad \text{cos. } \tfrac{1}{2}A = \sqrt{\frac{s(s-a)}{bc}}$$

$$\text{tan. } \tfrac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$$

$$\text{cos. } A = \frac{(a+b+c)(b+c-a)}{2bc} - 1.$$

The last of these expressions is to be computed by common arithmetic, and the cosine of A to be found in the table of natural sines and cosines; all the other formulæ are adapted to logarithmic computation. Whenever the sides *a*, *b*, *c*, have a factor common to all, it may be cancelled, and the results used instead, in any of the formulæ III.

CHAPTER II.

NAVIGATION.

GENERAL NOTIONS OF THE FIGURE AND ROTATION OF THE EARTH.—The surface of the sea is very nearly that of a perfect sphere or globe. For all the purposes of Navigation, it may be regarded as accurately so; for if the very small deviation from this figure were to be removed, no sensible difference would be made in any of the rules and operations by which the sailings of a ship are regulated, and its position determined.

That the surface of the ocean is globular may be inferred from the evidence of the senses. On whatever part of it an observer be placed, or however high above it he be raised, he sees around him an expanse in which no defect from sphericity can be discovered anywhere within the compass of his vision. He sees a receding vessel, in the distance, gradually disappearing behind the rotundity; he first loses sight of the hull, then more and more of the upper works, till at length even the most elevated parts sink below the circle that limits his field of view. These effects being observed, at whatever spot on the surface the spectator may be, lead to the natural impression that it is a portion of a globe that is everywhere spread around him. This impression is confirmed by the unquestionable fact that, on the assumption of the surface being uniformly spherical, and under the sole guidance of rules and directions based exclusively on that assumption, ships have actually circumnavigated the earth, and that by routes so various, as to leave on the mind not the slightest doubt that the inference, as to the general figure of the ocean's surface, drawn from observation of its appearance to the eye, is correct.

Again: an eclipse of the moon is caused by the passage of that body through the shadow cast by the earth, the earth being then between the sun and moon. As soon as the moon enters the shadow, the small part of her face thus obscured always presents a circular boundary; as she advances, and the obscuration increases, the boundary of the shadow enlarges, but it continues circular; and whenever the centres of the sun, earth, and moon are so nearly in the same straight line as to render the eclipse *annular*, as it is called, then the shadow projected on the moon's surface is observed to be a complete circle. These appearances being uniform, whatever part of the earth's surface is exposed to the sun's rays, we cannot resist the conclusion that the planet we inhabit does not differ in external figure from a perfect sphere, except in a very slight degree.

The earth rotates—turning once round every day; it revolves invariably about the same diameter, and completes each revolution invariably in the same time. That the rising and setting of the sun and stars are appearances really due to the diurnal rotation of the earth, and not to the motions of the celestial bodies themselves, is a truth not so obvious to the senses as the spherical figure of the earth—at least, till very lately, no contrivance had been thought of to render this rotation visible to our eyes. But there are means now of *showing* that the earth turns round; so that we may have the same visible proof of its diurnal revolution that we have of its general figure. This will be explained when we come to treat of NAUTICAL ASTRONOMY.

That the rotation is daily performed in exactly the same invariable period of time—without the difference of a single second—is proved by innumerable observations. Age after age, the same spot on the earth, after the lapse of the same interval of time, invariably returns to the same fixed star; which could not be the case if there were the slightest irregularity in the diurnal rotation of the earth. Nor could such be the case, if the diameter round which the rotation is performed, were shifted.

Admitting, then, from facts such as these, that the earth is a sphere—or that, at least, it differs from a sphere so little as for the purposes of navigation to be of no moment—that it revolves uniformly once in twenty-four hours—and that the diameter about which it turns is invariable, we may proceed to the following definitions:—

DEFINITIONS.

1. *Axis.*—The diameter about which the earth performs its daily revolution is called the axis of the earth: the revolution about this axis is from west to east.

2. *Poles.*—The extremities of this diameter are called the *poles* of the earth. The extremities of *any* diameter of a sphere are also called poles—the poles, namely, of that great circle of the sphere the circumference of which is at every point of it, at the same distance from each, this distance being a quadrant, or 90°: these same points are also spoken of as the poles of every *small* circle parallel to the great circle just mentioned; but from the circumference of any small circle, the poles are, of course, at unequal distances.

3. *Equator.*—The *equator* is that great circle of the earth, the axis of which is perpendicular to the plane of that circle: the poles of the equator are the poles of the earth. These poles are called—one of them the NORTH POLE, and the other the SOUTH POLE. Whenever, in navigation, we speak of the poles, the poles of the *earth*—that is, of the Equator—are always to be understood.

4. *Meridians.*—Every semicircle which terminates at the two poles, and which is therefore perpendicular to the equator, is called a *meridian:* it is said to be the meridian of each place on the earth through which it passes. For the convenience of Navigation and Geography, every civilised kingdom selects one of these innumerable meridians as a meridian of reference; it is usually that which passes through the national observatory, or the principal city, and is called the *first meridian*. In this country the first meridian is that of Greenwich; in France, it is that of Paris.

The plane of every meridian (as also the plane of the equator) is conceived to be extended to the heavens, and to mark out, on the celestial sphere, the celestial meridian of the place. The apparent daily motion of the sun and stars is across the celestial meridians; the path of a ship, easterly or westerly, is across the terrestrial meridian; but, in general, the distinctions *terrestrial* and *celestial* are dropped: a ship cannot be on a celestial meridian, nor a star on a terrestrial meridian.

5. *Latitude.*—The latitude of a place on the surface of the earth, is the distance of that place from the equator, measured on the meridian of the place. Latitude is, therefore, either north or south: a place cannot exceed 90° in latitude, this being the latitude of each pole.

6. *Parallels of Latitude.*—A small circle on the globe, parallel to the equator, is called a *parallel of latitude:* every point on the circumference of such a circle has the same latitude, as the parallel is everywhere equi-distant from the equator. The arc of a meridian, intercepted between two such parallels drawn through any two places on the globe, measures the *difference of latitude* of those places. When the places are both on the same side of the equator—that is, both north or both south—their difference of latitude is found by subtraction; when they are on opposite sides of the equator, their difference of latitude is found by addition.

7. *Longitude.*—The longitude of any place on the earth's surface is the arc of the *equator* intercepted between the meridian of that place and the *first meridian*. It is estimated, like latitude, in degrees and parts of a degree, and is, of course, the measure of the angle at the pole, included between the two meridians spoken of. When the place is to the east of the first meridian, it has east longitude; when to the west, west longitude.

As every place on the surface of the earth performs a complete revolution in twenty-four hours, 15° of longitude become the measure of one hour of time; the whole 360° of the equator, and of every parallel to it, having the measure of twenty-four hours. Longitude is thus sometimes expressed in *time;* a place 45° east of the meridian of Greenwich is, for instance, said to be three hours east of Greenwich. It is necessary to precision, that the *latitude* of a place should be designated either north or south, according as it is situated in the northern or southern hemisphere; but the distinction of longitude into east or west is unnecessary and inconvenient. "It would add greatly to systematic regularity, and tend much to avoid confusion and ambiguity in computations, were this mode of expression abandoned, and longitudes reckoned invariably *westward* from their origin round the whole circle from 0° to 360°."* In the present mode of reckoning, however, longitude, like latitude, is of two denominations; so that the difference of longitude of two places is found sometimes by subtraction and sometimes by addition: by subtraction, if both places are on the same side of the first meridian; and by addition, if they lie on opposite sides: the limit of longitude, whether east or west, is of course 180°. A place of which the longitude is 180° is on the meridian opposite to that of Greenwich.

---

* Sir John Herschel.

The learner must bear in mind that, in Geography and Navigation, the meridian of a place is limited by the poles of the earth: it is the semicircle passing through the place, and terminating in the north and south poles. As already remarked, the terrestrial meridian is extended to the concavity above us, and marks out the corresponding celestial meridian. Certain stars which are observed to come to this meridian are seen to pass the opposite meridian without setting; but the distinction, noticed above, between a meridian and the opposite meridian is not preserved here: the star is generally said to come to the meridian twice—once above and once below the pole. In the case of a ship, however, sailing round the pole from one meridian to its continuation, it is always said to have arrived at the *opposite* meridian, and to have advanced 180° in longitude.

8. *Horizon.*—The horizon of any place is a plane conceived to touch the surface of the earth at that place, and to be extended to the heavens—that is, to the region of the remotest of the stars. This plane is called the *sensible horizon.* A plane parallel to this, but passing through the centre of the earth, is called the *rational horizon.* These two imaginary planes, though separated from each other by an interval equal to the semi-diameter of the earth, cannot but be regarded as coincident at the distance of the stars. An eye, whether at the centre of the earth, or at the point on its surface immediately over it, would see a star in precisely one and the same direction: the altitude of it, referred to the rational horizon, would be exactly the same as the altitude referred to the sensible horizon. The observer, at the centre, sees the star higher above *his* horizon (that is, the parallel to the sensible horizon) than the observer at the surface sees it above his, by the apparent interval between the two horizons, at the distance of the star; which interval, however, although we here call it *apparent*, is in reality too minute to appear as any interval at all.

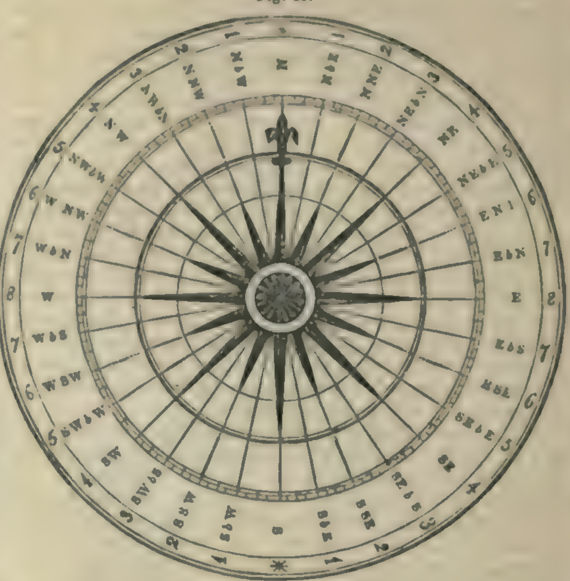
An eye situated *above* the surface of the earth, as is always practically the case, has an horizon different from the sensible horizon: the latter is an extended *plane;* the former is a *conical surface*, everywhere *dipping* below the sensible horizon, and of wider visible boundary. A very moderate elevation above the surface will give a sensible increase to the observed altitude of a heavenly body; namely, the whole of the angular distance between the two horizons—the whole of what may be called the angle of the dip.

The apparent circular boundary of the sea, as seen by an eye thus elevated above its surface, is called the visible, or *sea-horizon;* or, more frequently by sailors, the *offing.*

9. *The Compass.*—The straight line through any place, in which the plane of the meridian of that place cuts the sensible horizon, is called the horizontal meridian, or simply the meridian line, or the north and south line; and the horizontal straight line perpendicular to this is the east and west line of the horizon. The horizon is represented in miniature by a circular card, connected with a magnetised needle, which points out the direction of the horizontal meridian, and consequently also that of the east and west line: the *points* thus marked out on the rim of the card, namely, the North, South, East, and West points, are called the four Cardinal Points of the compass; the quadrantal arcs, intermediate between these, are subdivided each into *eight* equal parts, called also *points*, and these again each into four equal parts, called quarter-points. The above engraving is a representation of the *Mariners' Compass*, divided into its thirty-two points, with the intermediate quarter-points also marked.

This important instrument is so suspended on shipboard as always to assume a horizontal position under every change of motion in the vessel, so that the direction in which the ship is sailing, at any time, is always known by observing what *point* is in that direction; that is, in general, what point coincides with the line, through the centre of the compass-card, from stern to stem of the ship.

Fig. 13.



It is of importance to mention, however, that the magnetic needle does not point accurately north and south; the points to which it *is* directed are called the *magnetic* north and south: and the angular departure from the true north and south, at any place, is called the *variation* of the compass at that place. Its amount may be discovered, and the necessary corrections for it made, by Nautical Astronomy.

10. *Courses.*—A line on the globe, which cuts the successive meridians at the same angle, is called a *rhumb-line;* it marks the track of a ship, the constant angle referred to being called the ship's *course.* It is indicated by the compass; but if no corrections be made for variation, the course thus indicated is called the *compass-course;* after correction and allowance for what is called *deviation*, it is the *true-course.* These modifications of the compass-courses will be more fully noticed as we proceed.

11. *Leeway.*—Another correction of the course is also frequently requisite. The ship's progress is not always in the direction of her length; the wind often impels her sideways, or, as it is called, to *leeward* of the line from fore to aft. The necessary allowance for this divergence from the path indicated by the compass is the correction for *leeway;* its amount can be estimated only by practical experience.

12. *Rate of Sailing.*—The rate at which a ship sails on any course is measured by an instrument called the *log*, and a line attached to it called the *log-line*, about 120 fathoms in length. The log is a piece of wood in shape of a sector of a circle, and with its arc or rim so loaded with lead that, when thrown into the sea, it stands vertically in the water, with only its centre just above the surface.* The log-line is so attached as to keep the face of the log towards the ship, in order that it may offer the greater resistance to being dragged after it; the length of line unwound from a reel, by the advancing motion of the vessel, *half a minute*, gives the distance run in that time, and thus is inferred the rate of sailing. The log-line is divided into equal parts by means of a bit of string passed through the strands and *knotted*, the number of knots showing the number of parts—each part, which is the 120th of a nautical mile, is hence called a *Knot;* so that as many knots as are run out in half a minute, or the 120th of an hour, so many nautical miles per hour is the ship's rate of sailing. Sailors thus say that the rate is so many knots an hour, meaning so many nautical miles an hour. A nautical mile is the 60th

---

* This is the common log, still too much used; a more accurate instrument is Massey's log.

part of a degree of the equator or of the meridian; that is, about 6,080 feet. When the log is *hove*, about ten or twelve fathoms of line are suffered to run out before the counting commences; this is called the *stray-line*, which is an allowance for letting the log go clear of the ship, and settle in the water. As soon as the end of the stray-line, which is marked by a bit of red cloth, passes from the reel, the half-minute commences. The time is measured by a sand-glass, which runs out in thirty seconds, and which is turned when the end of the stray-line passes. The line is stopped as soon as the sand has run out.

13. *A Day's Work.*—By a day's work is meant the ordinary daily operations at sea to determine the position of a ship, and the advances made from noon till noon; it consists in keeping a record of the compass-courses sailed in the interim, of the different rates of sailing, of the variation of the compass, the velocity and direction of currents, &c., &c., and, finally, of the latitude and longitude. These particulars, as they become known, are recorded on the *log-board;* and the latitude and longitude, finally deduced, is called the *dead-reckoning*, or the latitude and longitude *by account.* The particulars of the log-board are transferred, from day to day, to the *log-book;* and, with the addition of whatever else may give the necessary completeness to the record—the astronomical observations made to correct the dead-reckoning, the state of the wind and weather, the bearings of points of land, &c., &c.—form the *journal* of the voyage.

POINTS OF THE COMPASS.—The following table gives the several angles which the different points of the compass make with the meridian, as also the angles for the quarter-points:—

North.		Points.	Angles.	South.	
		¼	2° 49′		
		½	5° 37½′		
		¾	8° 26′		
N. *b.* E.	N. *b.* W.	1	11° 15′	S. *b.* E.	S. *b.* W.
		1¼	14° 4′		
		1½	16° 52½′		
		1¾	19° 41′		
N. N.E.	N. N.W.	2	22° 30′	S. S.E.	S. S. W.
		2¼	25° 19′		
		2½	28° 7½′		
		2¾	30° 56′		
N.E. *b.* N.	N.W. *b.* N.	3	33° 45′	S.E. *b.* S.	S.W. *b.* S.
		3¼	36° 34′		
		3½	39° 22½′		
		3¾	42° 11′		
N.E.	N.W.	4	45° 0′	S.E.	S.W.
		4¼	47° 49′		
		4½	50° 37½′		
		4¾	53° 26′		
N.E. *b.* E.	N.W. *b.* W.	5	56° 15′	S.E. *b.* E.	S.W. *b.* W.
		5¼	59° 4′		
		5½	61° 52½′		
		5¾	64° 41′		
E.N.E.	W. N.W.	6	67° 30′	E. S.E.	W. S.W.
		6¼	70° 19′		
		6½	73° 7½′		
		6¾	75° 56′		
E. *b.* N.	W. *b.* N.	7	78° 45′	E. *b.* S.	W. *b.* S.
		7¼	81° 34′		
		7½	84° 22½′		
		7¾	87° 11′		
E.	W.	8	90° 0′	E.	W.

The angles in the above table nowhere differ from the truth by more than a quarter of a minute; a degree of accuracy amply sufficient for all the purposes for which it is used. It is necessary that the learner should commit this table to memory—at least, so far as to be able to state, without reference to it, how many points any of these courses, or rhumbs, are distant from the meridian, or north and south line; as each point is 11° 15′, the angle corresponding to any number of points is easily deduced. Repeating the points in order, completely round the compass, as figured at page 1050, or according to this table, is called by sailors *boxing the compass.*

We shall now proceed to consider the various sailings, first, however, making a few brief remarks in reference to the data, or observed conditions upon which the computations in the following articles are, in general, to be founded.

From what has been explained in the preceding pages, the learner will perceive that the principal measurements made at sea to determine the place of a ship, independently of astronomical observations, are the measurements of the *course* sailed on, and the *rate* of sailing. From the account given of the means and instruments employed for these purposes, he must see that the results furnished by them can scarcely ever be regarded as rigorously correct. The compass-card, valuable and indispensable as it is, has no divisions upon it to distinguish angles which differ from one another by less than a degree;* such differences, therefore, in steering a ship, have to be roughly estimated by guess—the course is thus liable to error to some extent. Again, the rate of sailing, as measured by the log, is equally exposed to error from the very nature of the operation, and thus the distance run, on any course, cannot be determined with strict accuracy. Even if these sources of error could be obviated, yet winds, currents, swells of the sea, and the various other accidents to which a ship is exposed, and which all act as disturbing causes, would often seriously affect the correctness of the position of the vessel, as deduced from the dead-reckoning.

The aim of the careful and experienced mariner is to be on the look-out for these external influences, and to allow, as best he can, for their effects; matters in reference to which there is room for the exercise of much practical tact and judgment.

These allowances being made, the courses on the log-board are modified accordingly, and, being corrected for the variation and local deviation of the compass, the actual distance made, as also the difference of latitude and longitude since the preceding noon, is computed, and the latitude and longitude, by *account*, are thus ascertained.

These last important particulars—the latitude and longitude—being derived from data so exposed to error, can be regarded, at best, as only approximately true; and therefore the properly qualified navigator loses no opportunity to correct his dead-reckoning by employing the more sure and certain methods which nautical astronomy supplies. In the following articles, however, none of these can be introduced; the object of this part of our subject is to treat exclusively on what concerns the dead-reckoning; and we shall, throughout, suppose that proper allowance for the variation of the compass, for the leeway, &c., have been made, and that the courses concerned are the *true* courses. The methods for ascertaining the variation of the compass must be deferred till we come to treat of Nautical Astronomy.

PLANE SAILING.—*Investigation of the Theoretical Principles.*—Let the following diagram represent the globe of the earth, P being one of its poles, and E Q the equator. Let A B be a rhumb-line or track of a ship on a single course. Imagine this oblique path to be divided, by equidistant meridians, into portions Ab, bc, cd, &c., so small that each portion may differ insensibly from a straight line; and, as in the figure, let the parallels of latitude $b'b$, $c'c$, $d'd$, &c., be drawn. A series of triangles Abb', bcc', cdd', &c., will thus be formed on the surface of the sphere, so small that each may be practically regarded as a *plane* triangle. It is obvious that this may be conceived without any sensible violation of strict accuracy. The triangles thus described, and thus assumed to be plane triangles, are all similar; for the angles at b', c', d', &c., are all right angles, and the ship's track cuts every meridian which it crosses at the same angle. Consequently, by Euclid, Prop. 4, Book VI., we have the proportions,

$$Ab : Ab' :: bc : bc' :: cd : cd' \text{ \&c.};$$

---

* The outer edge of the card is divided into 360 degrees; but as it is difficult to steer a ship to the nicety which these divisions imply, the marks on the extreme rim of the compass-card are seldom much attended to by mariners.

and therefore (Euclid, Prop. 5, Book V., or Prop. 10 of the Treatise on Proportion),[*]

$$Ab : Ab' :: Ab + bc + cd + \&c., : Ab' + bc' + cd' + \&c.$$

But $Ab + bc + cd + \&c.$, is the whole distance sailed on the course, and $Ab' + bc' + cd' + \&c.$, is the difference of latitude A C between A, the place left, and B, the place arrived at. Consequently, if a right-angled triangle, similar to the little right-angled triangle Abb', be constructed—that is, a right-angled triangle, in which A, Fig. 15, is the angle of the course, and if the hypotenuse A B be made to represent the distance sailed—that is, the track A B on the globe—then, obviously, the perpendicular A C will represent the difference of latitude, while the base C B—the side opposite to the course—will represent the sum of all the minute *departures* which the ship makes from the successive meridians which it crosses; for since

Fig. 14.

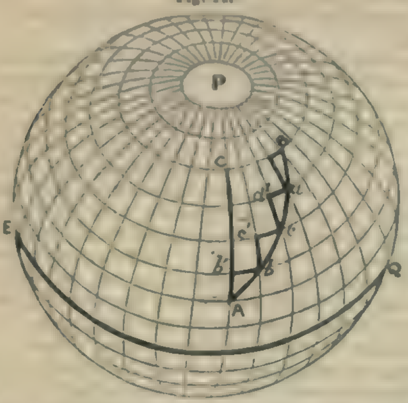


Fig. 15.

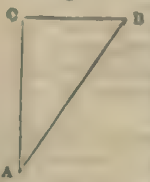


$$Ab : bb' :: A B : B C$$
$$Ab : bb' :: bc : cc' :: cd : dd', \&c.$$
$$\therefore Ab : bb' :: Ab + bc + cd + \&c. : bb' + cc' + dd' + \&c.$$

and since by construction $A B = Ab + bc + cd + \&c.$, therefore $B C = bb' + cc' + dd' + \&c.$ The length B C is called the *departure* made by the ship in sailing from A to B; and it therefore follows that the distance sailed, the difference of latitude made, and the departure, may be represented by the sides of a right-angled *plane* triangle, the angle opposite to the departure being the angle of the course.

Hence, when any two of the four things—Distance, Difference of Latitude, Departure, and Course—are known, the remaining two may be determined by the solution of a right-angled plane triangle; so that, as far as these particulars are concerned, the results are the same as if the ship were sailing on a plane surface, the meridians being replaced by parallel straight lines, and the perpendiculars to these, taken for the parallels of latitude. It is thus that that part of Navigation, which is concerned only with the four things just mentioned, is called PLANE SAILING.

The line B C, or the side of the right-angled triangle opposite to the course, is not the representation of any corresponding line on the globe: it is the entire sum of all the minute departures made by the ship in passing from meridian to meridian, from A up to B.

The foregoing investigation comprehends the whole mathematical theory of Plane Sailing, into which, it will be observed, the consideration of *longitude* does not enter.

The attentive reader will perceive, that in replacing the spiral track of a ship's run, and the great circle arc which measures the difference of latitude made good in that run, by the hypotenuse and perpendicular of a right-angled triangle drawn upon a *plane surface*, we sacrifice not the slightest amount of accuracy. It is shown above, that if this spiral track were unbent into a straight line A B, and at one extremity, A, of this straight line a plane angle equal to that of the course were made by A C, and the perpendicular B C drawn—it is shown that A C must accurately represent the difference of latitude, and B C the departure.

It cannot be any objection to this conclusion that we have taken small triangles on the sphere to be *plane* triangles; for the reasoning fixes no limit to the degree of smallness of the sides; nor must it be understood that we have assumed the sphere, on which these triangles are assumed to be figured, to be *itself* a plane. The assumption extends only to the length of supposing the sphere to present a succession of triangular plane faces; and as each face is contracted to any degree of minuteness, the error of this supposition ultimately disappears.

As a corollary to what is proved above, we may add that—In sailing upon a single rhumb, the differences of latitude made, are proportional to the distances run. And, from the theory of the right-angled triangle established in the INTRODUCTION,[†] we have all the proportions usually given on this part of the subject in books on Navigation; they are expressed as follows;[‡]—

I.	Radius	:	Sin. Course	::	Distance sailed	:	Departure.
II.	Radius	:	Cos. Course	::	Distance sailed	:	Diff. Latitude.
III.	Cos. Course	:	Radius	::	Diff. Latitude	:	Distance sailed.
IV.	Radius	:	Tan. Course	::	Diff. Latitude	:	Departure.
V.	Distance sailed	:	Diff. Latitude	::	Radius	:	Cos. Course.
VI.	Distance sailed	:	Departure	::	Radius	:	Sin. Course.
VII.	Sin. course	:	Radius	::	Departure	:	Distance sailed.
VIII.	Tan. course	:	Radius	::	Departure	:	Diff. Latitude.
IX.	Diff. Latitude	:	Departure	::	Radius	:	Tan. course.

If the table of natural sines, cosines,[§] &c., be used, then Radius = 1; if the table of logarithmic sines, cosines, &c., be used—and they are employed by seamen too indiscriminately—then log. Radius = 10.[‖]

In all books on Navigation, the latter tables, exclusively, are referred to; but, as already stated in the INTRODUCTION, we would recommend a departure from this practice; we shall, therefore, in general, exhibit the calculations by *both* tables.

It is not considered necessary, in the examples that follow, to introduce *diagrams* of the several triangles; but the learner should always roughly sketch the suitable triangles himself, observing that, as is usual in maps, the top of the page is to be regarded as North, and the bottom as South; the right-hand side East, and the left West. In sketching his right-angled triangle, therefore, he should first draw the N. and S. line, or the horizontal meridian, and then take a portion of it for the difference of latitude, drawing, from the latitude reached, the base of the triangle, to represent the departure—to the *right*, if the departure be east, to the *left* if it be west. The hypotenuse will then represent the distance sailed, and the angle between it and the difference of latitude, the course. It will be as well to regard the vertex of this angle as at the centre of the compass-card, since it is the centre of the sensible horizon at starting on the course, and thus no mistake can be made as to which side of the meridian line the angle of the course is to lie on, or whether its opening be upward or downward.

Examples.

1. A ship from latitude 47° 30′ N., has sailed S.W. by S., a distance of 98 miles: what latitude is she in, and what departure has she made?

---

[*] See *ante*, p. 581.

[†] See *ante*, p. 1037.

[‡] We have thought it as well to express the rules and formulæ given in the INTRODUCTION, in the form of proportions here, as seamen are more accustomed to use them in this shape; but the reader of the Introduction will see that this rule-of-three arrangement of the terms employed is not necessary, and he may therefore adopt it or not, as he pleases.

[§] See *ante*, p. 665.

[‖] See *ante*, p. 666, *et seq.*

The course being 3 points is 33° 45′; hence—

1. *To find the diff. lat.*

By logarithms.

As rad. . . . . . . −10
: cos. course, 33° 45′ . . 9·9199
: : distance = 98 . . . 1·9912

: diff. lat. = 81·49 . . . 1·9111

Without logarithms.

diff. lat. = cos. course × distance.

cos. course, 33° 45′ . . . ·8315
distance 98

66520
74835

Diff. lat. . . . . . = 81·487

Hence the difference of latitude is 81·49 miles, S.

2. *To find the departure.*

By logarithms.

As rad. . . . . . −10
: sin. course, 33° 45′ . . 9·7447
: : distance = 98 . . . 1·9912

: departure = 54·44 . . 1·7359

Without logarithms.

dep. = sin. course × distance.

sin. course, 33° 45′ . . . ·5556
distance 98

44448
50004

54·4488

Hence the deparure is 54·45 miles, W.

The latitude from . . . 47° .30′ N.
The difference of lat. . . 1° 21′ S.

Latitude in . . . . . 46° 9′ N.

☞ $\frac{81}{60}$ degrees = 1° 21′.

Departure 54½ miles W.

The example is here worked by *computation*; there is another way of obtaining the results—namely, by *inspection*. This latter method requires reference to a table called the Traverse Table, and which is to be found in every collection of navigation tables. The table is arranged much like a table of sines and cosines; the angles of the courses are inserted at the top of the page, when they do not exceed 45°, and at the bottom when they do, and the distances are placed down the margin. By entering the table with any given course and distance, the corresponding difference of latitude and departure can be taken out from the body of the table.*

This table is a very useful one for seamen, as it computes for him the two formulæ worked by in the right-hand column of operations above; that is, entering his table with the proper course and distance, he finds, under the respective heads "Lat." and "Dep.," the values of

cos. course × distance, and sin. course × distance

already worked out for him, usually as far as two places of decimals, which is an extent amply sufficient. A table of natural sines and cosines is thus all that is wanted to construct a traverse table. In such a table each sine and cosine is multiplied by all distances from 1 up to 120, which is the ordinary limit to which the columns of distances are carried. Distances which exceed 120 miles may be cut up into smaller distances, and the portions brought within the compass of the table.

2. A ship from latitude 47° 30′ N., sailing N.W. *b* W., finds that she has made 82 miles of departure: What is her distance run, and her latitude in?

The course being 5 points is 56° 15′; hence—

1. *To find the distance.*

By logarithms.

As sin. course, 56° 15′ . . − 9·9198
: radius 10
: : departure = 82 . . 1·9138

: distance = 98·62 . . 1·9940

Without logarithms.

dist. = dep. ÷ sin. course.

$$\text{sin. course, } 56^\circ\ 15' \quad \cdot8{,}3{,}1{,}5)\overset{\text{dep.}}{82}\ (98\cdot6$$
7484

716
665

51
∴ distance = 98·6 miles . . 50

2. *To find the diff. lat.*

By logarithms.

As tan. course, 56° 15′ . −10·1751
: radius 10
: : departure = 82 . . 1·9138

: diff. lat. = 54·79 . . 1·7387

Without logarithms.

diff. lat. = dep. ÷ tan. course.

tan. course, 56° 15′ . 1·4,9,6,6)82 (54·8
7483

717
599

118
119

∴ Diff. lat. = 54·8 miles = 55′ N.
Latitude from . . . 47° 30′ N.

Latitude in . . . 48° 25′ N.

3. A ship has sailed S.E. *b* S., from lat. 47° 30′ N. to lat. 46° 8′ N. Required the distance run and the departure made.

The course being 3 points is 33° 45′;

also { lat. from 47° 30′ N.
lat. in 46° 8′ N.

diff. lat. 1° 22′ N. = 82 miles.

1. *To find the distance.*

By logarithms.

As cos. course, 33° 45′ . . − 9·9198
: radius 10
: : diff. lat. = 82 . . 1·9138

: distance = 98·62 . . 1·9940

Without logarithms.

dist. = diff. lat. ÷ cos. course.

cos. course, 33° 45′ . ·8,3,1,5)82 (98·62
74835

7165
6652

∴ dist. = 98·62 miles 513
499

14
17

2. *To find the departure.*

By logarithms.

As radius . . . . −10
: tan. course, 33° 45′ . . 9·8249
: : diff. lat. = 82 . . 1·9138

: departure = 54·79 . . 1·7387

---

* See Tables at pages 1063 and 1069.

Without logarithms.

dep. = diff. lat. × tan. course.

tan. course, 33° 45′ . . ·06682
diff. lat. = 82, reversed . 28

53456
1336

departure = 54·792 miles.

4. A ship from lat. 50° 13′ N., while sailing on a course between south and east, a distance of 98 miles, makes 82 miles of departure: What course did she keep, and what latitude did she arrive at?

1. *To find the course.*

By logarithms.

As dist. = 98 . . . −1·9912
: dep. = 82. . . . 1·9138
: : rad. 10

: sin. course, 56° 48′ . . 9·9226

Without logarithms.

$$\text{sin. course} = \text{dep.} \div \text{dist.} = \frac{82}{98} = \frac{41}{49}$$

7)41

7) 5·8571

sin. 56° 48′ . . ·8367

Hence the course is S. 56° 48′ E.

2. *To find the diff. lat.*

By logarithms.

As rad. . . . . . − 10
: cos. course, 56° 48′ . . 9·7384
: : dist. = 98 . . . . 1·9912

: diff. lat. = 53·66 . . 1·7296

Without logarithms.

diff. lat. = dist. × cos. course.

cos. course, 56° 48′ . ·5476
dist. = 98, reversed . 89

49284
4381

diff. lat. = 53·665 miles = 54′

And 50° 13′ N.—54′ N. = 49° 19′ N., the lat. in.

5. Yesterday at noon we were in lat. 38° 32′ N.; and this day at noon we were in lat. 36° 56′ N. We have run on a single course between S. and E., at 5½ knots an hour: required our course and departure.

Lat. from 38° 32′ N.	24, number of hours.
Lat. in 36° 56′ N.	5½
Diff. lat. 1° 36′ N. = 96 miles	120
	12
	132 miles, the distance.

1. *To find the course.*

By logarithms.

As dist. = 132 . . . −2·1206
: diff. lat. = 96 . . . 1·9823
: : rad. 10

cos. course, 43° 20′ . . . 9·8617

Without logarithms.

$$\text{cos. course} = \text{diff. lat.} \div \text{dist.} = \frac{96}{132} = \frac{8}{11}$$

11)8

cos. course, 43° 20′ . . ·7273

∴ the course is S. 43° 20′ E. = S.E. *b.* S. ¾ E. nearly.

2. *To find the departure.*

By logarithms.

As rad. . . . . . — 10
: sin. course, 43° 20′ . . 9·8365
: : dist. = 132 . . . . 2·1206

: dep. = 90·58 . . . 1·9571

∴ departure = 90 58 miles E.

Without logarithms.

dep. = sin. course × dist.

sin. course, 43° 20′ . . . ·6862
dist. = 132, reversed . . . 231

6862
2059
137

departure = 90·58 miles E.

The foregoing examples have all been solved by computation. As remarked at page 1053, the same results, though with not precisely the same amount of accuracy, may be obtained by inspection of the Traverse Table. There is also a third method of proceeding, much practised by seamen, though less accurate still, by which the required conclusions may be reached: it is the method of *construction.*[*] A circle is described, and the north and south line, or the horizontal meridian, is drawn through its centre; then, from a scale of chords, constructed agreeably to the radius used, which radius is of course the chord of 60° on the scale, the chord of the course is pricked off in its proper direction from the N. or S. extremity of the meridional diameter; from the same extremity, a line is then drawn through the point of the circumference before marked: this is the line of distance, or hypotenusal line, and the line already drawn through the centre is the line of difference of latitude: whichever of these is given is now to be measured off from any scale of equal parts, and the right-angled triangle is then to be completed by introducing the third side, which, measured from the same scale, will give the length sought.

In this illustration, the course and one of the sides including it, are supposed to be given; but if the course be unknown, and any two of the sides of the triangle given, the mode of proceeding is readily suggested from that above: in all cases we have two parts of a right-angled triangle given to construct the triangle—a simple geometrical problem. The unmeasured parts are then to be measured, the angle of the course from the scale of chords, and the sides from the scale of equal parts already employed. We shall conclude this article with a few examples for the exercise of the learner: he will not forget that the given courses are always understood to be the true courses, that is, the compass courses corrected for variation, local deviation, and leeway. The means by which the variation of the compass is ascertained cannot be considered here, as the subject belongs to Nautical Astronomy. (See next Chapter.)

Examples for Exercises in Single Courses.

1. A ship from latitude 48° 40′ N. sails N.E. by N. 296 miles. Required the departure made and the latitude in.

Ans. Departure, 164·4 miles E. Latitude in, 52° 46′ N.

2. A ship from latitude 49° 30′ N. sails N.W. by N. 103 miles. Required her departure and the latitude in.

Ans. Departure, 57·2 miles W. Latitude in, 50° 56′ N.

3. A ship from latitude 47° 20′ N., sails on a course between N. and E. a distance of 98 miles, and arrives at lat. 48° 42′ N. Required the course steered and the departure made.

Ans. Course, N. 33° 12′ E. Departure, 53·7 miles E.

4. A ship sails S.E. ½ E. from latitude 15° 55′ S. till

---

[*] There is also a fourth method—by GUNTER'S SCALE—which it is not worth while to dwell upon. Any mechanical operation with scale and compasses is necessarily affected with inaccuracy; and as reference to the Traverse Table requires less time, and furnishes truer results, it is always to be preferred next to computation.

she is found by observation to be in latitude 18° 49′ S.: required her distance run, and departure.

Ans. Distance, 274 miles. Departure, 212 miles E.

5. A ship from latitude 34° 23′ S. sails between the south and west till she reaches latitude 36° 34′ S. and finds that she has made75 miles of departure. Required her course and distance run.

Ans. Course S. 29° 47′ W. Distance, 151 miles.

6. A ship from latitude 3° 16′ N. sails S.W. by W.¼W., till she has made 356 miles of departure. Required the distance sailed and latitude in.

Ans. Distance, 415 miles. Lat. in, 17′ S.

7. A ship in latitude 3° 52′ S., is bound to a port bearing N.W. by W. ½ W., in latitude 4° 30′ N. How far does that port lie to the westward, and what is the ship's distance from it? in other words, what departure and distance must the ship make to reach it?

Ans. Departure, 939 miles W. Distance, 1065 miles.

8. A ship, from latitude 42° 18′ N., sails S. 25° W. a distance of 150 miles. Required her departure and latitude in.

Ans. Departure 63⅓ miles W. Lat. in 40° 2′ N.

9. If a ship sail from latitude 48° 27′ S. on a S.W. by W. course at the rate of 7 knots an hour, in how many hours will she arrive at latitude 50° S.?

Ans. In 23$\frac{9}{10}$ hours.

10. A ship, from latitude 55° 30′ N., sails S.W. by S. for 20 hours, and then finds by observation that she is in latitude 53° 17′ N. Required her hourly rate of sailing, and the departure she has made.

Ans. Rate, 8 miles an hour. Departure, 88·87 miles W.

11. A ship sails for 18 hours on a single course between the S. and W. from latitude 38° 32′ N. to latitude 36° 56′ N., at the rate of 7⅓ miles an hour. Required the course, distance, and departure.

Ans. Course, S. 43° 20′ W. Distance, 132 miles. Departure, 90·58 W.

12. A ship sails for 53¾ hours on a S.E. ¾ E. course from latitude 52° 30′ N. to latitude 47° 10′ N. Required the average rate of sailing per hour, and the departure made.

Ans. Rate, 10 miles an hour. Departure, 432 miles E.

COMPOUND COURSES, OR TRAVERSE SAILING.—When, from contrary winds or other causes, a ship's track from one place to another is made up of several single courses, the zig-zag path it takes is called a Traverse, or a Compound Course; and the determination of the single course and distance, from the place left to the place arrived at, is called *working* or *resolving* the traverse.

To work a traverse, it is only necessary to find the difference of latitude and departure for each distinct course, as in the foregoing article; to take the aggregate of these for the whole difference of latitude and departure, and thence to find the corresponding single course and distance.

The most orderly way of proceeding is to form a little traverse table, consisting of six columns, to receive the proper entries for course, distance, diff. lat. N. and S., and dep. E. and W., as in the specimen in Example 1 following. When the entries are completed, the two diff. lat. columns are added up separately, and the difference of the results taken: this difference is the whole diff. lat., which is N. or S. according as the N. or S. column gives the greater result. In like manner, the results of the two departure columns being found, their difference is the resultant departure, to be used with the whole difference of latitude, to determine the direct course and distance.

Examples.

1. A ship from latitude 51° 25′ N. has sailed the following courses, namely—

1st, S.S.E. ¼ E., 16 miles.
2nd, E.S.E., 23 miles.
3rd, S.W. *b* W. ½ W., 36 miles.
4th, W. ¾ N., 12 miles.
5th, S.E. *b* E ¼ E., 41 miles.

Required the latitude in, and the direct course and distance to reach it.

TRAVERSE TABLE.

Courses.	Dist.	Diff. of latitude.		Departure.	
		N.	S.	E.	W.
S.S.E. ¼ E.	16		14·5	6·8	
E.S.E.	23		8·8	21·3	
S.W. *b* W ½ W.	36		17		31·8
W. ¾ N.	12	1·8			11·9
S.E. *b* E. ¼ E.	41		21·1	35·2	
Equivalent course, S. 18° 12′ E.		1·8	61.4	63·3	43·7
			1·8	43·7	
Direct distance 63 miles.			59·6	19·6	

The first two columns of this table are occupied with the given courses and distances; in the other four are inserted the diff. lat. and dep. corresponding to each course and distance, taken by inspection from the Traverse Table. The results of these latter columns show that the difference of latitude made is 59·6 miles S., and the departure 19·6 miles E. And from these the lat. in, and the direct course and distance from the lat. left to the place reached, is found by computation as follows:—

```
Latitude left.   .   .   .   51° 25′ N.
Diff. lat. 59·6 miles  .  .   1°  0′ S.
                             ----------
Latitude in  .   .   .   .   50° 25′ N.
```

1. *To find the direct course.*

By logarithms.

```
As diff. lat. = 59·6  .   .   .  −1·7752
  : departure = 19 6  .   .   .   1·2923
: : radius  .   .   .   .   .   . 10
                                 -------
   tan. course, 18° 12′  .   .    9·5171
```

Without logarithms.

tan. course = dep. ÷ diff. lat.

```
5,9·6)19·6(·3288 = tan. 18° 12′
      1788
      ----
       172
      1192
      ----
       528
       477
      ----
        51
        48
```

Hence the direct course is S. 18° 12′ E.

It thus appears that if the ship had left her port on the course S. 18° 12′ E., and had kept this course unaltered for a run of 63 miles (see next page), she would have arrived at the place reached by the above traverses. This conclusion, however, is not rigorously true, though near enough for practice. (See the remarks subjoined to Example 8).

2. *To find the distance.*

By logarithms.

```
As sin. course, 18° 12′   .   .  −9·4946
  : radius  .   .   .   .   .   . 10
: : departure = 19·6  .   .   .   1·2923
                                 -------
  : distance = 62·75  .   .   .   1·7977
```

Without logarithms.

dist. = dep. ÷ sin. course

```
sin. 18° 12′ = ·3,1,2,3)19·6   (62·75
                        18738
                        -----
                          862
                          625
                          ---
                          237
                          219
                          ---
                           13
                           16
```

Hence the nautical distance is 62·75 miles.

NOTE.—It will save time, and be a guard against mistake in the filling up the several columns from the Traverse Table, if, before that table is opened, a mark be put opposite to each course, and in each of the columns where the entries connected with that course are to be inserted. Thus, if N. occur in the course, mark a little cross against it in the N. column, near enough to the right-hand margin of that column to allow of room for the extract from the Traverse Table; if S. occur in the course, put a like mark in the S. column. If E. occur, mark the E. column; and if W. occur, mark the W. column. Then, when the Traverse Table is consulted, we shall have precluded the risk of writing the particulars from it in the wrong column.

2. A ship sails S.W. *b* S. 24 miles; N.N.W. 57 miles; S.E. *b* E. ½ E. 84 miles; and S. 35 miles. Required the direct course and distance.

Ans. Course, S. 43° E. Distance, 57 miles.

3. A ship from latitude 50° 13′ N. has sailed the following courses, namely—

1st. W.S.W., 51 miles. 2nd. W. *b* N., 35 miles. 3rd. S. *b* E., 45 miles. 4th. S.W. *b* W., 55 miles. 5th. S.S.E. 41 miles. Required the latitude in, and the direct course and distance sailed.

Ans. Lat. in, 48° 8′ N. Course, S. 39° 19′ W., or S.W. *b* S. ½ W. Distance, 162 miles.

4. A ship from latitude 28° 32′ N. has run the following courses, namely—

1st. N.W. *b* N., 20 miles. 2nd. S.W., 40 miles. 3rd. N.E *b* E., 60 miles. 4th. S.E., 55 miles. 5th. W. *b* S., 41 miles. 6th. E.N.E., 66 miles. Required the latitude in, and the direct course and distance.

Ans. The same latitude. Course, due E. Distance, 70·2 miles.

5. From noon to noon the following courses were run, namely—

1st. S.W. *b* S., 20 miles. 2nd. W., 16 miles. 3rd. N.W. *b* W., 28 miles. 4th. S.S.E., 32 miles. 5th. E.N.E, 14 miles. 6th. S.W., 36 miles. What difference of latitude has the ship made, and what is her direct course and distance?

Ans. Diff. lat., 50·7 miles S. Course, S.W. Distance, 71·7 miles.

6. A ship sails from latitude 10° 6′ S., the following courses, namely—

1st. N.N.E., 86 miles. 2nd. N., 74 miles. 3rd. E. *b* N., 53 miles. 4th. N.N.W. ¼ N., 40 miles. 5th. E.N.E. ½ N., 21 miles. Required the latitude in, and direct course and distance.

Ans. Lat. in, 6° 34′ S. Course, N. 23° 25′ E. Distance, 231 miles.

7. A ship from latitude 51° 30′ N., running at the rate of 8 knots an hour, sails W.S.W., 3 hours; N.W., 2½ hours; W., 4 hours; S.W. *b* S., 2¼ hours; and N.W. ½ W., 2 hours. Required her latitude in, and her direct course and distance.

Ans. Lat. in, 51° 30′ N. Course, W. Distance, 90·7 miles.

8. A ship from latitude 24° 32′ N., sails the following courses, namely—

1st. S.W. *b* W., 45 miles. 2nd. E.S.E., 50 miles. 3rd. S.W., 30 miles. 4th. S.E. *b* E., 60 miles. 5th S.W. *b* S. ¼ W., 63 miles. Required her latitude in, her departure, and the direct course and distance.

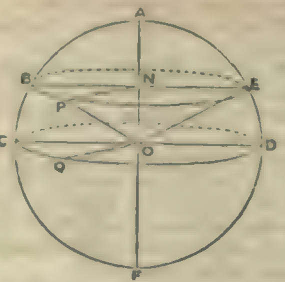
Ans. Lat. in, 22° 3′ N. Departure, 0. Course, S. Distance, 149·2 miles.

In this last example, the ship is said to have returned to the meridian from which she sailed, so that her course from the place arrived at to that left, is concluded to be due south. In the present case, the latitude being low, the error of this conclusion is practically of no consequence; but the balance, or aggregate of the several departures made on a traverse, is not, in strictness, the departure due to the direct course—a fact that sailors, in general, are not sufficiently sensible of. We shall advert more at length to this matter in our introductory observations to MERCATOR'S SAILING.

PARALLEL SAILING.—When a ship sails upon a parallel of latitude, her distance run is then the same as her departure; her difference of latitude is nothing, and her difference of longitude may be easily determined. The case is one of *parallel sailing*, the theory of which may be established in the following manner:

Taking the diagram at p. 596, Chapter VIII., *Spherical Geometry*, let C Q represent a portion of the equator corresponding to the portion B P of a parallel of latitude sailed over by a ship, the points P Q being on the same meridian. Then O C is the radius of the equator, and N B the radius of the parallel, and the difference of longitude of B and P will be measured by the arc C Q.

Fig. 16.



Now, since similar arcs are to one another as the radii of the circles to which they belong, we have

$$N B : O C :: \text{dist. } B P : \text{diff. long. } C Q.$$

But N B is the geometrical cosine of the latitude C B, to the radius O C; consequently N B is equal to O C multiplied by the trigonometrical cosine of the angle Q O P of the latitude; that is, expressing the latitude in degrees and minutes, and not in linear measure, we have

$$O C \cos. \text{lat.} : O C :: \text{dist. sailed} : \text{diff. long.} \quad (1)$$

$$\therefore \cos. \text{lat.} : 1 :: \text{dist. sailed} : \text{diff. long.} \quad (2)$$

And it follows from this, that if the distance between any two meridians on a parallel in latitude L, be D, and the distance of the same meridians on a parallel in latitude L′ be D′, then alternating the proportion (1)

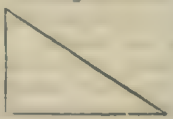
$$\cos. L : \cos. L' :: D : D' \quad . \ . \quad . \quad (A)$$

The proportion (2) evidently solves the problem—Given the latitude of the parallel and the distance sailed on it, to find the difference of longitude; the solution being

$$\text{difference of longitude} = \frac{\text{distance sailed}}{\cos. \text{latitude}} \quad . \ . \quad (3)$$

So that, as in the former cases, we may connect the three things concerned in a right-angled plane triangle (Fig. 17), the base representing the distance sailed, the hypotenuse, the difference of longitude, and the angle between the two the latitude of the parallel, because we know from the theory of the right-angled triangle that these three parts are related as in condition (3). Any problem in parallel sailing may, therefore, always be reduced to a case of right-angled triangles; and consequently may be solved, like a problem in plane sailing, by inspection of the Traverse Table. We shall only have to consider the latitude of the parallel as *course*, and the distance as *diff. lat.*; the corresponding distance in the Traverse Table will be the *diff. long.*

Fig. 17.



It must be observed, however, that the perpendicular of our right-angled triangle merely serves to connect together the three things here mentioned; it has no signification in navigation. The distance sailed on a parallel, the latitude of that parallel, and the difference of longitude between the place left and that arrived at, are related to one another as the three parts, noticed above, of a right-angled triangle, the perpendicular of which merely serves to complete the diagram in which these relations are geometrically embodied.

The proportion (2) above, is usually expressed thus:—

$$\cos. \text{lat.} : \text{radius} :: \text{dist. sailed} : \text{diff. long.}$$

where rad. = 1 when the table of natural sines and cosines is used; and log. rad. = 10 when the logarithmic table is used. As usual, we shall exhibit the working by both tables; but it will be perceived, as in most of the computations already given, that the former table is in general to be preferred.

Examples.

1. A ship from latitude 53° 36′ N. longitude 10° 18′ E., sails due west 236 miles: required the longitude in.

To find the diff. long.

By logarithms.

As cos. lat., 53° 36′ . . . –9·7734
: radius . . . 10
: : distance=236 . . . 2·3729
: diff. long.=397·7 . 2·5995

Without logarithms.

diff. long.=dist. ÷ cos. lat.
cos. 53° 36′=·5,9,3,4)236 (397·7
17802
5798
5341
457
415
42
42

Hence the diff. long. is 397·7 miles=398 miles nearly.

Reducing this to degrees,
60)398

diff. long.= 6° 38′ E. } The difference to be taken,
long. left . . 10° 18′ W. } as the longitudes are E. and W.
long. in . . 3° 40′ E.

2. A ship from latitude 32° N., sails due east till her difference of longitude is found to be 384 miles: what distance has she run?

To find the distance.

By logarithms.

As radius . . . –10
: cos. lat., 32° . . . 9·9284
: : diff. long=384 . . . 2·5843
: distance=325·6 . . 2·5127

Without logarithms.

Dist.=diff. long. × cos. lat.
cos. 32°=·8480
384 reversed, 483
2544
678
34
325·6

Hence the distance run is 325·6 miles.

3. From two ports in latitude 32° 20′ N., distant 256 miles, measured on the parallel, two ships sail directly north, till they come to the latitude 44° 30′ N.: how many miles, measured on the parallel arrived at, are they apart?

This question is to be worked by using the proportion (A).

By logarithms.

As cos. lat. from, 32° 20′ Arith. Comp. ·0732
: cos. lat. in, 44° 30′ . . . 9·8532
: : first dist.=256 . . . 2·4082
: secd. dist.=216·1 . . . 2·3346

Without logarithms.

D′=D cos. L′÷cos. L
cos. L′=cos. 44° 30′=·7133
D=256, reversed, 652
14266
3567
428
cos. L=cos. 32° 20′,=·8,4,5,0)182·61(216·1
1690
1361
845
516
507
9

Hence, measured on the parallel of 44° 30′ N., the ships are 216 miles apart. Their *least* distance apart is the arc of the great circle from one to the other; because an arc of a great circle of the sphere is the shortest distance between its extremities.

4. A ship from latitude 42° 54′ S., longitude 9° 16′ W., sails due west 196 miles: required her longitude in.
Ans. 13° 44′ W.

5. A ship has sailed due east for 3 days on the parallel of 43° 28′; her rate of sailing has been, on the average, 5 knots an hour. What difference of longitude has she made?
Ans. 8° 16′ E.

6. A ship from longitude 81° 36′ W. sails due west 310 miles, and is then found by observation to be in longitude 91° 50′ W.: on what parallel has she sailed?
Ans. The parallel of 59° 41′.

7. In what parallel of latitude is the length of a degree only one-third the length of a degree at the equator?
Ans. Lat. 70° 32′.

8. Two ships in latitude 47° 54′ N., but separated by 9° 35′ of longitude, both sail directly south 836 miles, and at the same rate: how many miles were they apart at starting, and how many after running the 836 miles?
Ans. First distance, 385½ miles; second distance, 477 miles.

9. If two ships in latitude 44° 30′ N., and distant from each other 216 miles, were both to sail, at the same rate, directly south until their distance on the parallel arrived at, became 256 miles, what latitude would they be in?
Ans. 32° 17′ N.

10. If a ship sail due east 126 miles, from the North Cape in latitude 71° 10′ N., and then due north, till she reaches latitude 73° 26′ N., how far must she sail west to reach the meridian from which she started?
Ans. 111·3 miles.

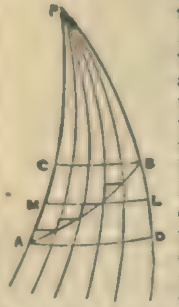
MIDDLE LATITUDE SAILING.—It has already been sufficiently seen that the principal object of plane sailing is to determine the difference of latitude made by a ship sailing upon an oblique rhumb. This sailing gives us no information respecting the change made in the ship's longitude; but if the rhumb sailed upon, instead of being oblique to the meridians crossed by it, cuts them all at right angles, as in parallel sailing, then, as just shown, the difference of longitude made may be accurately ascertained. Except in this particular case, the determination of the change of longitude made by a ship in sailing from one place to another, is a problem the strict solution of which is by no means easy. Independently of astronomical observations, there are two modes of proceeding:—one is called *Middle Latitude Sailing*, and can be regarded only as a close approximation to the truth, unless a certain correction, hereafter given, be applied to it.[*] The other is called *Mercator's Sailing*, and by this the problem is solved upon strict mathematical principles. Middle latitude sailing is a combination of plane sailing and parallel sailing, which are united in the following way :—

---

[*] In the year 1805, Mr. Workman published, under the sanction of the then Astronomer Royal, Dr. Maskelyne, a small and very useful table for correcting the errors of middle latitude sailing. The table is even now scarcely so well known as it ought to be; and as it removes the only objection to this mode of finding the difference of longitude, we have inserted it, a little abridged, at the end of these remarks on mid. lat. sailing, and would strongly recommend it to the notice of the practical navigator. (See page 1060).

It has been seen, in the theory of plane sailing, that the line called the departure, is a line equal to the sum of all the elementary departures made by a ship in sailing on an oblique rhumb. Thus, if A B, in Fig. 18, be the distance sailed, the departure is made up of all the elementary portions of the parallels of latitude lying between A D and C B; it is plain, therefore, that the departure is less than A D, and greater than C B, since the meridians approach closer together, the nearer the parallel is to the pole : there is, therefore, some parallel, M L, between A and C, such that the portion M L would be exactly equal to the departure ; and that, in latitudes near the equator, this parallel M L cannot differ materially from the *middle* parallel. It is on the supposition that the departure is equal to the distance between the meridians left and arrived at, measured on the middle parallel, that middle latitude sailing is founded.

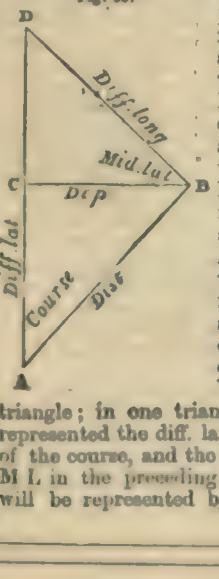
Fig. 18.



From a mere inspection of the diagram—or, better still, of a common globe—it is obvious that this supposition can differ but very little from the truth for low latitudes, and for such short distances, A B, as a day or two's run ; and more especially if the angle of the course be large, so that but little difference of latitude is made, and therefore the parallels A D, C B, are pretty close together. In such favourable cases, the method of middle latitude sailing—though, if uncorrected, only an approximation to the truth—is preferable to the method of Mercator's sailing, though this is theoretically accurate, for reasons that will be hereafter shown. In high latitudes, however, this method is not to be depended on, at least for more than a single day's run, if the angle of the course be small, and the middle latitude be uncorrected ; because the interval between the latitude left and that reached, may be too wide to warrant the supposition that the departure is equal to the middle parallel, between the meridians left and arrived at. But if the middle latitude be corrected by Workman's table, given at page 1060, all objection will be obviated.

Investigation of the Rules for Middle Latitude Sailing.—Let A B in the preceding diagram be the track of the ship, then the difference of longitude made will be the same as if the ship had sailed from M to L, along the middle parallel M L. By the present hypothesis, the distance on this middle parallel is the departure made in running from A to B; hence, the departure being known by plane sailing, we know the length of the parallel M L : and we know, also, the latitude of that parallel. Consequently, the difference of longitude may be found as in parallel sailing. Thus, if in the right-angled triangle B C D, Fig. 19, the base represent the departure, that is, M L, and the angle at the base be made equal to the latitude of M L, then the hypotenuse will represent the difference of longitude between M and L; that is, between A and B. As the base of the right-angled triangle represents the departure made, we may connect with it, as in the annexed diagram, the difference of latitude A C, and the distance A B, as in plane sailing. We shall thus have a sort of double triangle; in one triangle (the lower one here) will be represented the diff. lat. A C, the dist. A B, the angle A of the course, and the departure C B, equal in length to M L in the preceding diagram. In the other triangle will be represented by C B, the distance M L in the preceding diagram, the diff. long. B D, of M and L, and the angle C B D of the mid. lat. ; the lower triangles being constructed conformably to the principles of plane sailing, and the upper conformably to the principles of parallel sailing. In the latter the perpendicular C D is of no significance.

Fig. 19.



1. In the triangle D C B we have

cos. D B C : radius :: B C : D B,

that is, cos. mid. lat. : radius : : depart. : diff. long. . . . (1).

2. In the triangle D B A we have,

sin. D : sin. A : : A B : B D (INTRODUCTION, p. 1044).

that is, cos. mid. lat. : sin. course : : dist. : diff. long. . . (2).

3. Also, in the two triangles A B C, D B C, we have

A C tan. A = B C, B D cos. D B C = B C,

∴ A C tan. A = B D cos. D B C, consequently

A C : B D : : cos. D B C : tan. A ; that is,

diff. lat. : diff. long. : : cos. mid. lat. : tan. course. . . (3).

The proportions marked (1) (2) (3) comprehend the entire theory of middle latitude sailing. It is scarcely necessary to mention that the middle latitude is half the difference of the extreme latitudes when both are north or both south, and half their sum when one is north and the other south.

The three proportions given above may be united in one set of equations, by which mode of expressing them, they will, perhaps, appear in a form more convenient for memory. They are as follows :—

$$\text{diff. long.} = \frac{\text{departure}}{\text{cos. mid. lat.}} = \text{departure} \times \text{sec. mid. lat.}$$

$$= \frac{\text{dist.} \times \text{sin. course}}{\text{cos. mid. lat.}} =$$

$$\text{dist. sin. course sec. mid. lat.}$$

$$= \frac{\text{diff. lat.} \times \text{tan. course}}{\text{cos. mid. lat.}} =$$

$$\text{diff. lat.} \times \text{tan. course} \times \text{sec. mid. lat.}$$

But, by imprinting upon the mind the two connected triangles in the preceding diagram, any recurrence to formulæ will not be necessary on the part of any one familiar with what is taught in the INTRODUCTION to this Section ; and this is one advantage of making the plane triangle subservient to the purposes of Navigation. However, without reference to the triangle, the single equation, $\text{diff. long.} = \frac{\text{departure}}{\text{cos. mid. lat.}}$ embodies all that is peculiar in middle latitude sailing ; the other equations are, in fact, implied in this ; instead of *departure*, the equivalent to it is substituted.

1. A ship from latitude 51° 18′ N., longitude 9° 50′ W., steers S. 33° 8′ W., till she has run 1024 miles : required the latitude and longitude in.

1. *To find the difference of latitude.*

By logarithms.

As radius	— 10
: cos. course, 33° 8′ . .	9·9229
: : dist. = 1024 . . .	3·0103
: diff. lat. = 857·5 . .	2·9332

Without logarithms.

diff. lat. = dist. × cos. course

cos. 33° 8′ . . .	·8374
1024 reversed	4201
	·8374
	167
	34
	857·5

∴ the difference of latitude is 857½ miles.

2. *To find the middle latitude.*

6,0) 85,7
14° 17′ S. = diff. lat
51° 18′ N. = lat. left
37° 1′ N. = latitude in

$\left\{\begin{matrix}51° 18′\\37° \ 1′\end{matrix}\right\}$ = 88° 19′ = Sum of the latitudes

$\frac{88° \ 19′}{2}$ = 44° 9½′ = middle latitude.

3. *To find the difference of longitude* (Proportion 3).

As cos. mid. lat.,	44° 9½′	Arith. Comp.	·1442
: tan. course	33° 8′	. .	9·8147
: : diff. lat.	= 857·5	. .	2·9332
: diff. long.	= 780·1	. .	2·8921

6,0)78,0
13° W. diff. long
9° 50′ W. long. left
22° 50′ W. long. in

Hence the place of the ship is lat. 37° 1′ N., long. 22° 50′ W. We shall now work the last proportion by using the middle latitude as corrected by Workman's table on a following page.

Under the diff. lat. 14°, at the top of the table, and in a line with 44°, the middle latitude, we find the correction 27′; which, added to 47° 9½, gives 44° 36½′ for the corrected middle latitude.

As cos. corrected mid. lat.,	44° 36½′	Arith. Comp.	·1476
: tan. course	33° 8′	. .	9 8147
: : diff. lat.	= 857·5	. .	2·9332
: diff. long.	= 786·2	. .	2·8955

∴ diff. long. = 13° 6′ ∴ 9° 50′ + 13° 6′ = 22° 56′ W. long. in.

Hence the error in longitude, by taking the uncorrected middle latitude, is 6 miles.

The construction of the table here made use of, cannot be explained till we come to Mercator's Sailing. But the necessity for some such table may be readily made apparent; for since, as shown before,

diff. long. = departure × sec. mid. lat.,

it follows, that if there be any error in our estimation of the departure—that is, in our considering it to be exactly equivalent to the middle latitude distance between the meridians—there will be a still greater error in the resulting difference of longitude, because a *secant* is always greater than unity, when the angle to which it relates is of any value at all; and the greater the angle the greater the error. In high latitudes, therefore, where the middle latitude is considerable, the error in longitude, if left uncorrected, may be seriously wide of the truth. For example, when the difference of latitude is 20°, and the middle latitude 72°, the error in longitude would amount to nearly half a degree; that is, to nearly 30 miles. Mr. Workman's table shifts the middle latitude parallel a little higher up, as the mid. latitude parallel a little exceeds the departure in length; as will be shown presently.

2. A ship from latitude 49° 57′ N., and longitude 5° 11′ W., sails between the south and west till she arrives in latitude 38° 27′ N., and finds that she has made 440 miles of departure: required the course steered, the distance run, and the longitude in.

1. *To find the diff. lat. and mid. lat.*

Latitude left, 49° 57′ N.
Latitude in, 38° 27′ N.

Sum 88° 24′ ÷ 2 = 44° 12′ = mid. lat.
Diff. 11° 30′ = 690 miles = diff. lat.

2. *To find the course.*

By logarithms.

As diff. lat. = 690	. . .	— 2·8388
: departure = 440	. . .	2·6435
: : radius	. . . . .	10
: tan. course 32° 32′	. . .	9·8047

Hence the course is 32° 32′.

Without logarithms.

tan. course — dep. ÷ diff. lat. = $\frac{44}{69}$

69)44 (·6377 = tan. 32° 32′
414
26
207
53
483
47

3. *To find the distance.*

By logarithms.

As sin. course, 32° 32′	. .	— 9·7306
: radius	. . . . .	10
: : departure = 440	. . .	2·6435
: distance = 818·3	. . .	2·9129

Hence the distance is 818 miles.

Without logarithms.

dist. = dep. ÷ sin. course
sin. 32° 32′ = 5,3,7,7,9) 440 (818·2
43023
977
538
439
430
9

4. *To find the difference of Longitude* (Proportion 1).

As cos. correct mid. lat. 44° 28′		— 9·8535
: radius	. . . . .	10
: : departure = 440	. . .	2·6435
: diff. long. = 616·6	. .	2·7900

Longitude left	. . .	5° 11′ W.
Diff. long. 617 miles, =	. .	10° 17′ W.
Longitude in	. . . .	15° 28′ W.

If the mid. lat. had not been corrected, the long. would have been about 3′ in error.

3. A ship from latitude 51° 18′ N., longitude 9° 50′ W., sails S. 33° 19′ W. until her departure is 564 miles: required the latitude and longitude in, and the distance sailed.

1. *To find the difference of latitude.*

By logarithms.

As tan. course 33° 19′	. .	— 9·8178
: radius	. . . . .	10
: : departure = 564	. .	2·7513
: diff. lat. = 858	. .	2·9335

Hence the diff. lat. is 858 miles.

Without logarithms.

diff. lat. = dep. ÷ tan. course.
tan. 33° 19′ = ·06,5,7)564 (858
5256
384
329
55
52

2. *To find the middle latitude.*

6,0)858

14° 18′ S. = diff. latitude
51° 18′ N. = latitude left

37° 0′ = latitude in

$\left.\begin{matrix}51^\circ\ 18'\\37^\circ\ 0'\end{matrix}\right\} = 88^\circ\ 18'$ = sum of the latitudes

$\frac{88^\circ\ 18'}{2} = 44^\circ\ 9'$ = middle latitude.

3. *To find the distance sailed.*

By logarithms.

As sin. course, 33° 19′ . . — 9·7398
: radius 10
: : departure = 564 . . . 2·7513

: distance = 1027 . . 3·0115

Without logarithms.

dist. = dep. ÷ sin. course
sin. 33° 19′ = ·5,4,9,3)564 (1027
5493

147
110

37
38

Hence the distance sailed is 1027 miles.

4. *To find the difference of longitude* (Proportion 1).

As cos. correct mid. lat. 44° 36′ — 9·8525
: radius 10
: : departure = 564 . . . 2·7513

: diff. long. = 792 1 . . 2·8988
6,0)79,2

13° 12′ W. diff. long.
9° 50′ W. long. left

23° 2′ W. long. in

The error in longitude here, by using the uncorrected middle latitude, would be six miles.

4. A ship in latitude 51° 18′ N., longitude 22° 6′ W., is bound to a place in the S.E. quarter, of which the nautical distance is 1024 miles, and the latitude of it 37° N. Required the direct course, as also the difference of longitude between the two places.

Ans. Course, S. 33° 5′ E. Diff. long., 786½ miles.

5. A ship from St. Michael's in the Azores, lat. 37° 48′ N., long. 25° 10′ W., is bound for the Start Point, lat. 50° 13′ N., long. 3° 38′ W. Required her course and nautical distance.

Ans. Course, N. 51° 7′ E. Distance, 1187 miles.

6. A ship sails in the N.W. quarter 248 miles, till her departure is 135 miles, and her difference of longitude 310 miles. Required her course, the latitude left, and the latitude in.

Ans. Course, N. 32° 59′ W. Lat. left, 62° 27′ N. Lat. in, 65° 55′ N.

7. A ship from latitude 38° 42′ ½ N., long. 9° 8′ ½ W., sails W.S.W.½W. 168 miles. Required her latitude and longitude. Ans. Lat. 37° 51′ N., long. 12° 33′ W.

8. A ship sails from the Lizard, lat. 49° 57′ 44″ N., long. 5° 11′ 5″ W., for a distance of 700 miles, on a W.S.W. course. Required the latitude and longitude in.

Ans. Lat. in, 45° 29′ 50″ N. Long. in, 21° 13′ 33″ W.

Mercator's Sailing.—The two great problems of navigation are the determining the latitude and longitude of a ship at sea; the other demands of the science are easily provided for. Of the two leading problems mentioned, the former is, in general, by far the more simple; as, by the aid of the imaginary line, called the departure, we may readily discover it, either by construction or computation, by means of the common theory of the right-angled triangle, whenever the course and distance sailed are taken account of.

WORKMAN'S TABLE OF CORRECTIONS TO BE ADDED TO THE MIDDLE LATITUDE—DIFFERENCE OF LATITUDE.*

The departure, as used in plane sailing, is the occasion of some error in certain of the results of navigation: for instance, in the determination of the direct course and distance, as the result of a traverse. If a ship sail on several courses, and her departures east just balance her departures west, we conclude that she has returned to her meridian; but it is plain, from the principles of middle latitude sailing, that the amount of departure that would bring a ship in north latitude to any given meridian on a course inclined to the *north*, would be less than the departure necessary to bring her to the same meridian on a course inclined to the *south:* indeed, the first principles of plane sailing show that the elementary departures, in the latter case, exceed those in the former. And hence, in a traverse, the resultant of the departures will not be the correct departure due to the resultant difference of latitude; and consequently the resultant single course will not, in strictness, be the true one.

---

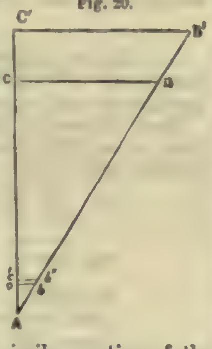
* When the difference of latitude is 2° and under 3°, add 1′.

In a day's run, the error will no doubt be in general of but little moment, and not worth taking note of practically, when we consider that the courses steered are not rigidly determinable; but it is well to apprise the learner of the mathematical shortcomings of our proceedings; and more especially to forewarn him, that if *longitude* be deduced from the balance of departures, even for a single day's run, in high latitudes—latitudes, for instance, above 52° or 53°—the result may be sensibly erroneous; and in latitudes of from 60° to 70°, the error may be such as to endanger the safety of the ship. Unfortunately, sailors are, in general, so much guided by prejudice, and so unwilling to adopt innovations, as they think certain improvements to be, that the common practice still is to confide as implicitly in the resultant departure of a set of departures, as in the departure made in a single course. And it is probably in deference to this erroneous impression, that even the most popular books on navigation are silent on the subject. In such books, the middle latitude distance of the meridians is still taken for the correct departure; though, as already noticed, the resulting error in longitude may amount to so much as 30 miles.

The place of a ship in reference to any given meridian, can be determined correctly only by correctly finding her longitude; and this is done by Mercator's sailing, in a very ingenious manner, as we shall now show.

Investigation of the Theory of Mercator's Sailing.—When a ship sails upon an oblique rhumb, it has already been shown that the difference of latitude, the departure, and the distance run, are all truly represented by the sides A C, C B, A B of a plane triangle, the angle A being that of the course (Fig. 20). The departure, C B, is not the representative of any line on the sphere: it is the equivalent of all the minute departures in the diagram at page 1052, united in one continuous line. Let A *b c*, in the annexed diagram, be one of the elementary triangles figured in the representation just referred to, *c b* being one of the elementary departures, and A *c* the corresponding difference of latitude. Now *c b* being a small portion of a parallel of latitude, it will be to a similar portion of the equator, or of the meridian, as the cosine of its latitude to radius, as was proved at page 1052; and this similar portion of the equator, or of the meridian, measures the difference of longitude between *c* and *b*. Suppose the distance A *b* prolonged to *b′*, till the departure *c′ b′* is equal to this difference of longitude: then we shall have

Fig. 20.



$$cb : c'b' :: \text{cos. lat. of } cb : 1 \text{ (the trig. radius).}$$

$$\text{But } cb : c'b' :: \text{A}c : \text{A}c' \text{ (Euclid, Prop. 4, VI.)}$$

$$\therefore \text{A}c : \text{A}c' :: \text{cos. lat. of } cb : 1 \;\therefore$$

$$\therefore \text{A}c' = \frac{\text{A}c}{\text{cos. lat. of } cb} = \text{A}c \times \text{sec. lat. of } cb \;.\;.\;.\;. \text{ (I)}$$

That is, the proper difference of latitude, A *c*, must be increased to A *c′* = A *c* × sec. lat., in order that the proper departure, *c b*, may be increased to an amount *c′ b′*, equal to the difference of longitude of *c* and *b*; in other words, the ship having made the small difference of latitude A *c*, and the corresponding departure *c b*, must continue her course till the difference of latitude has increased to A *c* × sec. lat. of *c*, in order that her increased departure, *c′ b′*, may give her difference of longitude made in sailing from A to *b*.

Suppose, now, that all the elementary distances are prolonged in this manner; it is then obvious that the sum of all the corresponding increased departures will necessarily be the whole difference of longitude made by the ship during its course from A to B. Hence, to represent the difference of longitude between A and B, we must prolong the difference of latitude A C, till the length A C′ becomes equal to the sum of all the increased elementary differences of latitude; this done, it follows that the departure C′ B′, due to this increased difference of latitude, will represent the difference of longitude made in sailing from A to B.

It is self-evident that, as the departure C B, actually made by the ship, is always *less* than the difference of longitude made, there must be some more advanced departure C′ B′, that would be exactly *equal* to this difference of longitude. The object of the foregoing reasoning, is to discover how the increased difference of latitude, due to this departure, is to be ascertained.

Now the finding the length of A C′ implies the finding of all its elementary parts: suppose we take each of the elementary parts of A C equal to 1′, that is, that we regard A *c* to be 1 nautical mile; then A *c′* will be equal to 1′ × sec. lat of *c*. And, generally, if *l* be the latitude of any point in A C, the length of a minute of latitude, terminating in that point, will be increased to 1′ × sec. *l*.

These enlarged portions of latitude are called **meridional parts**; so that we have

Meridional parts of
$1' = \text{sec. } 1'$
$2' = \text{sec. } 1' + \text{sec. } 2'$
$3' = \text{sec. } 1' + \text{sec. } 2' + \text{sec. } 3'$
$4' = \text{sec. } 1' + \text{sec. } 2' + \text{sec } 3' + \text{sec. } 4'$
$5' = \text{sec. } 1' + \text{sec. } 2' + \text{sec. } 3' + \text{sec. } 4' + \text{sec. } 5'$
&c. &c.

Consequently the meridional parts, on the proper enlargement of every portion of the meridian, measured from the equator up to any latitude, may be calculated by help of a table of natural secants: thus—

Meridional parts of
Nat. Sec. Mer. Parts.
$1' = 1{\cdot}0000000 = 1{\cdot}0000000$
$2' = 1{\cdot}0000000 + 1{\cdot}0000002 = 2{\cdot}0000002$
$3' = 2{\cdot}0000002 + 1{\cdot}0000004 = 3{\cdot}0000006$
$4' = 3{\cdot}0000006 + 1{\cdot}0000007 = 4{\cdot}0000013$
$5' = 4{\cdot}0000013 + 1{\cdot}0000011 = 5{\cdot}0000024$
&c. &c. &c.

If, therefore, a ship leave the equator, and sail upon any course till her latitude becomes 1′, and we desire to know how much she must increase her latitude in order that her corresponding increased departure may be equal to her advance in longitude, we find, from the above, that no further advance in latitude is to be made; for the difference between the departure corresponding to the 1′ of latitude already made, and the advance in longitude is, as might be expected, insensible; or, to speak more rigorously, the difference is too minute to have any numerical value within the limits of seven places of decimals. If her latitude become 2′, her corresponding departure falls short of her advance in longitude by a quantity so small that she has only to increase her latitude by ·0000002 miles to render her departure exactly equal to her difference of longitude.

In like manner, when 3′ of latitude are made, a further advance in latitude to the extent of ·0000006 miles is all that must be made to render her departure the same as her difference of longitude due to the 3′ of latitude. And in this way may a table of meridional parts be calculated, minute by minute. If we enter such a table with the latitude sailed from, and the latitude arrived at, and subtract the meridional parts for the lower latitude from the meridional parts for the higher, the remainder will be the *meridional difference of latitude*, or the line A C′, in the preceding diagram. If the latitude in be on the contrary side of the equator to the latitude left, then, of course, the *sum* of the meridional parts for the two latitudes will be the meridional difference of latitude.

Having thus obtained from the table the meridional difference of latitude (that is, the line A C′), the difference of longitude (that is, the line C′ B′) is then deduced by this proportion; namely—

As radius (1) is to the tangent of the course, so is the meridional difference of latitude to the difference of longitude; or, if instead of the course, the departure (C B) be given, then the proportion will be—

As the proper difference of latitude is to the departure, so is the meridional difference of latitude to the difference of longitude.

Such are the correct principles upon which a true sea-chart is constructed; but whether Gerrard Mercator, the Flemish Chart-maker, was really in possession of these principles, or whether he arrived at their practical results by a series of happy mechanical experiments, is not positively known; he never divulged the methods by which he proceeded, and his secret descended with him to the grave. The first chart he published was in 1556; and it was not till the year 1590 that the true theory of its construction was expounded. This was done by Edward Wright, Fellow of Caius College, Cambridge, who did not, however, communicate his discovery to the public till the year 1590, when his *Certain Errors in Navigation Detected and Corrected*, appeared; yet the key to the entire secret is furnished by the single equation marked (1) at page 1061; a property so obvious, that we cannot but suppose it must have been noticed by numbers of persons engaged in these investigations, before that time; but, like the common occurrence of the falling of an apple from a tree, it was not perceived to be the germ of a theory destined to change the aspect of an important department of science, till it arrested the attention of a superior mind.

Edward Wright constructed his table of meridional parts after the process already described; that is, by actually adding secant after secant through every minute of the quadrant. But it was subsequently shown, by Dr. Halley, that the meridional parts might be actually obtained in another way—we shall explain how at the end of the present article.

It is proper to remark that a table, constructed agreeably to Mr. Wright's plan, will be more mathematically correct the smaller the elementary portions of the meridian are made; as, for instance, if the portions, instead of a minute, be only half a minute in length. Such a table was accordingly constructed by Oughtred, and further extended by Sir Jonas Moore; but the modern table of meridional parts is based upon the strictly accurate theory of Dr. Halley. Mr. Wright, however, was fully sensible that, from the intervals in his table being so great as 1′, his meridional parts, for high latitudes, erred a little in excess, and he pointed out the method of diminishing the error to any extent.

It behoves every writer on Navigation to bring the name of Edward Wright prominently forward when treating of what is called Mercator's Sailing. Mercator has, no doubt, the merit of originating the scheme of enlarging the degrees of the meridian more and more as they approach the pole, or of widening the intervals between the successive parallels of latitude; he was thus instrumental in awakening attention to a more correct way of exhibiting longitudes on a chart than was known before his time; but that he was acquainted with the true principles discovered by Wright, there is strong reason to doubt: for the degrees in his chart were not lengthened in the due proportion which those principles pointed out.

It will occur to the reader that, when the course A is a large angle, a small inaccuracy in the measure of that angle may considerably affect the length of C′ B′; and, therefore, to diminish the influence of this error in the course, it is better and safer, when it differs but little from E. or W., to use the middle latitude method: there is no defect in the table of meridional parts, when the proper decimals are inserted, but in the *data* employed in connection with it.

In most collections of navigation tables, however, the decimals of the meridional parts are omitted, and the meridional parts given only to the nearest unit. It is possible, therefore, that in taking the *difference* between two numbers in the table, there may be an error of nearly a mile in the result. The equation

diff. long. = merid. diff. lat. × tan. course,

shows that the corresponding error in longitude will be proportional to the error in tan. course. Suppose, for instance, the course be 7 points, the tangent of which is about 5; then the error in longitude may *possibly* be 5 miles, which is of some consideration; but, as observed before, in such a large course the middle latitude method, for other reasons, should be employed. It would, however, be an improvement if the leading decimal belonging to each meridional part were actually inserted in the tables. Robertson, one of the most able and instructive writers on Navigation, *does* introduce the leading decimal;* and so, likewise, does Dr. Inman in his *Nautical Tables*. An extensive table of meridional parts will also be found in the quarto collection of *Tables* of J. De Mendoza Rios. The following short table will show the *true* meridional parts calculated agreeably to the mathematically-correct formulæ given at the end of the present article.

deg.	Wright's Mer. Parts.	True Mer. Parts.	deg.	Wright's Mer. Parts.	True Mer. Parts.
5	300·369	300·382	50	3474·605	3474·472
10	603·048	603·070	55	3968·188	3967·966
15	910·433	910·461	60	4527·711	4527·368
20	1225·129	1225·139	65	5179·308	5178·808
25	1549·988	1549·995	70	5966·681	5965·918
30	1888·377	1888·375	75	6971·549	6970·340
35	2244·305	2244·287	80	8377·342	8375·197
40	2622·756	2622·690	85	10769·620	10764·621
45	3030·127	3020·939	89	16317·532	16299·556

We shall now re-state the proportions given in words above, and proceed to examples.

As radius : tan. course : : Mer. diff. lat. : diff. long
As proper diff. lat. : departure : : Mer. diff. lat. : diff. long

Examples.

1. A ship from latitude 51° 18′ N., longitude 9° 50′ W., steers S. 33° 8′ W., till she has run 1024 miles. Required the latitude and longitude in.

The difference of latitude is found in Example 1, page 1058, to be 857½ miles, or 14° 17′ S.; and therefore the latitude in 37° 1′ N.

51° 18′ mer. parts . . 3597·5
37° 1′ . . . . 2393·9
Diff. 14° 17′ 1203·6

As radius . . . . – 10
: tan. course, 33° 8′ . . 9·8147
: : mer. diff. lat. 1204 . . 3·0806
: diff. long. 785·8 . . . 2·8953

Hence the diff. long. = 13° 6′ W.
long. left = 9° 50′ W.
∴ long. in = 22° 56′

2. A ship from latitude 49° 57′ N., and longitude 5° 11′ W., sails between the south and west till she arrives in latitude 38° 27′ N., and finds that she has made 440 miles of departure. Required the course steered, the distance run, and the longitude in.

The course and distance are found in Example 2, page 1059; and the difference of longitude is found by the table of meridional parts, as follows:—

lat. left 49° 57′, mer. parts . 3470
lat. in 38° 27′ . . . 2503
diff. lat. 11° 30′ 967

---

* We do not understand what Robertson means when he says—"But a table of meridional parts, constructed by the most accurate method, has only showed that Mr. Wright's table does nowhere exceed the true meridian parts by half a minute, and this only near the pole; for in latitudes as far as navigation is practicable, the difference is scarcely sensible."—*Elements of Navigation*, by John Robertson, formerly Head Master of the Royal Academy at Portsmouth; vol. 2. p. 136.

Robertson's work is a very valuable performance, and is well deserving a place in the seaman's library. It may be frequently picked up, at the book-stalls, at a very low price. For a correct table of meridional parts (the decimals omitted), the tables of Norie, Riddle, or Raper may be onsulted.

As diff. lat. 690 Arith. Comp.	7·1612
: departure 440 . . .	2·6435
: : mer. diff. lat. 967 . .	2·9854
: diff. long. 616·7 . .	2·7901

Hence diff. long. =	10° 17′ W.
Long. left	5° 11′ W.
Long. in	15° 28′.

3. A ship from latitude 51° 18′ N., longitude 9° 50′ W., sails S. 33° 19′ W., till her departure is 564 miles. Required her longitude in.

We must first find the difference of latitude made; this, by Example 3, page 1059, is 858 miles, or 14° 18′ S.: the latitude left and latitude in will then become known; and thence the meridional difference of latitude may be found by the table of meridional parts, by aid of which the difference of longitude is determined as below.

lat. left	51° 18′ mer. parts	3598
diff. lat.	14° 18	
lat. in	37° 0′	2393
	mer. parts for diff. lat.	1205

As diff. lat. 854 Arith. Comp. ...	7·0665
: departure 564	2·7513
: : mer. diff. lat. 1205	3·0810
: diff. long. 792·1	2·8988

Difference of longitude ...	13° 12′ W.
Longitude left	9° 50′ W.
Longitude in ...	23° 2′ W.

Hence the longitude reached is 23° 2′ W.

4. Required the course and distance from the east point of St. Michael's to the Start Point.

To find the course we must know the meridional difference of latitude and the difference of longitude; the course being determined, the distance will be found by combining it with the proper difference of latitude, as below.

Start Point lat.	50° 13′ N.	Mer. pts. 3495	Lon. 3° 38′ W.
St. Michael's lat.	37° 48′ N.	Mer. pts. 2453	Lon. 25° 13′ W.
Diff. lat.	12° 25′	1042	21° 35′ W.
	60		60
Proper diff. lat.	745 miles.		1295 m.

To find the course.

As mer. diff. lat.	1042	—3·0178
: diff. long.	1295	3·1123
: radius	... ...	10
: tan. course, 51° 11′	... ...	10·0945

To find the distance.

dist. = diff. lat. ÷ cos. course

$$\begin{array}{rr}
\text{cos. } 51° 11' = \cdot 6{,}2{,}6{,}8) & 745\ (1189 \\
 & 6268 \\ \hline
 & 1182 \\
 & 627 \\ \hline
 & 555 \\
 & 501 \\ \hline
 & 54
\end{array}$$

Hence the course is N. 51° 11′ E., and the distance 1189 miles.

It may be as well to exhibit here the work of finding the difference of longitude in Example 2, and the course in this last example, without logarithms.

For the diff. long. Ex. 2.

$$\text{Diff. long.} = \frac{\text{mer. diff. lat.} \times \text{dep.}}{\text{diff. lat.}}$$

$$\begin{array}{rr}
\text{mer. diff. lat.} = & 967 \\
 & 44 \\ \hline
 & 3868 \\
 & 3868 \\ \hline
6{,}9) & 42548(616\cdot 6 \text{ miles} \\
 & 414 \\ \hline
 & 114 \\
 & 69 \\ \hline
 & 458 \\
 & 414 \\ \hline
 & 44 \\
 & 41 \\ \hline
\end{array}$$

∴ diff. long. = 10° 17′ W.

For the course Ex. 4.

$$\text{tan. course} = \frac{\text{diff. long.}}{\text{mer. diff. lat.}}$$

$$\begin{array}{rl}
1{,}0{,}4{,}2) & 1295(1\cdot 243 = \text{tan. } 51° 11' \\
 & 1042 \\ \hline
 & 253 \\
 & 208 \\ \hline
 & 45 \\
 & 42 \\ \hline
 & 3
\end{array}$$

Hence the course is N. 51° 11′ E.

The examples already given, under the head of Middle Latitude Sailing, may serve for exercises in Mercator's Sailing. A comparison of the results of the two methods will also show the value of Workman's table for correcting the middle latitude. It is necessary, however, that the learner should notice, that the two reasons given at page 1061, both conspire to render it unadvisable to use the ordinary table of meridional parts when the course much exceeds 45°; from 50° and upwards the middle latitude method is to be preferred; and, for the first of the reasons mentioned, a small error in the course had better be in defect than in excess. We shall now explain the principles on which that table is constructed.

CONSTRUCTION OF THE TABLE FOR CORRECTING THE MIDDLE LATITUDE.—Let l represent the proper difference of latitude, l' the meridional difference of latitude, L the difference of longitude, and m the latitude in which the distance measured on the parallel between the two meridians is exactly equal to the departure. Then, first by middle latitude and then by Mercator's sailing, we have for the tangent of the course

$$\text{tan. course} = \frac{L \times \cos. m}{l} = \frac{L}{l'}, \therefore \cos. m = \frac{l}{l'}$$

Consequently, by dividing the difference of latitude l taken in miles, by the meridional parts corresponding to that latitude, we shall get cos. m, and thence m, the degrees of latitude in which the parallel between the two meridians is exactly equal to the departure. It is the difference between m and the latitude of the middle parallel that is given in the table at page 1060.

By means of the corrected middle latitude, the difference of longitude, and the course, the nautical distance is found thus:—

The expressions for the departure by plane sailing and by middle latitude sailing, are—

departure = dist. × sin. course = diff. long. × cos. m
∴ sin. course : cos. corrected mid. lat. : : diff. long. : distance.

Construction of a Table of Meridional Parts by Dr Halley's Method.—In Mr. Wright's method of constructing a table of meridional parts, every tabular number, after the first, depends upon the number previously calculated, as already shown at page 1061. Dr. Halley proposed another plan, by which the meridional parts corresponding to any given latitude may be computed independently of previous calculations. As the matter is of so much practical interest, we shall here show how this may be effected.

To transcribe Dr. Halley's investigation (*Philosophical Transactions*, No. 219) would be to occupy more room than we can spare: we must therefore employ a different process; and, if the reader be unacquainted with the first principles of the Differential and Integral Calculus, he may pass it over, and omit this article altogether.

It is shown at page 1061, that if a ship in latitude x vary her latitude by a small portion of the meridian $\triangle x$, and that she continue her course till her departure becomes equal to the difference of longitude due to the difference of latitude $\triangle x$, then the increased difference of latitude $\triangle y$, necessary to produce this effect, will be

$$\triangle y = \sec. x \triangle x, \therefore \frac{\triangle y}{\triangle x} = \sec. x.$$

This equation is rigorously true only when $\triangle x$, and consequently $\triangle y$ is diminished to the last degree of smallness; so that, employing the notation of the differential calculus, we strictly have

$$\frac{dy}{dx} = \sec. x \therefore dy = \sec. x\, dx$$

and the integral of this is the equation

$$y = \log. \tan. (45^\circ + \tfrac{1}{2} x) \quad . \quad . \quad . \quad (1)$$

The logarithm here implied, is the *Napierian* logarithm. To change it into Brigg's, or a common logarithm, we must multiply it by the modulus $\frac{1}{2 \cdot 302585 \ldots}$ (see the article on Logarithms, page 519); we shall then get the logarithm of the *natural* tangent of $45^\circ + \frac{1}{2} x$, according to Brigg's system. But in the tables it is not the log. of the *natural* tangent of $45^\circ + \frac{1}{2} x$, but this log. increased by 10, that is inserted: hence, for the *common* logarithms, the equation (1) is

$$\frac{y}{2 \cdot 302585 \ldots} = \log. \tan. (45^\circ + \tfrac{1}{2} x) - 10$$

$$\therefore y = 2 \cdot 302585 \left\{ \log. \tan. (45^\circ + \tfrac{1}{2} x) - 10 \right\}$$

This is the correct expression for the increased meridian length, measured in miles, in reference to a globe whose radius is 1 mile; to adapt it to the globe of the earth, we must multiply the expression by the radius of the earth, or by 3437·74679 nautical miles; for in every circle the radius is equal to 3437·74679 minutes of that circle, thus:—

Rad. earth × 3·14159 . . . = length of 180° = 10,800 nautical miles.

$$\therefore \text{Rad. earth} = \frac{10800}{3 \cdot 14159 \ldots} = 3437 \cdot 74679 \text{ nautical miles.}$$

Hence, for the number of miles in the lengthened meridian y, from the equator to the latitude x, we have the formula

$$y = 7915 \cdot 7044679 \left\{ \log. \tan. (45^\circ + \tfrac{1}{2} x) - 10 \right\}$$

or, since $\tan. (45^\circ + \frac{1}{2} x) = \cot. (45^\circ - \frac{1}{2} x)$ and that

$$\cot. = \frac{R}{\tan.}, \text{ and } \therefore \log. \cot. = 20 - \log. \tan.$$

the preceding formula may be otherwise written, as follows:—

Meridional lat. = 7915·7044679 {10 − log. tan. (45° − ½ proper lat.)} . . . (2)

It thus appears, that if the log. tan. of half the complement of any latitude be subtracted from 10, and the remainder be multiplied by 7915·7044679, the product will be the meridional parts, in nautical miles, corresponding to that latitude; and, therefore, as observed already, the meridional parts for any latitude may be computed independently of previous results.

The logarithm of the constant multiplier 7915·704 . . . is 3·8984895; so that from (2) we have

$$\log. \text{ merid. lat.} = 3 \cdot 8984895 + \log. \left\{ 10 - \log. \tan. \tfrac{1}{2} \text{ comp. lat.} \right\} \ldots (3)$$

from which formula, the *true* meridional parts for all latitudes may be calculated.

We shall conclude this part of our subject with a few remarks upon the peculiar character of the *Rhumb line*, or, as it is sometimes called, the *Loxodromic curve*.

On the Continued Rhumb Line.—From the principles of Mercator's sailing, or from the diagram at page 1061, which connects the enlarged meridian with the difference of longitude, it is clear that if a ship set out from any point on the globe, and sail on the same oblique rhumb towards the pole, it can reach it only after circulating an infinite number of times round it; for, from any point to the pole, the enlarged meridian is infinite in length, and so, therefore, is the difference of longitude due to this advance in latitude, provided longitude be measured round the globe in one uniform direction: the longitude, thus measured, being infinite, the ship must wind round the pole an infinite number of times.

But—paradoxical as the statement may appear—it is nevertheless true, that the infinite number of revolutions about the pole are performed in a finite time, and that the entire length of the spiral track of the ship is a finite line. However strange this may seem, it follows, as a necessary consequence, from the principles of *plane sailing*; for these principles correctly give,

$$\text{length of track} = \frac{\text{diff. lat.}}{\text{cos. course}}$$

which is finite; and, therefore, the rate being uniform, is described in a finite time.

The matter may be explained as follows:—Whatever be the progressive rate of the ship along its undeviating course, the *times* of performing the successive revolutions about the pole continually diminish as the latitude increases; both the extent of circuit, and the time of performing it, evidently tending to zero—the limit is actually attained, only at the pole itself. Consequently, an infinite number of circuits must ultimately be performed to occupy a finite portion of time.

The case is somewhat analogous to those infinite descending series so frequently met with in arithmetic and algebra; they are infinite—not in their aggregate amount, but only in the number of the continually-diminishing parts into which that amount is divided, these parts becoming less and less, and ultimately vanishing altogether.

In like manner, every additional circuit the ship makes round the pole, increases the length of the previously-described track by a quantity less and less, the successive increments continually diminishing, and ultimately vanishing altogether; so that, just as in a common decreasing geometrical series, the sum of the increments —thus continually tending to, and ultimately terminating in zero—is finite; and hence the time of describing the track must be finite too.

Traverses by Mid-Latitude and Mercator's Sailing.—In order to work a traverse with a view to finding the ship's place, and the direct course and distance to it, we may proceed in either of the two ways following:—

1. Form a traverse table, in the first two columns of which insert the several courses and distances, and in the remaining columns put the corresponding differences of latitude and departures, found either by computation or by reference to the already computed traverse table,

and thence determine the whole difference of latitude and departure, as also the corresponding direct course and distance, exactly as in plane sailing. (See page 1052).

The traverse now being reduced to a single course, find the corresponding difference of longitude, either by mid-latitude or Mercator's sailing.

This method is less accurate than that which follows; because, as already observed (page 1056), the aggregate of the several departures is not, in general, the same as the single departure due to the correct course and distance. It is better, therefore, to take the several differences of latitude and departures separately, and thus to determine the difference of longitude due to each distinct course, and thence the whole difference of longitude made. The second method is, therefore, this:—

2. Fill up the columns of the traverse table, as directed above; but find the aggregate of the diff. latitude columns only. By means of the successive latitudes reached at the end of each course, find the corresponding mid-latitude; and with this, and the departure, deduce the difference of longitude made at the end of each course by mid-latitude sailing, and thence the whole diff. long. made good.

But if Mercator's, instead of the mid-latitude method be employed, then the several departures need not be inserted in the traverse table at all. An example will sufficiently show the mode of proceeding by each method.

Examples.

1. A ship from latitude 38° 14′ N., longitude 25° 56′ W., has sailed the following courses and distances, namely—1st. N.E. *b* N. ½ E., 56 miles. 2nd. N.N.W., 38 miles. 3rd. N.W. *b* W., 46 miles. 4th. S.S.E., 30 miles. 5th. S. *b* W., 20 miles. 6th. N.E. *b* N., 60 miles. Required the latitude and longitude in, and the direct course and distance to it.

BY THE FIRST METHOD.

Courses.	Dist.	Diff. Lat.		Departure.	
		N.	S.	E.	W.
N.E. *b* N. ½ E.	56	45		33·4	
N.N.W.	38	35·1			14·5
N.W. *b* W.	46	25·6			38·2
S.S.E.	30		27·7	11·5	
S. *b* W.	20		19·6		3·9
N.E. *b* N.	60	50		33·3	
		155·7	47·3	78·2	56·6
		47·3		56·6	
		108·4		21·6	

∴ Direct course, 11° 15′, or N. *b* E.
Distance, 111 miles.

The direct course and distance, due to diff. lat. 108·4, and dep. 21·6, are found by reference to the traverse table, or by computation, as at page 1055, to be as above.

To find the diff long. by Mid-Latitude Sailing.

Latitude left . . . 38° 14′ N.
Diff. lat. 108 m. . . . 1° 48′ N.
Latitude in . . . 40° 2′ N.
Sum of lats. . . . 78° 16′
Half sum = mid. lat. . . 39° 8′
Diff. long. = dep. ÷ cos. mid. lat.
= 21 6 ÷ ·7757 . . = 28′ E.
Longitude left . . . . 25° 56′ W.
Longitude in . . . . 25° 28′ W.

BY THE SECOND METHOD (MID-LATITUDE).

Courses.	Dist.	Diff. Lat.		Departure.		Lats. left.	Lats. in.	Sum. Lats.	Mid. Lats.	Diff. Long.	
		N.	S.	E.	W.					E.	W.
1st.	56	45		33·4		38° 14′	38° 59′	77° 13′	38° 36′	43′	
2nd.	38	35·1			14·5	38° 59′	39° 34′	78° 33′	39° 16′		19′
3rd.	46	25·6			38·2	39° 34′	40°	79° 34′	39° 47′		50′
4th.	30		27·7	11·5		40°	39° 32′	79° 32′	39° 46′	15′	
5th.	20		19·6		3·9	39° 32′	39° 12′	78° 44′	39° 22′		5′
6th.	60	50		33·3		39° 12′	40° 2′	79° 14′	39° 37′	43′	
		155·7	47·3							101′	74
		47·3								74′	

Diff. latitude 108·4 N. Difference of longitude 27′ E.

Meridional diff. lat. . . . 139

Diff. long. = mer diff. lat. × tan. course.
= 139 × ·199 = . . 28′ E.
Longitude left . . . . 25° 56′ W.
Longitude in . . . . . 25° 28′ W.

The diff. long. columns may be filled up from the traverse table, by taking the complement of each mid. lat. as a course, and, with the corresponding departure, finding the proper number of miles or minutes in the *distance* column of the table; or, which is somewhat simpler, take the middle latitude itself as a course, and seek the corresponding departure in the *diff. lat.* column of the table, against which, in the *dist.* column will be found the number of miles of diff. long. In this way the two diff. long. columns, as exhibited above, have been formed.

BY THE SECOND METHOD (MERCATOR).

Courses.	Dist.	Diff. Lat.		Lats.	M. parts.	M diff. l.	Diff. Long.	
		N.	S.	38° 14′	2486		E.	W.
N.E. *b* N. ½ E.	56	45		38° 59′	2544	58	43	
N.N.W.	38	35·1		39° 34′	2589	45		18·7
N.W. *b* W.	46	25·6		40°	2623	34		50·5*
S.S.E.	30		27·7	39° 32′	2586	37	15	
S. *b* W.	20		19·6	39° 12′	2560	26		5·1
N.E. *b* N.	60	50		40° 2′	2625	65	43·4	
			47·3					
		155·7					101·4	74·3
		47·3					74·3	

Difference of latitude 108·4 N. Difference of longitude 27·1 E.

The diff. long. columns are here also supplied from the traverse table by entering it with the given course and mer. diff. lat. taken as the proper diff. lat.: the corresponding departure, furnished by the table, is the diff. long.

The longitude in, by the second method, whether the mid. latitude, or Mercator's sailing be employed, is 25° 20′ W., and the latitude and longitude left being given, the direct course and distance, and the corresponding departure, may be readily found by Mercator's sailing.

---

* The 40 corresponding to this in the "Lat." column is more nearly 39¾, so that 50·5 is written instead of 50·7, given in the table

2. A ship, from latitude 52° 20′ N., and longitude 14° 38′ W., has sailed the following courses, namely—

1st, E.S.E., 43 miles ; 2nd, S.W., 32 miles ; 3rd, S.E. *b* S., 58 miles ; 4th, S.S.W., 60 miles. Required the latitude and longitude in.

Ans. Latitude, 49° 57′ N. Longitude, 13° 57′ W.

3. A ship, from latitude 52° 36′ N., and longitude 21° 45′ W., has sailed the following courses, namely—

1st, N.E., 36 miles ; 2nd, N. *b* W., 14 miles ; 3rd, N.E. *b* E. ½ E., 58 miles ; 4th, N. *b* E., 42 miles ; 5th, E.N.E., 29 miles. Required the latitude and longitude in.

Ans. Latitude, 54° 35′ N. Longitude, 18° 4′ W.

4. A ship, from latitude 66° 14′ N., and longitude 3° 12′ E., has sailed as follows :—

1st, N.N.E. ½ E., 46 miles ; 2nd, N.E. ½ E., 28 miles ; 3rd, N. ¾ W., 52 miles ; 4th, N.E. *b* E. ¼ E., 57 miles ; 5th, E.S.E., 24 miles. Required the latitude and longitude in.

Ans. Latitude, 68° 24′ N. Longitude, 7° 54′ E.

5. A ship, from latitude 67° 30′ N., longitude 8° 46′ W., has sailed the following courses, namely—

1st, N.E., 64 miles ; 2nd, N.N.E., 50 miles ; 3rd, N.W. *b* N., 58 miles ; 4th, W.N.W., 72 miles ; 5th, W., 48 miles ; 6th, S.S.W., 38 miles ; 7th, S. *b* E., 45 miles ; 8th, E.S.E., 40 miles. Required her present latitude and longitude by Mercator's sailing.

Ans. Latitude, 68° 43′ N. Longitude, 11° 43′ W.

SAILING IN CURRENTS.—In what has preceded, the course of the ship is supposed to have been indicated by the compass, and that she has actually moved through the water in the direction of her length. It is plain, however, that if a current act upon the ship, she will be diverted from the course shown by the compass, unless the set of the current be itself in the direction of the ship's length, when the rate of sailing only will be interfered with.

The *set* of a current is the point of the compass *towards* which the stream runs ; its rate, or velocity, is called the *drift* of the current.

The common way of ascertaining the set and drift of a current unexpectedly met with at sea, is to take a boat, if the weather permit, a small distance from the ship ; and, in order to keep it from driving with the stream, to let down, to the depth of about 100 fathoms, a heavy weight attached to a rope fastened to the stem of the boat ; steadiness being in this way secured, the log is hove into the current ; the direction in which it is carried is observed by means of a boat-compass, and the number of knots run out in half a minute gives the hourly drift. In this way the set and velocity, or drift, of the current is estimated.

The set of the current being ascertained, we can apply it to correct the compass-course of the ship ; and the drift, or velocity, of the current being known, we can apply it to correct the ship's rate of sailing as indicated by the log. The rate indicated by the log, it will be observed, is only the rate at which the ship moves faster than the log moves in the ship's direction, and, in still water, is the velocity of the ship itself, since the log remains stationary ; but, as in a current, the log also moves in the direction and with the rate of the current, the absolute velocity of the ship cannot be directly determined by the log in the customary manner : yet the distance sailed, as indicated in this way by the log, and the course steered as indicated by the compass, though both modified by the action of the current, and therefore both inaccurate, are necessary helps to the determination of the true course and distance.

For the ship has, in fact, been making a sort of double course : the wind has carried her on a certain course (shown by the compass) a certain distance ; and the current has carried her a certain other course and distance in the same time ; the final effect being the same as if the two courses and distances had been sailed in succession ; so that the case becomes a very simple one of traverse sailing, as in the following example.

Examples.

1. A ship runs N.E. *b* N. 18 miles in three hours, in a current setting W. *b* S. two miles an hour. Required the course and distance made good.

This is evidently the same as saying—A ship sails the following courses, namely—

1st, N.E. *b* N., 18 miles ; 2nd, W. *b* S., 6 miles. Required the course and distance.

TRAVERSE TABLE.

Courses.	Dist.	Diff. Latitude.		Departure.	
		N.	S.	E.	W.
N.E. *b* N.	18	15		10	
W. *b* S.	6		1·2		5·9
	Diff. lat. 13·8			Dep. 4·1	

And, with the difference of latitude and departure thus found, we have, by plane sailing, or by the traverse table, the distance made good, 14 miles, and the course 1½ points, or N. *b* E. ½ E.

2. A ship sails N.W. 60 miles, in a current that sets S.S.W. 25 miles in the same time. Required the course and distance made good.

Ans. Course, N. 69° 38′ W. Distance, 55½ miles.

3. A ship has sailed the following courses and distances in twenty-four hours :—

1st, S.W., 40 miles ; 2nd, W.S.W., 27 miles ; 3rd, S. *b* E., 47 miles ; but she has been the whole time in a current setting S.E. *b* S. at the rate of 1½ mile an hour. Required the ship's direct course and her distance made good. Ans. Course, S. *b* W. Distance, 117 miles.

4. A ship has sailed by reckoning N. ½ W. 20 miles; but it is found by observation, that, owing to a current, she has actually sailed N.N.E. 28 miles. Required the set of the current and the amount of drift upon the ship.

Ans. Set N., 64° 48′ E. Drift, 14 miles.

The method described above, of estimating the set and drift of a surface-current, by sinking a weight, and observing the direction and velocity of the log, is often likely to lead to conclusions not strictly correct. Lieut. Walsh and Lieut. Lee, of the United States' Navy, while carrying on a system of observations in connection with the wind and current charts, had their attention directed to the subject of *submarine currents*, upon which they made some interesting experiments. A block of wood was loaded to sinking, and, by means of a fishing-line, was let down to the depth of one hundred and five hundred fathoms. A small float, just sufficient to keep the block from sinking farther, was then tied to the line, and the whole let go from the boat.

To use their own expressions—"It was wonderful, indeed, to see this *barrega* move off, against wind, and sea, and surface-current, at the rate of over one knot an hour, as was generally the case, and on one occasion as much as 1¾ knot. The men in the boat could not repress exclamations of surprise, for it really appeared as if some monster of the deep had hold of the weight below, and was walking off with it."

The effects of such under-currents must sometimes interfere with the results, deduced in the ordinary way, for the set and drift of a surface-current, since to hidden influences, of the existence of which the observer has no suspicion, part of what he attributes to the surface-current may be really due ; the boat, though apparently steady, may have an imperceptible drift. Such drifts are not caused so much by the action of the under-current upon the sunken weight, as by the bellying of the line in the direction of the set. The surface-current, too, if of any considerable depth, may operate in a similar way.

Admiral Sir Francis Beaufort, when in the Mediterranean, made several experiments on this subject. He says—

"The counter-currents, or those which return beneath the surface of the water, are very remarkable. In some parts of the Archipelago they are at times so strong as to prevent the steering of the ship; and, in one instance, on sinking the lead, when the sea was calm and clear, with shreds of bunting of various colours attached to every yard of the line, they pointed in different directions all round the compass."

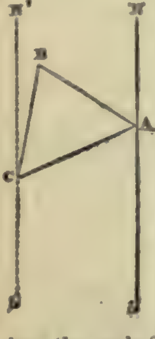
For the foregoing quotations, on the under-currents of the ocean, we are indebted to a recent publication of great value and ability—*The Physical Geography of the Sea*, by Lieut. Maury, of the United States' Navy, the author of *The Wind and Current Charts*, in which the results of extensive observation and experience, in different seasons, and during a course of years, in all parts of the globe, are recorded. Speaking of these charts, the distinguished writer says—"The young mariner, instead of groping his way along till the lights of experience should come to him by the slow teachings of the dearest of all schools, would here find, at once, that he had already the experience of a thousand navigators to guide him on his voyage. He might, therefore, set out upon his first voyage, with as much confidence in his knowledge as to the winds and currents he might expect to meet with, as though he himself had already been that way a thousand times before."*

Oblique Sailing—Taking Departures.—From what has hitherto been explained, the learner has perceived that oblique-angled triangles may be dispensed with in all the ordinary computations which enter into the dead reckoning. But, at the commencement of her voyage, before the ship is out of sight of some known point of land, or other object on shore, the distance and bearing of that object is found, and thus a first course and distance obtained. This is called taking a *departure*. It is a common practice to observe the bearing by compass, and to estimate the distance by guess; and experienced navigators can, in this way, come pretty near the truth: but as our object is to describe the most accurate methods of performing the various calculations of Navigation, we shall devote a short article to the more correct way of taking a departure, which is by observing two bearings of the object, and measuring, by the log, the distance sailed by the ship in the interim between the observations. The solution of an oblique-angled triangle will thus become necessary, as in the following example.

Examples.

1. In sailing down the Channel the Eddystone Lighthouse bore N.W., and after running W. *b* S. 8 miles, it bore N.N.E. Required the ship's course and distance from the Eddystone at the last place of observation.

Fig. 21.



In the annexed diagram (Fig. 21), A represents the first position of the ship, and B the lighthouse, the bearing of which from A, that is, the angle of N A B, is N.W., or 4 points. C is the second position of the ship; and the bearing of B from this position, that is, the angle N'C B, is N.N.E., or 2 points. Also the course of the ship in the interim, that is, the angle S A C, is W. *b* S., or 7 points. Hence the angle B A C is 16 points—11 points + 5 points; also, since the angle S A C = N'C A, we have B C A = 7 points − 2 points = 5 points. Consequently, the angle B is 16 points — 10 points = 6 points; so that in the triangle A B C are given A C = 8, A = 56° 15′, and B = 67° 30′, to find B C as follows:—

As sin. B, 67° 30′ Arith. Comp. .	·0344
: sin. A, 56° 15′	9·9198
: : A C = 8°	·9031
: C B = 7·2	·8573

Consequently, the distance of the Eddystone from the last place of observation is 7·2 miles; and, as the course *to* the Eddystone is N.N.E., the course *from* the Eddystone to the place of the ship must be S.S.W., the opposite point.

As the triangle B C A, in this example, happens to be isosceles, the angle at A and C being equal, a perpendicular upon A C from B will bisect A C, so that we shall have

$$C\,B = 4 \text{ sec. } 56° 15' = 4 \div \text{cos. } 56° 15';$$

that is, C B = 4 ÷ ·556 = 7·2, as in the margin. And this is an easier way of finding the distance than that exhibited above; but when, as is usual, the triangle is scalene, the operation by logarithms, as in the specimen above, is to be preferred.

```
cos. 56° 15′ = ·5,5,6)4   (7·2
                     389
                     ———
                      11
                      11
```

2. Sailing down the Channel the Eddystone bore N.W. *b* N., and after running W.S.W. 18 miles, it bore N. *b* E.: required the course and distance from the Eddystone to both stations.

Ans. Course, S.E. *b* S. Distance, 21·2 miles from the first station. Course, S. *b* W. Distance, 25 miles from second.

3. Coasting along shore, a headland bore N.E. *b* N.; then having run 15 miles E. *b* N., the headland bore W.N.W. Required the distance from the headland at each time of observation.

Ans. First distance, 8½ miles; second, 10·8 miles.

4. Two ships sail at the same time from one port; one sails E.S.E., and the other S.S.E. Required their bearing and distance when each has run 37½ miles.

Bearing from first ship, N. 45° E. Distance, 28·7 miles.

Great Circle Sailing—Shortening of Passages.—The great object of the navigator is to reach the port he intends to make by the shortest route. The path described by a ship, sailing on what is called a direct course from one place to another, is not the *shortest* path, unless the ship sail either on the equator or on a meridian. The oblique spiral track, or rhumb-line, of a ship, sailing in any other direction, exceeds the arc of the great circle, joining the two places, by an amount that becomes more and more considerable as the distance increases. The shortest distance between any two points on the globe is the arc of the great circle between them; for the curvature of this arc is less than that of any other line drawn on the surface, from point to point, and, therefore, approaches more nearly to a straight line.

If, therefore, a ship could sail accurately on the arc of a great circle, voyages might, in general, be considerably shortened. But a great circle cuts all the meridians it crosses in different angles; so that to keep on such a circle the course must be continually varying. The practical impossibility of changing the course every instant, renders Great Circle Sailing—strictly speaking—a matter of mere theoretical speculation. Much advantage, however, has been found to arise from dividing the great circle path, from one place to another, into short portions, or stages, and to reach these in succession by the ordinary methods of sailing. A ship making these several stages, though never actually moving on the great circle, always keeps so closely in its neighbourhood as to be a considerable gainer, in point of time, in a long voyage.

Mr. Towson, of Devonport, has been at the pains of constructing tables, by which the proper successive courses, necessary to cause the entire track of the ship to approximate as closely as conveniently practicable to the great circle path, may be found; they are published by the Admiralty, under the title of *Tables to Facilitate the Practice of Great Circle Sailing*. We can do no more than allude to them here, and recommend them to the notice of the practical seaman.

But, without the aid of tables, a twelve or eighteen-inch globe would be of service in suggesting how to shape the different courses: a line stretched from one point to another, on such a globe, would show the great circle track between them. If a brass circular rim, two or three inches in diameter, made to lie close to the surface of the globe, were divided, like a compass-card, and if a tubular box inclosing a reel, with a yard of thread, were to rise from its centre, this centre might be applied to any proposed spot; and, by means of the thread, pulled out under the disc, each successive course could be ascertained; the only care being, that the north and south line of the disc—which should be marked on the only metallic diameter it need to have—be made to coincide with the meridian of the place under the centre of the instrument. We offer this suggestion as one that might, perhaps, be turned to practical account in long voyages. But, to give perfection to the problem of shortening passages, the *Sailing Directions*, and *The Wind and Current Charts*, by Lieutenant Maury, are of the greatest use. The winds blow and the currents run in all parts of the ocean. "These control the mariner in his course; and to know how to steer his ship on this or that voyage, so as always to make the most of them, is the perfection of navigation. When one looks seaward from the shore, and sees a ship disappear in the horizon as she gains the offing, on a voyage to India, or the antipodes, perhaps, the common idea is that she is bound over a trackless waste; and the chances of another ship, sailing with the same destination the next day, or the next week, coming up and speaking with her on the 'pathless ocean,' would, to most minds, seem slender indeed. Yet the truth is, the winds and the currents are now becoming to be so well understood, that the navigator, like the backwoodsman in the wilderness, is enabled literally 'to blaze his way' across the ocean—not, indeed, upon trees, but upon the wings of the wind. The results of scientific inquiry have so taught him how to use these invisible couriers, that they, with the calm belts of the air, serve as sign-boards to indicate to him the turnings, forks, and crossings by the way."*

---

* *The Physical Geography of the Sea.* By M. F. Maury, LL.D. Lieut. U.S. Navy. 1855. Introduction, p. vi.

We here terminate our exposition of the Principles of NAVIGATION, in so far as these are independent of astronomical observations. What has hitherto been taught, the learner will remember, concerns only what is called the dead-reckoning, which is generally affected with errors, more or less, on account of the practical difficulty of measuring course and distance with strict precision, as well as on account of disturbing causes, either operating unseen, or, where observed, but imperfectly estimated. It is the business of Nautical Astronomy to rectify these unavoidable defects, to adjust the place of the ship, from time to time, to its true position, and thus to enable the mariner to take, as it were, a new departure, and start afresh upon each successive stage of his journey.

As an introduction to this important branch of our subject, we shall treat, in the next chapter, on the rotation of the earth, agreeable to our promise at page 1049.

---

* Maury's *Physical Geography of the Sea*, p. 263. (1855.)

[The following Tables of Differences of Latitude and Departure have been frequently referred to in the previous pages. They are given for each degree, and quarter-point of the Compass.—ED.]

A TABLE of Difference of Latitude and Departure to every Degree and Quarter-point of the Compass.

CHAPTER III.

NAUTICAL ASTRONOMY.

On the Rotation of the Earth.—The common arguments in support of the doctrine that the earth has a diurnal rotation about one of its diameters, give to that doctrine a degree of probability, so nearly approaching to absolute certainty, that the mind readily acquiesces in the reality of the phenomenon. Since the time of Copernicus, the evidence for the earth's rotation has been continually increasing; but still this evidence is not of that direct and positive kind that is necessary to give to it the character of demonstration. All the other hitherto-discovered planets of our system revolve on their axes, and, as might be expected as a consequence of this revolution, those of them upon which the examination can be made are seen to be flattened at their poles. It is probable, therefore, that the planet we inhabit *also* revolves on an axis; if so, it too may be expected to be flattened at its poles. Whether or not *this* is the case can be actually ascertained by experiments: these have been undertaken and repeated, again and again, with the greatest care, and by independent and widely different means: the results all show that the earth *is* flattened at the poles. There is thus a very high degree of probability that the earth rotates; and this is further increased by the fact that all the phenomena of the heavens are completely consistent with the hypothesis of such a rotation; that it is, moreover, the simplest hypothesis upon which the celestial appearances can be explained; and that to attempt to account for them on any other hypothesis, involves the system of the universe in such intricacy and extreme complication, that, judging from all the other operations of nature, we cannot bring ourselves to suppose that such complex machinery should really be the "handiwork" of an all-wise Creator, when means so immeasurably simpler presented themselves, of bringing about the same ends. It can scarcely be charged to the King Alphonso, as a sentiment of impiety, when he exclaimed, in reference to the confused astronomical systems of the ancients—"If I had been the Almighty's counsellor when he framed the universe, I would have advised him better."

But, notwithstanding all this, a sensible or experimental *proof* that the earth rotates was still wanting: its general figure, as already declared (page 1049), can be experimentally discovered: its superficial rotundity can be *seen*. It is very desirable that we should have the same ocular evidence of its rotation. A profound writer on Physical Astronomy has observed—"We must, however, be content, at present, to take for granted the truth of the hypothesis of the earth's rotation. If it continue to explain, simply and satisfactorily, other astronomical phenomena than those already noted, the probability of its being a true hypothesis will go on increasing.

"We shall never, indeed, arrive at a term when we shall be able to pronounce it absolutely *proved* to be true. The nature of the subject excludes such a possibility."

This prediction of Professor Woodhouse has been falsified: we can *now* obtain sensible evidence of the rotation of the earth.

The idea of proving this interesting phenomenon to the senses occurred a few years ago to M. Foucault, of Paris: it was suggested to him by accidentally observing the motion of a weight suspended by a string to a high ceiling, and which, by chance, had been set vibrating. Most of our readers must remember the sensation produced in the scientific world, in the spring of 1851, by the remarkable **Pendulum Experiment** of Foucault. We here propose to submit to them, without going into any minute mathematical details, what appears to us to be a conclusive and satisfactory explanation of the manner in which this experiment renders the rotation of the earth a matter of personal observation; but as we write chiefly for the young, and for those who may be supposed to be but little habituated to scientific research, we shall previously offer to their attention a few general remarks in reference to what may be called the two great postulates of astronomy: these are the rotation of the earth, and the hypothesis of gravitation.

We speak of gravitation as a physical *hypothesis*: it is not, like a proposition in Geometry, a necessary truth; nor is it an observed fact recognisable by our senses. Certain phenomena in nature are observed: they exhibit a regularity of succession, and a mutual dependence, that suggest the idea of a connecting principle and a governing law. The phenomena are *seen*, their proximate cause is *inferred*. The philosopher looks abroad upon nature, and carefully studies the facts presented to him, the order of their recurrence, and the measure of their intensities; he retires to his closet, and endeavours to frame a law, of which, the appearances he has been studying, shall be the outward—the practical manifestation. This is an *hypothesis*. An hypothesis, therefore, need not be more than co-extensive with the phenomena actually observed; but it is a strong confirmation of the soundness of an hypothesis when it is found that new and unexpected phenomena are equally comprehended in it, and a stronger confirmation still, when such phenomena can actually be predicted. The two fundamental hypotheses of Astronomy—the rotation of the earth, and the law of gravitation—have this character in the highest degree: every new discovery in the science has only the more firmly established the truth of both.

The learner will perceive that we could not, with any propriety, speak in this way of the truths of geometry: *they* are quite independent of the confirmations of experience, and hence the marked difference between physical and geometrical science. When Dr. Halley had predicted the return of the comet of 1682 in 1759, and Clairault had computed, from the hypothesis of gravitation, the time when it ought to appear, its return was watched for by astronomers with the greatest interest—not from any anxiety to see the comet, but to learn how the hypothesis of gravitation would stand so severe a test; and the reappearance of the same comet, in 1835, was anticipated with like interest, solely in reference to the planetary attractions—that is, to the general theory of gravitation.

"The rude supposition of the uniform revolution of the moon in a circle about the earth as a centre, led Newton at once to the true law of gravity, as extending from the earth to its companion. The uniform circular motions of the planets about the sun, in times following the progression assigned by observation in Kepler's rule, confirmed the law, and extended its influence to the boundaries of our system. Everything more refined than this—the elliptic motions of the planets and satellites—their mutual perturbations—the slow changes of their orbits and motions, denominated secular variations—the deviation of their figures from the spherical form—the oscillatory motions of their axes, which produce nutation and precession of the equinoxes—the theory of the tides, both of the ocean and the atmosphere—have all in succession been so many trials for life and death, in which this law has been, as it were, pitted against nature: trials, whose event no human foresight could predict, and where it was impossible even to conjecture what modifications it might be found to need. Even at this moment, if, among the innumerable inequalities of the lunar or planetary motions, any one, however small, should be discovered decidedly not explicable on the hypothesis of a force varying as the inverse square of the distance, that hypothesis must be modified till it accounts for it."*

From these statements the student will perceive that one of the two fundamental hypotheses of astronomy—the hypothesis of gravitation—is not irrefragably established like a proposition in Euclid; nor is it a truth set at rest, once and for ever, by observation and experiment. Indeed, no physical truth can be regarded as thus unalterably fixed, like a *necessary* truth of geometry. The laws of nature *may* change; the supposition of such a change would involve no such absurdity as that which would be implied in the supposition that the three angles of a triangle could ever exceed or fall short of two right angles. This truth would remain undisturbed, however the properties of matter might be modified, and even though matter were to be altogether annihilated. It is obvious that we reckon upon the continuance of the properties of matter, and the return of natural phenomena, only to the extent to which we reckon upon the permanence of the existing natural laws. And Laplace, in extension of this idea, has even calculated the probability that the sun will not rise to-morrow.

But, assuming the unchangeableness of nature's laws, we are authorised in regarding certain of its phenomena as unalterable truths. For instance, if the planet we inhabit is clearly ascertained *now* to be a round body, we conclude that it will remain round as long as it lasts. If it be as clearly seen to rotate, we conclude, in like manner, that it will always rotate; its rotation ceases then to be an hypothesis—it becomes an observed fact, the evidence for the truth of which is not increased by the confirmations of future experience, nor by its satisfactorily accounting for whatever phenomena may be referred to such rotation. It is a matter of some importance, therefore, that the rotation of the earth is taken out of the category of hypothesis, and classed among observed physical truths, as we now proceed to show.

Foucault's Pendulum Experiment.—Let the reader conceive before him a circular table, upon which, passing through its centre, the meridian line is drawn. If the earth have no rotation about an axis, this line can never change its direction; if it do rotate, the direction must continually vary, except the place of observation be at the equator: this will readily appear from the following considerations.

Let our horizontal meridian line be indefinitely extended; we shall thus have an indefinite straight line, in the plane of the terrestrial meridian, and touching the surface of the earth, the point of contact being the centre of the table;—we may, of course, regard the table-top as lying horizontally on the ground.

For any place of observation between the equator and the pole, it is obvious that if the earth turned round its axis, this tangent line will, in one complete rotation, describe a conical surface enveloping the globe; and, as the vertex of the cone is necessarily at a finite distance, the line which generates its surface—thus always pointing to a fixed determinate point (the vertex)—must continually change its direction, which, however, it cannot do if the earth be at rest.

But if the place of observation be at the equator, what, in the case just considered, is a *conical* surface, would evidently be a *cylindrical* surface; the straight line generating it would thus always be parallel to itself, and, therefore, though the earth should really rotate, there would be no more change of direction in the meridian line than if it were at rest.

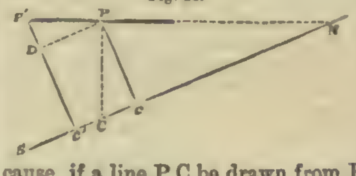
If, however, the centre of the table were directly over the pole, then, taking any diameter of the table for a meridian line, the changes in its direction—if the earth rotate—would clearly be more rapid and more considerable; it would pass through a revolution of 360° for every complete rotation, and the surface described by the line would be a plane surface.

It is thus easy to see what must necessarily happen, as to the direction of the horizontal meridian, if the earth have any rotation about its axis. At the equator, the direction would remain undisturbed, and the line would generate a cylindrical surface; at a small distance from the equator, the cylinder would become a cone, and the direction of the line would regularly, but only slightly change. At a greater distance from the equator the cone would differ more palpably from the cylinder, and the angular deviation of the line—always directed to the vertex of the cone—would be more considerable. As the place of observation approaches the pole, the cone would, as it were, widen out more and more, the deviation of the line would become greater and greater, in a given time, till at length, when the pole is reached, the cone would spread into a plane, and the change of direction would be the greatest possible.

The reader will find it of much assistance, towards clearly apprehending what is to follow, if he keep constantly before his mind the idea of the enveloping cones. Every parallel of altitude is to be regarded as the circle of contact of a cone, the apex of which becomes less and less remote as the parallel approaches the pole; we shall call the cone adapted to any particular parallel, the *cone of latitude* of that parallel—a designation which is sufficiently significant. The extreme cases of the cone of latitude are the cylinder and the plane—the former belongs to the equator, the latter to the pole; the angle of the former is 0, that of the latter 180°. The straight line from a point of contact to the vertex of the cone, is the horizontal meridian of that point of contact. The imaginary cone, of course, rotates with the earth, if the latter rotate, but not else; and the axis of the earth is, when prolonged, also the axis of the cone. All this is obvious.

Let now P (Fig. 22), be the centre of the circular top of the table, P P′ half its meridional diameter, N S the axis of the earth, prolonged to meet the vertex of the cone of latitude in N. The angle N will be equal to the latitude of the point of contact P; because, if a line P C be drawn from P to the centre of the earth, the angle P C N will evidently be the complement of the latitude; consequently, since N P C is a right angle, the angle N is the latitude.

Fig. 22.



Over the point P, let now the bob of a pendulum freely hang—the longer the wire or cord by which it is suspended the better; but it must be so attached to the support above, as to be equally free to vibrate in any direction. Let the pendulum be made to vibrate in the direction of the meridian line N P′; and, *if* the earth rotate, let us try to anticipate the phenomena that will be presented to us.

The point P immediately under the bob, at rest, must rotate *slower* than the points in the meridian line more remote from the apex of the cone; so that, as the bob sweeps over these points, they must keep proceeding in *advance* of it, that is, towards the east, if P be in the north latitude, as here supposed. The rate of rotation of the bob round the cone must be the same whether it oscillate or not; because the fact of its oscillating cannot interfere with any motion of revolution round the cone it may have had, when hanging freely. We see, therefore, that the path of the pendulum, that is, its line of vibration, must *appear* to be gradually receding from the meridian line P P′ towards the *west*, making with P P′ an angle of deviation, which increases at every oscillation.

Actual experiment fully justifies these anticipations: the deviation of the track of the bob is *seen* to be in complete accordance with them; and although, in the following mathematical investigation of the exact amount of deviation in a given latitude and in a given time, allowance must be made for mechanical imperfections, and for the accidental impulse to the right or left communicated to the bob by the hand in giving the initial impulse, and which will give rise to what is called an apsidal motion, yet, with only very ordinary care, the natural tendency of the pendulum sufficiently overrules these hindrances to render the deviation of its path towards the west always palpable, and always accumulative.[*] The rotation of the earth from west to east is the only way of accounting for this apparent deviation of the path of the bob; what we really *see* is the motion of the line P P′, receding from the track of the bob, with an angular movement about the centre P, towards the east. If the pendulum can be kept swinging sufficiently long, it is plain that, as the angular deviation is always accumulative, a time will come when it shall have described a complete revolution, or 360°; or, to speak more accurately, when the radius P P′ of the table shall have revolved completely round. Let us seek to determine this time.

---

* "Physical Astronomy," in the *Encyclopædia Metropolitana*, by Sir J. F. W. Herschel; p. 648.

Time in which the Meridian Line completes a Revolution.—As the absolute direction of the oscillations remains invariable, it follows that, when the cone of latitude has turned through any angle, the original horizontal line must have turned through an equal angle; so that, when the cone has made a complete revolution, the deviation of the path of the bob, from the horizontal line, amounts to an angle equal to the plane angle given by developing the conical angle.[†] This, it is obvious, can never amount to so much as 360°, or a complete revolution of the table, except when the bob is suspended over one of the poles of the earth, the conic surface then becoming a *plane*, tangential to the sphere of the pole. Proceeding from this extreme limit towards the equator, the angle of the cone becomes less and less, till, on reaching the equator, it vanishes altogether, as before remarked; the cone then becomes a cylinder, and no deviation can take place.

It thus appears that the angle of deviation in any time, at any place, is a plane angle exactly equal to the development of the corresponding conical angle, turned through in that time by the rotation of the cone of latitude. It remains to be ascertained what part this angle of deviation is of a complete rotation, or 360°. In other words, we have to ascertain what part of 360° the developed angle at the apex of the cone of latitude amounts to.

Conceive an upright cone, unconnected with the globe, and from its apex let any two straight lines be drawn along the slant side, intercepting an arc of the base; this arc will measure a certain angle at the centre of the base. Measure from the apex along either of the two lines drawn from it, a length equal to the radius of the base, and describe with this length, as radius, a circular arc, limited by the two straight lines on the cone: this arc will evidently measure the conic angle; it will therefore be to the corresponding arc of the base, as the angle at the apex to the corresponding angle at the centre of the base; but the developed arcs are also to one another as their distances from the apex: for these distances are their radii. Hence, the conic angle is to the corresponding plane angle—or angle at the base on the horizontal plane—as the radius of the base of the cone to the length of the slant side; that is, as the sine of half the plane angle of the cone to unity. Consequently, the whole conic angle is to 360° as the sine of half the plane angle of the cone—that is, as the sine of the latitude is to unity. Hence, from what is shown above, the angle of deviation, or of the path of the bob, in one entire rotation of the earth, is to 360° as the sine of the latitude is to unity. The *time* of this rotation is 24 hours; consequently, 24 hours divided by the sine of the latitude, is the time in which the path of the pendulum makes a complete revolution in that latitude. Thus, assuming the deviation to be 360°, we have—the angle of rotation of the earth in any time being x—

$$x = \frac{\text{angle of deviation}}{\text{angle of rotation}}$$

$$360 = x \text{ sin. lat.}, \therefore x = \frac{360^\circ}{\text{sin. lat.}}, \text{ in } \textit{degrees.}$$

$$\therefore x = \frac{24 \text{ hours}}{\text{sin. lat.}}, \text{ in } \textit{time.}$$

And all the more carefully conducted experiments justify this result, within those limits of difference that they may reasonably be attributed to the disturbing causes adverted to above.

We have further obtained, from a few simple considerations, the following interesting proposition, namely:—

The length of the arc of the rim of the table, subtending the angle of deviation at its centre, which a pendulum oscillating over it makes during one rotation of the earth, is exactly equal to the difference between the parallel of latitude described by that centre, and the parallel described by the extremity P′ of the meridional diameter of the table.

Draw P*c* (Fig. 22), P′*c*′ perpendiculars upon the axis of the earth, and P D parallel to the axis N S. It has been proved above that the angle of deviation in one revolution of the earth is

$$360^\circ \text{ sin. N} = 360^\circ \frac{P'c'}{P'N} = 360^\circ \frac{P'D}{P'P}$$

This angle, multiplied by the radius P P′ of the table, and by 3·1416, and the product divided by 180°, is the arc of the rim of the table subtending it; that is, the measure of this arc is 2 P′ D × 3·1416. But twice P′ D is the difference between the diameters of the two parallels described by P and P′. Hence the arc that measures the angle of deviation in one rotation of the earth, is equal to the difference between the two circumferences described by P and P′. And the arc of deviation, due to any portion of a complete rotation of the earth, is equal to the difference between the two portions of parallels described by P and P′.

The same conclusion may be obtained by aid of considerations still more simple. It is plain that the difference between the circumferences of any two equidistant circles on the surface of a cone is always the same; hence, if a circle be described about the apex, with a radius equal to P P′, the circumference of it will be equal to the difference between the two circumferences described by P and P′. But this same circumference, when the cone is developed, is the arc of deviation, on the table, due to a complete rotation of the earth: hence, this arc must be equal to the difference between the two parallels described by P and P′ in a complete rotation.

It thus appears, not only that the pendulum experiment affords ocular demonstration of the rotation of the earth, but that it moreover exhibits to us the actual velocity, in linear measure, with which the point P′ proceeds in advance of P. It is the velocity with which the arc of deviation increases.

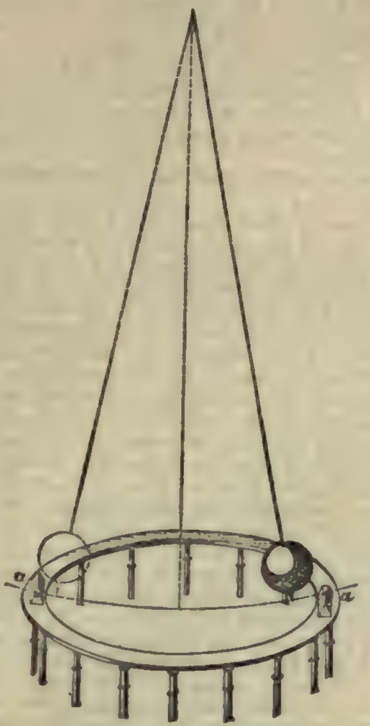
If the length of this arc, described in any interval of time, be measured, we may readily deduce the arc that would be described in a complete rotation of the earth. If the length of this arc be taken for the circumference of an entire circle, the diameter of that circle may be inferred; this diameter, applied as a chord to the circle of deviation, will subtend an arc of it, the degrees and minutes of which will be double the latitude of the place. And thus we may conceive it possible that a person, conveyed to a dungeon in some unknown part of the world, with a piece of string and a weight at hand, might form an estimate of the latitude of his position. The following diagram shows the method of trying the experiment. The path of the bob is between the points *a a* (Fig. 23):—

---

[*] In the experiment as performed at the Royal Institution of Great Britain, the impulse was not given by the hand; the bob was drawn out of the vertical by a silken thread, the end of which was fastened to a peg in the floor; a flame was then applied to the thread, and the ball set free. The author of this treatise first witnessed the experiment at the house of a scientific friend, W. H. Spiller, Esq., of Highgate: in the different repetitions of it the suspending wire, nearly twenty feet in length, was of different metal, and the hand was employed to let the bob go; the deviation was quite palpable in eight minutes.

[†] The proper distinction must, of course, be observed by the reader between the angle of the cone and the conical angle. The angle of the cone is the plane angle of the isosceles triangle, which the section of the cone through its axis presents; the conical angle is the angle at the vertex, formed by the surface of the cone: if this surface be cut along the straight line which may be conceived to generate it, and then the surface developed or unfolded into a plane, the conical angle will become an equivalent plane angle.

Fig. 23.



Application to an Unexplained Phenomenon in Falling Bodies.—The idea of the cone of latitude will subserve the purpose of accounting for circumstances in the late M. Oersted's experiments on falling bodies, hitherto, we believe, involved in some obscurity. The following quotation is from the *Literary Gazette* of March 22, 1851:—"One of the most important observations first made by Oersted, and since then confirmed by others, was, that a body falling from a height, not only fell a little to the east of the true perpendicular—which is, no doubt, due to the earth's motion—but that it fell to the *south* of that line: the cause of this is, at present, unexplained. It is no doubt connected with some great phenomenon of gravitation which yet remains to be discovered."

The explanation of this phenomenon is very easy. Suppose a heavy body to be let fall from a point at a considerable height vertically over P (Fig. 22): when it is let go, the body will have a progressive velocity towards the east, *greater* than the velocity of P at the foot of the vertical; and this velocity it will preserve throughout its descent, which, from the nature of the gravity, must be in a vertical plane through P C, C being the centre of the earth. Now the point P, at the foot of the vertical line, *recedes* from this plane, towards the north, during the descent of the body: it always keeps in the plane through P*c*, and perpendicular to the axis of the earth, and describes a circle whose radius is *c*P on the cone of latitude. The body, therefore, must necessarily fall towards the *south* of P, as well as towards the east. If the experiment be made in south latitude, the deviation will, of course, be north instead of south.

It is plain that, in Oersted's experiment, the falling body, by the rotation of the earth, and, therefore, by its own more rapid easterly motion, had advanced more towards the east, when it reached the ground, than the point P at the foot of the vertical, but it had not advanced at all towards the south; it was the foot of the vertical—the point P—that had receded towards the *north*.

These experiments prove, in the most satisfactory manner, that the earth really rotates on its axis: we are made sensible of this rotation in other ways also. "It is well known to engineers, that when railway carriages are going north, their tendency is to run off the rails on the east side; but when the train is going south, their tendency is to run off on the west side of the track; that is, always on the right hand."* In the former case, the train, at starting, is moving eastward with a velocity greater than that with which any more northerly point of the track moves; and in the latter case, it is moving more slowly towards the east than any more southerly point of the track, and hence the uniform tendency to escape the confinement of the rails towards the right.†

Explanation of Terms in Nautical Astronomy.—What are called the heavenly bodies, appear, to an observer on the earth, to occupy a surrounding spherical concavity, at the centre of which our planet is placed: the phenomena of their rising and setting are appearances which necessarily present themselves in consequence of the rotation of the earth about its axis. This apparent concavity is called the celestial sphere, and the imagination traces upon it a variety of circles, analogous to those conceived to be traced on the terrestrial globe.

To assume, however, that what we call the starry heavens is really a concave sphere, whose centre coincides with that of the earth; and, therefore, that all the celestial bodies situated in it are at equal distances from that centre, would be to oppose what is well known to be truth; but the part of Astronomy with which we are at present concerned is occupied mainly with appearances, not with realities; or, we should rather say, it is chiefly occupied with the consideration of those astronomical phenomena which are independent of actual distances, and which would equally present themselves were these distances other than what they are, or, as they all appear to be, the same.

The learner will readily perceive how this assumption of a surrounding celestial sphere is perfectly consistent with correct deductions in certain departments of astronomy—all those departments, for instance, which regard only the angular distances of the stars from one another, or from the imaginary circles before alluded to. The angular distance of two objects—whether on the earth or in the heavens—is the angle formed at the eye of the observer by lines drawn to it from the objects observed. If one or both of these objects move nearer to the eye, along the line of vision, or recede further from it, it is plain that the *angular* distance of the two must remain the same;—the objects cannot, in this way, increase or diminish their angular separation. The observer therefore may, if he please, consider the linear distances of the two objects from his eye to be the same.

Nautical Astronomy has a good deal to do with observations of this kind—that is, with the measurement of angular distances, and but very little with linear distances. It would have *nothing* to do with linear distances if the earth were really a point, or if observations were all carried on at the centre instead of on the surface; but, as it is, the semi-diameter of the earth is a linear measure of which cognizance must be taken, simply because *appearances*—in reference to the sun and moon, but not in reference to the stars—are different at the surface, from what they would be at the centre. Hence, the angular distances are not exactly the same from the two points of observation.

What is here said of distances applies equally to magnitudes. The linear diameters of the sun and moon are not matters of concernment in Nautical Astronomy, only their apparent diameters, the diameters (taken in angular measure) they would appear to have, to an observer at the centre of the earth.

All observations made upon these two bodies, for the purpose of determining the latitude and longitude at sea, are reduced to what they would be if the place of observation were the centre of the earth. As to the stars, it is found that observations on them, though made at the surface, would require no modification if made at the centre—the radius of the earth being a mere point in comparison to their immense distance. We shall now define the principal circles of the celestial sphere.

---

* Maury's *Physical Geography of the Sea*, p. 39.

† We may observe, that whilst personally agreeing with most of the arguments which Professor Young has advanced, and having made the experiment repeatedly, the whole subject has excited great difference of opinion; and we are inclined to suggest, that the theory of the pendulum experiment is more satisfactorily established than its facts.—Ed.

Axis.—The axis of the heavens is the diameter of the celestial sphere, about which the apparent diurnal revolution of the celestial sphere takes place, and which, as we have seen, is due to the real rotation of the earth. The axis of the heavens is, therefore, only the axis of the earth prolonged; and the extremities of this axis—of course the *imaginary* extremities—are the poles of the heavens.

Equinoctial.—The celestial great circle, to the plane of which the axis of the heavens is perpendicular, is called the *equinoctial*, or the celestial equator. It is traced out merely by extending the plane of the terrestrial equator to the heavens.

Meridians.—The celestial meridians are, in like manner, marked out by extending the planes of the terrestrial meridians; or they are semicircles terminating in the poles of the heavens, and perpendicular to the equinoctial.

Zenith, Nadir.—The zenith is that point in the heavens which is directly over the head of the spectator; or, if a straight line be drawn from the centre of the earth to any spot on its surface, and then prolonged to the heavens, the point on the celestial sphere which it would mark out is the *zenith* of that spot. The same line continued in the contrary direction would mark a point in the celestial sphere called the *nadir*. These two points, therefore, in reference to any place on the earth, are at the extremities of that diameter of the celestial sphere which is perpendicular to the plane of the horizon of that place:—that is, they are the *poles* of the horizon.

Vertical Circles.—Vertical circles of any place are those which pass through the zenith and nadir of that place; they are all perpendicular to the horizon of that place. They are hence, also, called circles of altitude.

The *altitude* of a celestial body is its distance above the horizon, measured on the vertical circle passing through the body. The complement of the altitude is the *zenith distance*. In the case of the sun and moon, the *true* altitude is measured from the rational horizon, and is a little greater than the altitude measured from the sensible horizon. In the case of the stars, as observed above, the difference in altitude is insensible, whichever horizon be referred to.

The most important of all the vertical circles of any place is the *meridian*. When a celestial object is on the meridian, its altitude is the greatest which that object can possibly have; it is called the meridian-altitude of the object.

The vertical circle which cuts the meridian at right angles, and which, therefore, passes through the east and west points of the horizon, is distinguished next to the meridian. It is called the *prime vertical*. When a celestial object arrives at the prime vertical, it is either due east or due west.

Azimuth.—The azimuth of a celestial object is the arc of the horizon, comprehended between the meridian of the observer and the vertical circle passing through the object. The arc of the horizon here spoken of is, of course, the measure of the angle at the zenith, between the meridian and the vertical, through the object. Vertical circles are, sometimes, called azimuth circles.

Amplitude.—Amplitude is also an arc of the horizon. It is the arc comprised between the east point of the horizon and the point where the body rises, or between the west point and where it sets; the former arc is called the rising amplitude of the body, and the latter its setting amplitude. Azimuth is measured either from the north or south points of the horizon; amplitude either from the east or west. When we speak of the azimuth of a body, we refer merely to the azimuth of the vertical on which the body is, whatever its altitude on that vertical may be; when we speak of its amplitude, we refer exclusively to its position with respect to the east or west point of the horizon at rising or setting.

Declination.—The declination of a celestial object is its distance from the equinoctial, measured on the celestial meridian passing through it, and is either north or south. What is latitude as respects a point on the earth, is declination in reference to a point in the heavens. Celestial meridians are thus, sometimes, called circles of declination; and what are parallels of latitude on the earth, become parallels of declination on the celestial sphere.

The distance of an object from the elevated pole is the polar distance of it. It is the complement of the declination when the elevated pole and the object are both on the same side of the equinoctial; but when they are on contrary sides the polar distance is the declination plus 90°. The elevation of the pole above the rational horizon of any place is always equal to the latitude of that place, for the latitude is equal to the distance of the zenith of the place from the equinoctial; the distance between the zenith and the elevated pole is, therefore, the complement of the latitude, and it is equally the complement of the elevation of the pole above the rational horizon: this elevation, therefore, is equal to the latitude of the place. Consequently, the depression of the equator below the horizon, or its elevation above the horizon, in the opposite quarter, is the complement of the latitude, or, which is the same thing, the latitude is the measure of the angle which the horizon makes with the equator.

The celestial circles now defined, have especial reference to the earth. The meridian and the equinoctial are merely extensions to the heavens of corresponding circles on the earth; and the vertical circles, or perpendiculars to the horizon, are imagined for the purpose of recording altitudes above the horizon, measured on the earth. But there are some circles peculiar to the celestial sphere; the principal of these are the *ecliptic*, or the circle of celestial longitude and the perpendiculars to it—the circles of celestial latitude.

The Ecliptic.—The ecliptic is the great circle described on the celestial sphere by the sun in its apparent annual motion about the earth: in reality, it is the path of the earth about the sun in the contrary direction; but, as already remarked, we are in this subject only concerned with the appearances. The ecliptic crosses the equinoctial at an angle subject to continuous but very small variation, determinable by observation. It is always given, with the utmost attainable accuracy, in the *Nautical Almanac*. The obliquity at present is about 23° 27½′.

The two points where the ecliptic crosses the equinoctial are called the equinoctial points. The sun, in its apparent annual course, passes through these points about the 21st of March and the 23rd of September; the former being the time of the vernal equinox, and the latter of the autumnal equinox: these names being given because the night is then equal to the day at all places where the sun rises and sets. This is obvious, because any point in the equinoctial, by the diurnal rotation of the earth—or the apparent rotation of the heavens—is just as long below the horizon of any place as it is above it.

Celestial Longitude.—The circle on which the longitude of any heavenly body is measured is the ecliptic, not the equinoctial; and as terrestrial longitude is measured from a fixed point of the equator, the point (with *us*) where the meridian of Greenwich crosses it, so celestial longitude is measured from a fixed point in the ecliptic—namely, the vernal equinoctial point, which is called the first point of the constellation Aries.

As respects terrestrial longitude, the fixed point from which the reckoning commences is only fixed for particular nations, each kingdom choosing its own: this is some inconvenience. But, as respects celestial longitude, there is perfect uniformity of reckoning among astronomers; and this reckoning—unlike that for terrestrial longitude—is carried on in one direction round the celestial sphere; so that a body may have any longitude short of 360°.

The ecliptic is conceived to be divided into twelve equal parts, called *signs;* a sign is therefore an arc of 30°. The twelve signs have the names and symbols following:—

1. ♈ Aries (The Ram).
2. ♉ Taurus (The Bull).
3. ♊ Gemini (The Twins).
4. ♋ Cancer (The Crab).
5. ♌ Leo (The Lion).
6. ♍ Virgo (The Virgin).
7. ♎ Libra (The Balance).
8. ♏ Scorpio (The Scorpion).
9. ♐ Sagittarius (The Archer).
10. ♑ Capricornus (The Goat).
11. ♒ Aquarius (The Water-bearer).
12. ♓ Pisces (The Fishes).

The first six of these lines are to the north of the equinoctial, and the others to the south: they are also called Signs of the *Zodiac*—the name given to a belt of the heavens 8° on each side of the ecliptic.

Celestial Latitude.—As the ecliptic is the circle of longitude, the perpendiculars to it, that is, the great circles through the poles of the ecliptic, are the circles of latitude. The distance of a celestial object from the ecliptic, measured on one of these perpendiculars, is its latitude; it is north or south, according as the object is on the north or south side of the ecliptic.

Right Ascension.—The right ascension of a celestial object is the arc of the equinoctial intercepted between the first point of Aries and the declination circle, or meridian passing the object.

The learner will perceive that the first point of Aries is the starting-point from which both longitude and right ascension are measured; and that, what on the terrestrial globe would be longitude and latitude, on the celestial globe are right ascension and declination—the first point of Aries being substituted for the meridian of Greenwich.

Great circles, all of which pass through the poles of any of the more important great circles of the sphere, are frequently called *secondaries* to the latter. This is a very convenient term: thus, vertical circles are secondaries to the horizon; meridians, or declination circles, are secondaries to the equinoctial; and circles of celestial latitude are secondaries to the ecliptic.

ON TIME.—The most important portion of time, in matters connected with nautical astronomy, is the *day* and its subdivisions. There are several kinds of day referred to in astronomy; but the period occupied by a single rotation of the earth, comprises, in each case, nearly the whole of the time so designated. If the heavenly bodies were all fixed, and the earth had no progressive motion, but only its present diurnal rotation on its axis, all days would be alike as to length, since the diurnal rotation is always performed in the same time; the interval between the departure from, and the return to, the meridian of any heavenly body would then be invariably the same. But, as the earth is continually shifting its place in its orbit, and that by an amount which is not uniform, the interval between two successive passages of the sun over the meridian of any place is variable. This interval is called an *apparent solar day.*

Apparent Time.—When the sun is on the meridian of any place, it is *apparent noon* at that place; when it is in any other position, the angle between the meridian of the place and that on which the sun is, is called the *hour angle* from noon at that place and instant; this angle, converted into time, at the rate of 15° to an hour, is the apparent time at the place.

Mean Time.—As, on account of the inequality of the earth's motion in its orbit, the solar day is continually varying in length, a day that is the average, or mean, of these variable days is fixed upon for civil reckoning; and it is the length of such a mean day that is marked out by the twenty-four hours of a common clock or watch. This length of time is called a *mean solar day;* and any time shown by a correct clock or watch is mean solar time, or simply *mean time.* At certain periods of the year the sun will thus arrive at the meridian before the clock points to XII.; and at other periods the clock will be in advance of the sun: the interval between the arrival of the index of the clock to XII., and of the sun to the meridian, is called the *equation of time.* It is given for every day in the year, at page 1 of the *Nautical Almanac,* for the meridian of Greenwich; that is to say, when it is apparent noon at Greenwich, on any day of the year, the almanac shows the time to be added or subtracted to obtain the corresponding mean time at that meridian.

Sidereal Time.—A sidereal day is the time occupied by one complete rotation of the earth on its axis. This interval is ascertained by observing the time elapsed between two successive passages of the same fixed star over the meridian. Such is the immense distance of the stars, that the earth's change of place, from day to day, produces not the slightest effect upon their apparent positions, which are preserved the same as if the earth were at rest. Whatever star be observed, and whatever be the place of the earth in its orbit, it is uniformly found that the interval of two successive passages of the star over the meridian is invariable—namely, 23h. 56′ 4·09″ of mean time.[*]

Besides the *three* kinds of day here described, there is also the *lunar day,* which is the interval between two successive passages or transits of the moon over the meridian; the *average* length of it is 24h. 54m. But navigators have nothing to do with lunar time; what they are most concerned with are apparent time and mean time—the time that would be shown by a properly constructed sun-dial, and the time shown by a well-regulated chronometer. The time determined by observations at sea, which is in general deduced from the sun's hour-angle with the meridian of the place, is, of course, apparent time. It is turned into mean time by help of the table of the equation of time at page 1 of the *Nautical Almanac*—the phenomena, predicted in that important publication, for the use of seamen in finding the latitude and longitude at sea, being recorded in mean time, just like the transactions of common life.

But there is this difference between the civil and the astronomical mode of reckoning: the civil day reckons from twelve o'clock, at *midnight,* and the whole twenty-four hours is divided into two sets of twelve, the counting recommencing at twelve o'clock, noon; but astronomers commence their day at noon, and count on through the twenty-four hours, from 0 hours up to 24 hours, when another day begins. Consequently, the common or civil reckoning is always twelve hours in advance of the astronomical reckoning, both reckonings being in reference to mean time: so that, to deduce the civil from the astronomical time at any instant, we have only to add twelve hours to the latter. For instance, Jan. 1, 15h. 35m., astronomical time, is Jan. 2, 3h. 35m., in the morning, civil time.

It is indispensably necessary that the learner have clear conceptions of apparent and mean time: the former is at once ascertained by observation of the true sun's hour-angle from the meridian; the latter is not pointed out by nature, but is arbitrarily chosen for practical convenience: its measure is not ascertained immediately from observation, but computed from the actual phenomena. Astronomers conceive an imaginary sun, called the *mean* sun, to move uniformly in the equinoctial, and with a motion in right ascension exactly equal to the real sun's mean or average motion in right ascension, so that the interval between two consecutive transits of the mean sun is a mean solar day—the mean, that is, of all the variable solar days of the year of the true sun. It is the motion of this imaginary sun that is measured by a chronometer; it completes every revolution in exactly twenty-four common hours; the twenty-four hours completed by the real sun—which twenty-four hours is a variable interval—is the apparent solar day. The twenty-four hours completed in one revolution of a star is a fixed and invariable period; and, as already remarked, is about 3m. 56s., mean time, less than a mean solar day. The sidereal day commences when the first point of Aries is on the meridian, and continues till its return.

---

[*] The whole starry heavens have, however, a slow apparent movement, arising from a real motion of the earth distinct from its rotation on its axis. This motion causes the axis to describe a minute circle round the poles of the ecliptic in about 26,000 years; the effect is to cause the apparent approach of some stars towards the pole, and the recession of others. Thus, the pole-star, as it is called, has, for many centuries, been getting nearer to the pole; it is now about 1° 34′ from it: the star will continue its approach till within about 30′, and will then recede. The physical cause of the phenomena has been noticed in treating of the Precession and Nutation, in the previous section on Astronomy.

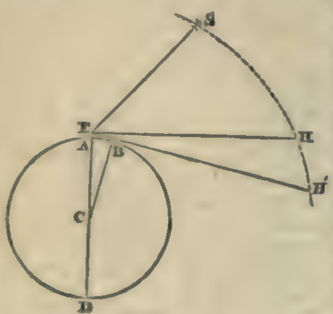
On the Corrections to be Applied to the Observed Altitudes of Celestial Objects.—The true altitude of a celestial object is the angular distance of it above the horizon of the place of observation. It is of course measured (by a quadrant or sextant) in degrees and minutes, the altitude of the zenith being 90°.

The altitude is estimated, not from the visible, but from the sensible horizon of the observer; and in the case of the sun or moon it is measured up to the centre of the body. The *observed* altitude is the angular distance of the visible horizon from the lower or upper limb of the body, so that a correction has to be made for the dip or depression of the horizon, and for the semi-diameter of the body. If the object be a star, then there is no correction for semi-diameter. These corrections being made, the result is called the *apparent altitude* of the body.

Some other corrections are necessary to obtain the *true* altitude from the apparent; these we shall speak of presently.

Dip of the Horizon.—As the eye is always elevated above the surface of the sea, the visible horizon dips below the sensible horizon, and forms an angle with it. It is the amount of this angle which must be subtracted from the observed altitude. Let E (Fig. 24) be the place of the observer's eye, and S the position of the celestial object whose altitude is to be found. The visible horizontal line is E H′, the true horizontal line E H; the altitude of S, as shown by the instrument, is the angle S E H′, instead of the angle S E H; the angle H E H′, by which the latter angle is increased, is the *dip* which must be subtracted from the observed altitude to give the apparent altitude S E H.

Fig. 24.



The angle H E H′ is equal to the angle C, since the angle C E B is the complement of each. The height, A E, of the eye being known, as also the radius C A of the earth, E B becomes known for E B² = E D × E A (Euclid, Prop. 36, Book III.), so that the amount of the angle of depression can always be found when the height of the eye above the surface is given.

Thus, let r be put for the radius of the earth, and h for the height of the eye above its surface; then, as just shown,

$$EB^2 = (2r + h)\,h = 2rh, \text{ very nearly,}$$

the quantity h^2 being omitted as insignificant in relation to $2rh$. Hence, because by right-angled triangles, $\sin. C = \frac{EB}{EC}$, and since C being always very small—only a few minutes—the arc may be taken for its sine, we have

$$\text{Dip.} = \frac{\sqrt{2rh}}{r+h} = \frac{\sqrt{2rh}}{r} \text{ (very nearly)} = \sqrt{\frac{2h}{r}}$$

which is the length of the arc (to radius 1) that measures the angle of the dip due to the height h. This length, for different values of h, is converted into minutes, and in this way the correction for dip is calculated for different altitudes of the eye, and the results arranged in a table.

Semi-diameter.—The foregoing correction for the dip of the horizon having been applied to the altitude of the point observed, if this point be the uppermost or lowermost point of the disc of the sun or moon, a correction for the semi-diameter of the body must be applied in order to obtain the apparent altitude of the centre. As the measurements in the present subject are all *angular* measurements, the correction here adverted to is the angle subtended at the eye, by the semi-diameter of the observed body. This angle, both for the sun and moon, is given in the *Nautical Almanac*. In the case of the moon, the diameter is seen under a greater angle as she approaches towards the zenith; for at the zenith she is nearer to the observer than when she is in the horizon, by a semi-diameter of the earth; and such is the comparative nearness of the moon that this difference in her distance makes a sensible difference in her apparent magnitude. The semi-diameter given in the *Nautical Almanac* is the horizontal semi-diameter, or that under which she would be seen when in the horizon; or, which is the same thing, it is the angle subtended by the semi-diameter at the centre of the earth. As this semi-diameter increases with her altitude, the increase being so much as one-sixtieth part of the whole when the moon is in the zenith—for she is about sixty semi-diameters of the earth off—the amount of increase for any altitude is found by multiplying one-sixtieth of the moon's linear semi-diameter by the sine of the altitude; and in this way the table entitled *Augmentation of the Moon's Semi-diameter*, and given in some collections of Nautical Tables, is constructed: it supplies the proper correction, to be applied additively to the horizonal semi-diameter, to obtain the semi-diameter at the given altitude.[*]

On account of the great distance of the sun, the variation of his semi-diameter, as he increases in altitude, is too minute to give any correction: it is practically insensible.

The corrections for dip and semi-diameter being thus applied, the result is the apparent altitude of the centre. As to the stars, the only correction of the observed altitude of a star, to reduce it to the apparent altitude, is the correction for dip. It remains to be shown how the true altitude is obtained from the apparent altitude: this requires two additional corrections—one for refraction, and the other for parallax.

Refraction.—The atmosphere which surrounds the earth is of variable density, the lower parts being compressed by the weight of the upper. A ray of light, therefore, from a celestial object passes through a medium, which opposes some obstruction to its free passage, the density of the medium increasing as the ray advances from the upper to the lower regions of the atmosphere, where it meets the eye of the observer. This disturbance causes the ray to be deflected or bent, the deflection being greater as the density of the medium through which it passes increases. Instead, therefore, of reaching the eye in a direct line from the object, it begins to curve as soon as it enters the atmosphere, and the curvature increases as it reaches the earth: the direction of the object from which it proceeds—which direction is judged of by the last direction the ray takes, and in which it enters the eye—thus appears to be different from its true direction: the object always, except when in the zenith, seems *higher* than it really is. Consequently, the correction for this *refraction*, as it is called, of the rays of light, like that for dip, is always *subtractive*. At the horizon it is greatest, for the rays become more bent the more obliquely they enter a refracting medium; when they strike upon it perpendicularly they are not bent at all. These facts are proved by many optical experiments.[†]

The refraction takes place entirely in the vertical plane; for contiguous to this plane, to the right and left, the medium being the same, there is nothing to divert it from its path either on one side or the other. Refraction, therefore, like dip, affects *altitudes* only. Tables for the corresponding correction of the altitude, from the horizon to the zenith, are given in all nautical collections: these, however, are computed for the *mean* state of the atmosphere; and it must occur to the reader that, as this state is continually varying in certain latitudes, it becomes necessary to modify the numbers in the table, when the true altitude of a celestial object is required with the utmost accuracy, by taking note of the actual state of the atmosphere, as indicated by the thermometer and barometer. To the table of mean refractions a table of these corrections is generally annexed. When the *latitude* only of the ship is required, the correction of the mean refraction is of comparatively little consequence; but, in determining the longitude by lunar observations, it is deserving of attention.

---

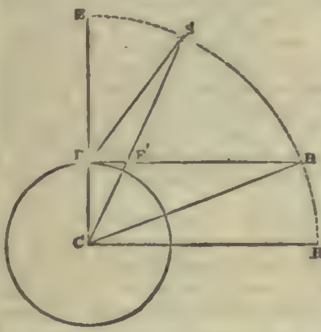
[*] This correction, amounting only to a few seconds, is frequently omitted in nautical tables, and, therefore, often neglected at sea.

[†] The student may refer to the article Refraction, in the section on Light, for fuller details on this subject.—Ed.

When the corrections, now explained, are applied to the observed altitude of a celestial object, the result is the true altitude of it above the sensible horizon of the observer; and it now only remains to reduce this to the altitude above the *rational* horizon of the place, as if the object were observed from the centre of the earth, instead of from the point on its surface immediately above the centre. In the case of a star, the altitude would be the same, whether the observation be made on the surface or at the centre—the change of position being insensible in reference to objects so remote as the stars; but, for the sun and moon, especially for the latter, the angle subtended at the body by the radius of the earth, called its *parallax in altitude*, is of sensible amount.

PARALLAX.—Let S (Fig. 25) represent the place of the celestial body observed from the surface of the earth at E; the observed angle S E H, when corrected for dip, semi-diameter, and refraction, will be the true altitude of the centre of S above the sensible horizon E H; and the angle S C R, will be the true altitude of the centre above the rational horizon C R. It is the difference of these angles that is called the parallax in altitude. If the body be in the sensible horizon, as at H, then the difference spoken of will be the whole angle H C R: this is called the horizontal parallax. For any other position of the body the parallax is less—diminishing as the object approaches the zenith, and vanishing at that elevation. Since parallax in altitude = S E′ H — S E H = E S C, the parallax is always the angle subtended by the semi-diameter of the earth at the object; and since the true altitude above the rational horizon is

Fig. 25.



$$S C R = S E' H = S E H + E S C,$$

the correction for parallax in altitude must be applied *additively* to the true altitude above the sensible horizon, to obtain the true altitude above the rational horizon. The sun's horizontal parallax is always about 9″; the moon's horizontal parallax varies considerably, and is given, together with her semi-diameter, for every noon and midnight, at page 3 of the *Nautical Almanac.* And from the horizontal parallax being known, the parallax in altitude is easily found thus. Referring to the triangle S E C, we have the proportion

$$S C : E C :: \text{sin. } S E C : E S C = \frac{E C}{S C} \text{ sin. } S E C;$$

but sin. S E C = sin. S E Z = cos. S E H; and as E C, S C are constant, it follows that the sine of the parallax in altitude varies as the cosine of the altitude; that is,

1 : cos. alt. : : sin. hor. par. : sin. par. in alt.

The parallax being always a very small angle, it is usual to substitute the seconds in the arc for the sine, so that we have, as above,

par. in alt. in seconds = hor. par. in seconds × cos. alt. And in this way the table for parallax in altitude is constructed.

We have now explained the necessary corrections for reducing the observed altitude of a celestial object to its true altitude, as seen from the centre of the earth. When the object is the sun or moon, these corrections are four in number—namely, for dip, semi-diameter, refraction, and parallax in altitude; when it is a star, there are only two corrections—namely, those for dip and refraction. The *Nautical Almanac* furnishes the necessary particulars for the other two corrections when either the sun or moon is observed: the semi-diameter of the moon, as seen from the centre of the earth, is given for intervals of twelve hours throughout the year; its value for any intermediate time is to be found in proportion, and it is the same for the horizontal parallax. In the "Explanation" which accompanies the *Nautical Almanac*, every needful information is given as to how values which vary continuously, may be determined for any proposed time, from the recorded values at stated intervals: thus—

To find the moon's semi-diameter and horizontal parallax at 6h. A.M. (that is, *before* noon) on February 23rd, 1846, at a place 15°, or 1h., to the east of Greenwich.

The civil time at the place, expressed in mean astronomical time, is February 22nd, 18h., from which, subtracting 1h., because the place is to the east of Greenwich, we have, February 22nd, 17h. for the corresponding time at Greenwich, or 5h. after midnight. Proceeding from the semi-diameter given for midnight of the 22nd, we must compute the proportional part of the variation in 12 hours, due to the time elapsed, viz., 5h.; thus, the semi-diameter for midnight, or 12h. of the 22nd, is 16′ 31″·6, and for the 23rd, at noon, or 24h., it is 16′ 34″·7; the difference, 3″·1, is the variation in 12 hours. Therefore,

12h. : 5h. : : 3″·1 : 1″·3,

which *added* (because the quantities are increasing) to 16′ 31″·6, gives 16′ 32″·9 for the moon's semi-diameter at the time proposed. Similarly, the horizontal parallax at midnight of the 22nd, is 60′ 39″, and at noon of the 23rd, it is 60′ 50″·4; the difference 11″·4 is the variation in the 12 hours, which include the given time: therefore,

12h. : 5h. : : 11″·4 : 4″·75 or 4″·8,

which *added* (because the quantities are increasing) to 60′ 39″, gives 60′ 43″·8 for the horizontal parallax required. And if with this horizontal parallax, and the apparent altitude of the moon, we enter the table entitled "Moon's Parallax in Altitude," we shall obtain the parallax in altitude. But in most nautical tables, the two corrections for refraction in altitude and parallax in altitude are combined, and the results tabulated under the head of "Correction of the Moon's Apparent Altitude," and this is the preferable arrangement when the true altitude is to be deduced.

Besides the foregoing corrections for obtaining the true altitude of a celestial object from the observed altitude, the observed altitude itself generally requires a little correction for the known error of the instrument (quadrant or sextant) employed in taking the altitude. "Human hands, or machines, never formed a circle, drew a straight line, or erected a perpendicular;"* there are, in consequence, unavoidable departures from strict mathematical accuracy in all mechanical constructions. The shortcomings may be discovered and allowed for, though not remedied—just as the gain or loss of a chronometer may be discovered, though to construct one, without gain or loss, be a practical impossibility. The *index error*—as it is usually called—of the instrument, is to be allowed for before any of the astronomical corrections are introduced; it is not constant, but varies with temperature. The following examples will sufficiently show how the several corrections are supplied.

EXAMPLE OF CORRECTING ALTITUDES AT SEA.—1. Suppose the observed altitude of a star to be 47° 10′, the height of the eye 18 feet, and the index error of the instrument to be 3′ 12″ *subtractive*. Required the true altitude.

---

* Sir John Herschel's *Treatise on Astronomy.*

Observed altitude . . .	47° 10′ 0″
Index error	−3′ 12″
	47° 6′ 48″
Dip of the horizon . .	−4′ 11″
Apparent altitude . .	47° 2′ 37″
Refraction	− 53″
True altitude . . .	47° 1′ 44″

The refraction here taken from the table is that for the mean state of the atmosphere. If the height of the barometer and thermometer be observed, the mean refraction may be corrected accordingly, by aid of a table usually placed beside that for the mean state of the atmosphere.

2. The observed altitude of the sun's lower limb on a certain day was 16° 33′, the height of the eye was 17 feet, the index error was 3′ *additive*; the barometer stood at 29 inches, and the thermometer at 58°. Required the true altitude of the sun's centre, his semi-diameter, as given in the *Nautical Almanac*, for the day, being 16′ 17″.

Observed alt. sun's L. L. . .		16° 33′ 0″
Index error		+3′ 0″
		16° 36′ 0″
Dip		−4′ 4″
Apparent alt L.L. . . .		16° 31′ 56″
Refraction .	−3′ 10″	
Correction for barom. −	7″	
„ „ therm. −	3″	
	=	−3′ 20″
True altitude of L. L. above sensible horizon . . .		16° 28′ 36″
Semi-diameter (*Naut. Alm*).		+ 16′ 17″
Parallax in altitude . . .		+ 8″
True alt. of sun's centre . .		16° 45′ 1″

The corrections for the barometer and thermometer being, as in this example, always very small, they are not attended to at sea when the latitude is the only thing to be determined. The error in the latitude arising from omitting these small quantities is too trifling to be of any consequence.

3. The observed altitude of the moon's lower limb (index error allowed for) is 31° 18; the horizontal parallax, from the *Nautical Almanac*, 58′ 37″; semi-diameter, 15′ 58″; and the height of the eye 16 feet. Required the true altitude of the moon's centre.

Observed alt. moon's L. L. . . .			31° 18′ 0″
Dip		. − 3′ 50″	
Semi-diam.	15′ 58″	. +16′ 6″	
Augmentation	8″		
		=	+ 12′ 16″
App. alt. moon's centre			31° 30′ 16″
Cor. for par. and ref. (hor. par. 58′ 37″, alt. 31½°)			+ 48′ 26″
True alt. moon's centre . . .			32° 18′ 42″

4. The observed altitude of the moon's upper limb, corrected for index error, was 41° 25′; the horizontal parallax, 55′ 40″; semi-diameter, 15′ 10″; and the height of the eye, 15 feet. Required the true altitude of the moon's centre.

Observed alt. moon's U. L. . . .			41° 25′ 0″
Dip		. − 3′ 42″	
Semi-diam.	15′ 10″	. −15′ 20″	
Augmentation	10″		
		=	−19′ 2″
App. alt. moon's centre			41° 5′ 58″
Correction for parallax and refraction .			+ 40 51″
True alt. moon's centre . . .			41° 46′ 49″

To Determine the Latitude at Sea from the Meridian Altitude of a Celestial Object whose Declination is Known.—The determination of the latitude of the ship by means of the altitude, when on the meridian, of a celestial object of known declination, is the easiest, and in general the safest, method for the purpose. The observations and the subsequent calculations being but few, they may be readily accomplished, and with but little liability to error in the result. This method, therefore, is always used at sea, whenever foggy or cloudy weather does not render it impracticable.

The celestial object observed must be one of which the declination is given in the *Nautical Almanac*, for the meridian of Greenwich. This declination may be reduced to the meridian of the ship—or rather to the time at Greenwich corresponding to that at the ship—by turning the longitude by account into time, and then applying the variation for declination due to that time, as explained at page 1077; the hourly variation of the sun's declination is given in the *Nautical Almanac*, at page 1, of each month. The longitude by account is always sufficiently near the truth for the determination of this element, though greater precision is required for the moon than for the sun, as the declination of the former changes more rapidly. The declination of the object observed being thus known at the time of observation, and, from its altitude, the zenith distance of it being also known, we have the distance of the object both from the equinoctial and from the zenith of the ship: consequently, the distance of the zenith from the equinoctial—that is, the distance of the ship from the equator—becomes known either by simple addition or subtraction; and thus the latitude is found.

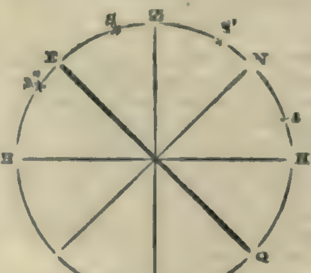
The object observed may be either above the pole or below it; that is, it may be on either the mid-day or the mid-night portion of the celestial meridian of the place; and, in the former case, it may be in either of the three following positions in reference to the equinoctial and the zenith, namely—

1. The zenith, and the object observed, may both be on the same side of the equinoctial, and the object nearer to the equinoctial than the zenith is, as at S, in the diagram below.

2. The zenith and the object being on the same side of the equinoctial, the zenith may be nearer to the equinoctial than the object is, as at S′.

3. The zenith and the object may be on different sides of the equinoctial, as at S″.

Fig. 26.



Let N Z H be the meridian, Z the zenith of the ship, N the elevated pole—the north pole suppose—and E Q the equinoctial.

First.—Let the object observed be at S, between the zenith and the equinoctial, and both *north* of the equinoctial: then for the latitude E Z, we have E Z = E S + S Z: that is,

(1). The latitude is equal to the declination, *plus* the co-altitude.

Second.—Let the object be at S′, on the contrary side of the zenith, then the latitude E Z is E Z = E S′ − S′ Z; that is, (2). The latitude is equal to the declination, *minus* the co-altitude.

Third.—Let the object be at S″, on the contrary side of the equinoctial; that is, let its declination be *south*, then the latitude is E Z = S″ Z − E S″: that is,

(3). The latitude is equal to the co-altitude, *minus* the declination.

Hence, if we call the co-altitude, or zenith distance of the object, *north*, when the zenith is north of it, and *south*, when the zenith is south of it, we shall have the following rule for all the three cases—namely,

RULE.—When the object observed is above the pole, if the zenith distance and the declination have the *same* name, that is, be both north or both south, their *sum* will be the latitude. If the zenith distance and the declination have *different* names, their *difference* will be the latitude, of the same name as the greater.

It is assumed above that the north is the elevated pole; but if it be the south, then, by merely writing south for north and north for south, the reasoning will remain the same: the rule will require no modification.

It is obvious that the elevation of the pole above the horizon of any place is always equal to the latitude of that place, for Z N is equally the complement of the latitude E Z, and of H N the elevation of the pole. The elevation of the equator, or the angle it makes with the horizon, is also clearly equal to the co-latitude.

It should be remarked, that when celestial objects are near the horizon, they are in a position less favourable for observation than when they are more elevated, because the refraction near the horizon is very variable in its effects.

LATITUDE FROM THE SUN WHEN ABOVE THE POLE.—The sun is the celestial object most commonly appealed to by mariners for the determination of the latitude of the ship: it is more frequently visible in the daytime, when, except in bad weather, the sea horizon is more clearly defined, and the corrections to be applied to the observed, in order to get the true altitude, are few and simple. The corrections for a star are still fewer; but, as the horizon is usually getting obscure when the stars begin to appear, a star is, in general, less favourable for the purpose than the sun: the moon, however, is often on the meridian under favourable circumstances, but the corrections necessary are more in number, and require to be made with greater care. We shall give suitable directions for each of these objects separately, detailing the proper corrections to be made preparatively to inferring the latitude, as briefly indicated by the general rule given above.

RULE 1.—From the longitude by account, find the *apparent* time at Greenwich; this is called the Greenwich *date.*

2. From page 1 of the *Nautical Almanac* get the noon declination at Greenwich; and, by means of the hourly difference in declination there given, and the previously found Greenwich date, find the correction due to that date; the declination at the time of observation will thus be discovered.

3. Apply to the observed altitude the proper corrections for dip and semi-diameter; the apparent altitude of the centre will then be obtained; and the corrections for refraction and parallax will reduce the apparent to the true altitude.

4. Mark the zenith distance N. or S. according as it is N. or S. of the sun: then, if the declination and zenith distance have the same marks, their sum will be the latitude; if they have different marks, their *difference* will be the latitude.

NOTE.—The first step in the foregoing rule requires the conversion of degrees, minutes, &c., of longitude into time, which is readily done from the known relations—

15° = 1h., 15′ = 1m., 15″ = 1s.;

for from these it is evident that if we multiply the degrees of longitude by 2, and then divide by 30, the quotient will be hours, and so many *thirtieths* of an hour; so that twice these thirtieths will be the additional minutes of time.

In like manner, if we multiply the minutes of longitude by 2, and divide by 30, the quotient will be the minutes of time, and so many thirtieths; that is, twice that number of seconds of time.

Suppose, for instance, the longitude is 93° 37′ 41″, we may easily convert it into time, as in the margin, thus: multiplying the degrees, minutes, and seconds by 2, we have 186° 74′ 82″.

Dividing each, separately, by 3, cutting off the unit figure of each for the 0 suppressed in the 30, we have, for the first quotient, 6 hours and 6 thirtieths—that is, 6h. 12m.; for the second quotient, 2 minutes and 14 thirtieths—that is, 2m. 28s.; and for the third quotient, 2·73s.—decimals of a second being always used instead of *thirds:* hence the time corresponding to 93° 37′ 41″ of longitude is 6h. 14m. 30·73s.

As noticed in the Introduction, page 1048, it is always advisable to make all the use we can of Tables when they are once in hand. The first Table referred to in the foregoing operation, is that given at page 1 of the *Nautical Almanac* for the sun's declination at apparent noon at Greenwich, with the hourly variation; the semi-diameter should be taken out at the same time, and inserted in its proper place; but seamen, in general, use invariably 16′ for the sun's semi-diameter. A blank form of the several particulars in such operations is of considerable assistance, as the work is thereby facilitated, and the risk of mistake diminished. The "correction in altitude"—that is, the allowance for refraction and parallax—should be taken from the Nautical Tables at the same time as that for dip in working examples;

though at sea the dip generally differs but little throughout the voyage.*

It may be remarked, that in computing the declination of the sun for the time of observation, seconds of time may be disregarded, and even a few minutes is of no practical consequence: indeed, the longitude by account is only an approximation to the correct longitude.

But, as a little consideration will be sufficient to show, the error in the estimated longitude must be very great indeed to occasion any error of practical importance in the declination of the sun at the instant of observation. If only the altitude be observed with proper care, the computer may trust to the accuracy of the resulting latitude without any nice determination of his longitude: 1° of longitude is only 4′ of time.

2. On August 14th, 1846, in north latitude, and in longitude 51° W., the meridian altitude of the sun's upper limb was 47° 26′ (zenith N.); the index correction — 1′ 47″, and the height of the eye 20 feet. Required the latitude.

Latitude . . .		49° 6′ 14″ S.

It may be remarked here, that in reducing the declination to the time at Greenwich when the observation is made, the hourly variation should, in strictness, be taken equal to 44·06, which is the average variation during the *preceding* 24 hours, or from the noon of Nov. 7th to the noon of Nov. 8th, because the 4h. 8m., for which the correction is made, is a portion of *this* 24 hours; but the difference in the correction would amount only to about 2½ seconds. Such small quantities are not worth attending to in the present problem, as the altitude of a celestial object, taken at sea, cannot be measured to within a few seconds of the truth; and if the latitude can be deduced to the nearest minute, it is all that can be reasonably expected.

To save the trouble of the preliminary reductions here adverted to, a table is given in most nautical collections, by entering which, with the sun's noon-declination and the longitude by account, the correction for declination is found with accuracy sufficient for the purposes of navigation. The table referred to is, in Norie's *Tables*, the twenty-first; we shall use it in the following example.

4. On November 21st, 1841, in longitude 165° E., the meridian altitude of the sun's lower limb was observed to be 47° 38′ (zenith N.); the index correction was — 1′ 15″, and the height of the eye 17 feet. Required the latitude.

LATITUDE FROM A STAR ABOVE THE POLE.—A fixed star changes its declination so slowly, that its variation, even in a month, is scarcely sensible; no correction, therefore, for longitude, will be necessary; the declination, as given in the *Nautical Almanac*, on the day of observation, may be taken as that at the time of observation. As a fixed star has no parallax in altitude, the only corrections will be those for dip and refraction; the rule for deducing the latitude is therefore as follows:—

---

* In some cases, however, when the voyage is long, and the complement of men considerable, the dip may sensibly increase. Captain Parry, after wintering in "Winter Harbour," in 1820, estimated the consumption of stores and provisions to have amounted, in the *Hecla*, to about seventy tons: the dip must, therefore, have increased.

Rule.—1. Apply to the observed altitude the corrections for dip and refraction; the result will be the true altitude; and this, subtracted from 90°, will give the true zenith distance.

2. Mark the zenith distance N. or S. according as it is N. or S. of the star; then, if the declination and zenith distance have the same marks, their sum will be the latitude; if they have different marks their difference will be the latitude.

Examples.

1. January 22, 1846, the meridian altitude of Arcturus was observed at sea to be 43° 27′ (zenith north); the index correction was + 2′ 10″, and the height of the eye 20 feet. Required the latitude.

Latitude	13° 57′ 15″S.

Note.—In some nautical tables the corrections for dip and refraction are united under the head of *Correction of star's observed altitude.*

Latitude from the Moon above the Pole.—The moon's declination is given in the *Nautical Almanac* for every hour of the day, and the time of her meridian passage from day to day. These elements are computed for *mean time*, the reckoning being from mean noon at Greenwich. Hence, to find the moon's declination corresponding to the time of taking her meridian altitude at sea, we must know the time at Greenwich at the instant of observation. This is ascertained as follows:—

As the motion of the moon in her orbit is eastward, her transit over the meridian of any place is delayed from day to day. In consequence of this retardation, she will pass the meridian of a place to the west of Greenwich later in the day at that place than she passes the meridian of Greenwich, and her transit over a meridian to the east of Greenwich will take place earlier in the day. How much later, or how much earlier, will be ascertained by converting the longitude of the meridian into time, and applying the corresponding proportional part of the daily variation as furnished by the *Nautical Almanac.* By help of the following short table, and the daily change in the time of transit, the correction to be added to the Greenwich time of transit, to obtain the time of transit over a meridian west of Greenwich, or to be subtracted to obtain the time of transit over a meridian east of Greenwich, may be at once found.

The daily variation, as given by the *Nautical Almanac*, is to be sought for in the top row of figures, and the longitude of the place in the marginal column on the left; the proper correction of the Greenwich mean time, to reduce it to the mean time of transit at the place, is then to be taken out from the body of the table. It is sufficient that the daily variation be taken to the nearest minute.

It must be observed, however, that in the case of the moon, there must not be the same indifference as to the accuracy of the longitude by account as is allowable in the case of the sun; the following examples will show, that on account of the moon's more rapid change in declination, a comparatively short interval of time makes a sensible difference in this element.

Table for finding the Time of the Moon's Transit over a given Meridian when the Time of the Transit at Greenwich is known, and the Daily Variation of the Time.

Longitude.	Daily Variation in Minutes of Time of Moon's Transit.													
	40m.	42m.	44m	46m.	48m.	50m.	52m.	54m.	56m	58m.	60m.	62m	64m.	66m.

180	19	20	21	22	23	24	25	26	27	28	29	30	31	32

By the aid of this table, the latitude from a meridian altitude of the moon, when above the pole, may be found as follows:—

Rule.—1. From the *Nautical Almanac* take out the time of the moon's passage over the meridian of Greenwich on the given day, as also the daily variation.

2. From the longitude by account, and the foregoing table, reduce this to the time, at the place, of the moon's passage over the meridian of the ship; the time of observation, at the place where that observation is made, will thus be found.

3. From the ship's time and longitude, find the corresponding time at Greenwich.

4. Find now the moon's declination at that time from the *Nautical Almanac*, computing the variation for the odd minutes by means of the difference in declination for 10m.

5. From page 3 of the month, take out the moon's

semi-diameter, and increase it by the "Augmentation" given in the Nautical Tables. The correction for index error, dip, and semi-diameter, will reduce the observed altitude of the limb to the apparent altitude of the centre.

6. To the apparent altitude of the centre add the correction in altitude, that is, the parallax in altitude *minus* the refraction, and the true altitude of the centre will be obtained. Subtract this from 90°, and then, by adding or subtracting the moon's declination at the time, as in the case of the sun, the latitude of the place will be ascertained.

Examples.

1. On May 27th, 1846, in longitude 49° W., the meridian altitude of the moon's lower limb was found to be 47° 18′ 30″ (zenith S.); the index correction was + 1′ 40″, and the height of the eye 20 feet. Required the latitude of the ship.

1. *For the mean time at Greenwich when the observation was made.*

Moon's transit at Greenwich, May 27th	1h. 56m.	Daily variation, 48·7m.
Cor. for long. 49° W. and 48m. variation	+ 6m.	
Time at ship when alt. was taken	2h. 2m.	
Long. 49 W. in time	3h. 16m.	
Time at Greenwich when alt. was taken	5h. 18m.	

2. *For the moon's declination at that time.*

Declination May 27th, at 5h.	18° 56′ 16″ N.	Var. in 10m., 26″·55 (dec.)
Decrease in 18m. = 2″·655 × 18 =	− 48″	
Declination at 5h. 18′.	18° 55′ 28″ N.	

3. *For the true altitude of the Moon's centre, and thence the latitude.*—At page 3, of MAY, in the *Nautical Almanac*, the moon's semi-diameter at noon on the 27th is 15′ 1″; and her horizontal parallax at the same time is 55′ 16″. Hence we get the latitude thus:—

Observed alt. of moon's L. L.		47° 18′ 30″
Index cor.	+ 1′ 40″	+ 12′ 32″
Dip	− 4′ 24″	
Semi-diameter + 11″ for augmen.	+ 15′ 16″	
App. alt. of moon's centre		47° 31′ 2″
Parallax and refraction		+ 36′ 10″
True alt. of moon's centre		48° 7′ 12″
		90°
True zenith distance		41° 52′ 48″ S.
Moon's declination		18° 55′ 28″ N.
Latitude		22° 57′ 20″ S.

It is plain that whatever be the celestial object observed, the error in the latitude will be the sum of the errors in the zenith distance and declination when both are of the same name, and the difference when they are of contrary names.

The latitude at sea is seldom computed to seconds, as the exact longitude and time of the ship, as inferred from the dead-reckoning, generally deviates from the truth. It is customary, therefore, to aim at deducing the latitude only to the nearest minute: thus, in the present example, the latitude would be concluded to be 22° 57′ S.

2. On Dec. 7th, 1840, in longitude 16° W., at 10h. 43m. apparent time, the meridian altitude of the moon's lower limb was 83° 7′ (zenith S.); the index correction was − 1′ 55″, and the height of the eye 16 feet. Required the latitude to the nearest minute. Here the time at the ship being given, we shall not require to take out of the *Nautical Almanac* the time of the moon's meridian passage at Greenwich: the Greenwich date, or mean time at Greenwich when the altitude was taken, is found thus:—

1. *For the mean time at Greenwich when the observation was made.*

Apparent time at ship, Dec. 7	10h. 43m.
Long. 16° W. in time	1h. 4m.
App. time at Greenwich	11h. 47m.
Equation of time (*Naut. Alm.*, p. 1)	−8m.
Mean time at Greenwich	11h. 39m.

2. *For the Moon's declination at that time.*

Declination, Dec. 7, at 11h. (inc.) Var, in 10′, 8″.	24° 45′ N.
Increase in 39m.	+ 6′
Declination at 11h. 39m.	24° 51′ N.

3. *For the true altitude of the Moon's centre, and thence the latitude.*

True alt. of moon's centre		83° 25′
		90°
True zenith distance		6° 35′ S.
Moon's declination		24° 51′ N.
Latitude		18° 15′ N.

Examples for Exercise.

NOTE.—In the following examples the latitude is to be determined to the nearest minute.

1. On the 2nd of May, 1833, the meridian altitude of the sun's lower limb was 47° 20′ (zenith N.); the index correction − 2′; the height of the eye 20 feet, and the longitude by account 32° E.

Also sun's dec. May 2nd, 15° 23′ 21″ N. (inc.) Hourly difference 45″.

Semi-diameter 15′ 53″ (*Nautical Almanac*).

Required the latitude to the nearest minute.

Ans. Latitude, 58° 53′ N.

2. On Jan. 9th, 1840, in longitude 116° W., the meridian altitude of the sun's upper limb was found to be 69° 14′ (zenith N.); index error 0, and height of the eye 27 feet. Required the latitude to the nearest minute.

Sun's dec. Jan. 9, 22° 12′ S. (dec.) Correction for long. 116 W., − 3′. Semi-diam. 16′.

Ans. Latitude, 1° 2′ S.

3. On May 15th, 1828, the meridian altitude of the star, Spica, was observed to be 30° 17′ (zenith N.); index correction + 1′ 10″; the star's declination was 10° 16′ S. Required the latitude to the nearest minute, the dip being − 5.

Ans. Latitude, 46° 32′ N.

4. The meridian altitude of the star Rigel was observed to be 85° 4′ (zenith N.); the index correction was + 2′, and the star's declination 8° 22′ 45″ S.; the height of the eye was 20 feet. Required the latitude to the latest minute.

Ans. Latitude, 3° 24′ S.

5. On February 19th, 1823, in longitude 40° W., the meridian altitude of the moon's lower limb was observed to be 55° 8′ (zenith N.); the index correction was − 2′, and the height of the eye 16 feet.

The moon's passage over the merid. of Greenwich, Feb. 19th . .	was 6h. 56m.
The moon's passage over the merid. of Greenwich, Feb. 20th . .	was 7h. 59m.
Declination, Feb. 19th, at noon .	26° 38′ 17″ N.
,, ,, midnight	26° 54′ 39″ N.
Semi-diameter	16′ 12″
Horizontal parallax . . .	59′ 32″

Required the latitude to the nearest minute.

Ans. Latitude, 61° 1′ N.

6. On November 12th, 1853, at 2h. 20m. mean time, in longitude 60° 42′ W., the meridian altitude of the moon's lower limb was observed to be 30° 30′ 40″ (zenith N.); the index correction was + 10′ 42″; and the height of the eye 16 feet.

Moon's declination, Nov. 12, at 6h.	2° 44′ 20″ N.
,, ,, ,, 7h.	2° 57′ 38″ N.
Semi-diameter	15′ 12″
Horizontal parallax	55′ 13″

Required the latitude to the nearest minute.

Ans. Latitude, 61° 11′ N.

To determine the latitude from the meridian altitude of a celestial object when below the pole.—In the diagram (Fig. 26), at page 1078, let *s* be the position of a celestial object when on the meridian of the place whose zenith is Z, and below the elevated pole N; the altitude of it will be H *s*, and *s* N will be the complement of its declination Q *s*. Consequently, the altitude added to the co-declination will be the latitude H N of the place whose zenith is Z (page 1078). The sun is on the meridian of any place, below the pole, 12 hours after the apparent noon at that place; consequently, 12 hours, increased or diminished by the longitude in time, according as the place is W. or E. of Greenwich, will be the apparent time at Greenwich when the observation was made; and the declination corresponding to this time may be found as in the foregoing examples.

For a star, the declination will be the same as that given for the day, in the *Nautical Almanac*; since, as before remarked, the change in the declination of a fixed star is insensible till after the lapse of several days.

For the moon, the time of transit over the mid-day portion of the meridian of the place may be found as at page 1081; and this time increased by 12 hours, and by half the daily difference of time, will be the time of her returning to the meridian below the pole; and the proper reduction being made for longitude, as in the case of the sun, the time at Greenwich, and thence the corresponding declination, may be found. The rule for computing the latitude is therefore as follows:

RULE.—1. Find the declination of the object at the time of observation.

2. To the observed altitude apply the proper corrections for deducing the true altitude.

3. To the true altitude add the co-declination; the sum will be the latitude, of the same name as the declination.

LATITUDE FROM THE SUN WHEN BELOW THE POLE.—As the rule just given applies equally to the sun, moon, or star, special directions for each case will be unnecessary; we shall, therefore, give a practical illustration of the mode of working for each object separately, and then add an example or two for exercise. The following is an example when the object is the sun:—

Example.—On June 18th, 1853, in north latitude, and in longitude 96° W., the meridian altitude of the sun's lower limb, at apparent midnight, was observed to be 8° 36′; the index correction was − 2′; and the height of the eye 20 feet. Required the latitude.

For the declination at the Greenwich time of observation.

Apparent time at ship, June 18 . .	12h. 0m.
Longitude 96° W. in time	6h. 24m.
Apparent time at Greenwich . . .	18h. 24m.
Sun's declination at noon, June 18 .	23° 25′ 36″ N. (inc.)
Correction for 18h. 24m.	+ 40″
Declination at time of observation .	23° 26′ 25″ N.
	90°
Co-declination	66° 33′ 35″

Observed alt. of sun's L.L. . . .		8° 36′ 0″
Index cor. − 2′	. . . .	+ 9′ 22″
Dip . . − 4′ 24″		
Semi-diam. + 15′ 46″		
App. alt. of centre		8° 45′ 22″
Refraction and parallax		− 5′ 49″
True alt. of centre		8° 39′ 33″
Sun's co-declination		66° 33′ 35″
Latitude		75° 13′ 8″ N.

LATITUDE FROM A STAR WHEN BELOW THE POLE.—In northern latitudes, the star called the pole star is very convenient for the purpose of finding the latitude of the ship, and is, therefore, frequently observed by mariners for this object. The following is an example:—

Example.—On March 1st, 1823, the observed altitude of the pole star when on the meridian below the pole, was 30° 7′; the index correction was + 2′; and the height of the eye 18 feet. Required the latitude.

Observed altitude of pole star . .		30° 7′ 0″
Index cor. + 2′	. . . . .	− 2′ 11″
Dip . . − 4′ 11″		
		30° 4′ 49″
Refraction		− 1′ 38″
True altitude of star		30° 3′ 11″
Co-declination Mar. 1, 1823 . . .		1° 38′ 2″
Latitude		31° 41′ 13″ N.

LATITUDE FROM THE MOON WHEN BELOW THE POLE.—The preliminary corrections for the moon, as already seen, are more numerous than those for the sun or for a star; a specimen of them is given in Example 1, p. 1082. These corrections are of course the same, whether the moon be observed on the meridian above the pole or below it. In the following example the moon's declination is found as at the page just referred to, so that the reductions need not be repeated here.

Example.—On the 27th of May, 1846, in longitude 49° W., the meridian altitude of the moon's lower limb, when below the pole, was found to be 7° 12′; the index correction was − 1′ 40″; and the height of the eye 20 feet. Required the latitude.

The moon's declination at the time when the observation was made, was found, at page 1082, to be 18° 55′ 28″ N.: hence the operation for finding the true altitude of the moon's centre, and thence the latitude of the place, is as follows:—

Observed alt. of moon's L.L. . .		7° 12′ 0″
Index cor. . — 1′ 40″	. . .	+ 9′ 12″
Dip . . . . — 4′ 24″		
Semi-diam. augmented + 15′ 16″		
App. alt. of centre		7° 21′ 12″
Parallax and refraction		+ 47′ 31″
True alt. of moon's centre . . .		8° 8′ 43″
Co-declination		71° 4′ 32″
Latitude		79° 13′ 15″ N.

Examples for Exercise.

1. On June 28th, 1841, in longitude 126° W., the altitude of the sun's lower limb at midnight was 6° 28′; the index correction was + 2′ 15″; and the height of the eye 20 feet. Required the latitude to the nearest minute, the sun's declination at noon, Greenwich time, on the 28th, being 23° 17′ 59″ N. decreasing, and his semi-diameter 15′ 45″. Ans. Latitude, 73° 19′ N.

2. The observed altitude of the sun's lower limb, when on the meridian below the pole, was 7° 5′; its declination at the time of observation was 23° 8′ 17″ N.; its semi-diameter 15′ 45″, and the height of the eye 20 feet. Required the latitude, the index error of the instrument being 0. Ans. Latitude, 74° 1′ N.

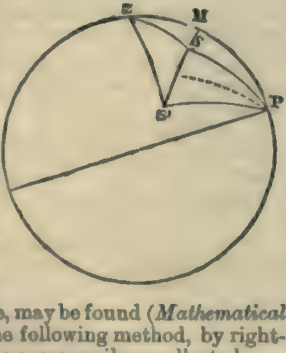
3. June 1st, 1823, the observed altitude of the star Capella, when on the meridian below the pole, was 10° 1′ 30″; its declination was 45° 48′ 27″ N.; and the height of the eye 17 feet. Required the latitude.

Ans. Latitude, 54° 4′ N.

The foregoing examples exhibit the different means of determining the latitude at sea, by taking the altitude of a celestial object when upon the meridian of the ship. Whenever practicable, the sun is always the object observed, and its mid-day altitude is that which is to be preferred, because at mid-day it attains its greatest elevation, and the refraction is less liable to variation from the mean state of the atmosphere. The altitude below the elevated pole can be taken only in high latitudes, where the sun is above the horizon during the whole twenty-four hours for a part of the summer, and, therefore, the horizon clearly visible: the obscurity of the horizon often precludes the possibility of accurately measuring the altitude of a star; and on account of its rapid change in declination, the moon is less suited for the purpose of deducing the latitude, when there is much uncertainty as to the longitude of the ship, or the time at Greenwich when the observation is made. In preparing for a meridian altitude, the observer holds himself in readiness, before the object attains its greatest elevation, and continues to observe it till it ceases to rise and appears for a moment stationary; at this instant its altitude is noted, and it is regarded as upon the meridian. Strictly speaking, however—at least as respects the sun and moon—the centre of the object is not necessarily exactly on the meridian when its altitude is the greatest or least; for the change in declination may more than counterbalance its change in altitude during the few minutes which precede its meridian transit, especially in the case of the moon; but these differences are too trifling to lead to any error of practical importance. It may, however, happen that the object becomes hidden by a cloud at the time of transit, so that the meridian observation cannot be made; it is of importance, therefore, to take note of the altitudes before the transit, as an altitude *near* the meridian may be made available for the determination of the latitude, as we are now about to show: we shall first, however, explain how to find the latitude generally when the object observed is off the meridian, provided the hour angle, which its declination-circle makes with the meridian of the ship, is known.

To find the Latitude from the Declination, Altitude, and Hour Angle.—Let Z be the zenith, and P M Z the celestial meridian of the ship, P the elevated pole, and S the place of the heavenly body off the meridian; then P S is the co-declination, Z S the co-altitude, and P Z the co-latitude. In the spherical triangle P Z S, there is supposed to be known the three parts, P S, Z S, and the hour angle P, which, for the sun, is the time from noon. Hence, by Spherical Trigonometry, P Z, the co-latitude, may be found (*Mathematical Sciences*, page 661). But the following method, by right-angled triangles only, will be more easily recollected.

Fig. 27.



Draw S M, perpendicular to the meridian: we shall then have two right-angled triangles P M S and Z M S; and applying Napier's rules to these (page 660), we have—

From the triangle P M S, taking P for middle part, and P S, P M, for adjacent parts,

$$\text{cos. } P = \text{cot. } PS \text{ tan. } PM \therefore \text{tan. } PM = \text{cos. } P \text{ tan. } PS \quad . \quad . \quad (1)$$

Also, from the same triangle, taking the hypotenuse P S for middle part, and P M, S M, for opposite parts,

$$\text{cos. } PS = \text{cos. } PM \text{ cos. } SM \quad . \quad . \quad (2)$$

And from the triangle Z M S, taking in like manner the hypotenuse Z S for middle part, and Z M, S M for opposite parts,

$$\text{cos. } ZS = \text{cos. } ZM \text{ cos. } SM \quad . \quad . \quad (3)$$

Therefore, dividing (2) by (3), in order to get rid of S M we have—

$$\frac{\text{cos. } PS}{\text{cos. } ZS} = \frac{\text{cos. } PM}{\text{cos. } ZM} \therefore \text{cos. } ZM = \text{cos. } PM \text{ cos. } ZS \text{ sec. } PS \quad . \quad . \quad (4)$$

As Z M is thus expressed in terms of the given quantities, and as P M is also in like manner known from (1), the difference (or the sum, if M fall between P and Z) P Z, that is, the co-latitude becomes known.

The formulæ (1) and (4) to be combined are

$$\left.\begin{array}{l}\text{tan. } PM = \text{cos. hour angle} \times \text{cotan. dec.} \\ \text{cos. } ZM = \text{cos. } PM \text{ sin. alt.} \times \text{cosec. dec.}\end{array}\right\} (A)$$

To know the hour-angle P, it is necessary to know the time at the ship. The chronometer shows the mean time at Greenwich; and hence, by help of the longitude by account, we may find the mean time of observation nearly; this, reduced to apparent time, by applying the correction for the equation of time taken from the *Nautical Almanac*, will make known the time from apparent noon at the ship. The longitude by account is, however, most likely affected with error, and it is therefore desirable that the altitude off the meridian be taken at such a time as that a small error in the hour angle may have the least influence on the determination of tan. P M. Now, whenever we have to employ the cosine of a small angle, and have reason to suspect that the angle itself has not been accurately determined, the error in the cosine will be smaller as the angle itself is smaller; for the cosines of arcs near the beginning of the quadrant differ very little from one another within the limits of several seconds, and the difference becomes less as the arc approaches to zero (see *Introduction*, page 1046).

It follows, therefore, that when the time at the ship is only approximately known, the altitude should be taken when the object is as near to the meridian as it is likely to be, before being obscured by clouds.

The formulæ just established is, we see, generally applicable, however distant from the meridian the observed object may be, provided we know the apparent time at the ship; and we see, also, that they may be employed when the time *nearly* is known, provided the object be pretty close to the meridian. But for this latter case there is a special method somewhat more convenient, which may be investigated as follows:—

Referring to the preceding diagram, we have, by the fundamental theorem of Spherical Trigonometry, which expresses the relations among the three sides and one of the angles of a spherical triangle,

$$\text{cos. } ZS = \text{cos. } PZ \text{ cos. } PS - \text{sin. } PZ \text{ sin. } PS \text{ cos. } P.$$

$$\therefore \text{cos. } P = \frac{\text{cos. } ZS - \text{cos. } PZ \text{ cos. } PS}{\text{sin. } PZ \text{ sin. } PS}$$

Let z be the zenith distance that S would have when upon the meridian, and z' the difference between this meridian zenith distance and that Z S actually observed; that is, let $ZS = z + z'$; then the equation above is

$$\text{cos. } P = \frac{\text{cos. } (z + z') - \text{cos. } PZ \text{ cos. } PS}{\text{sin. } PZ \text{ sin. } PS}$$

Subtracting each side from 1, we have

$$1 - \text{cos. } P = 2 \text{ sin.}^2 \tfrac{1}{2} P$$

$$= \frac{\text{sin. } PZ \text{ sin. } PS + \text{cos. } PZ \text{ cos. } PS - \text{cos. } (z + z')}{\text{sin. } PZ \text{ sin. } PS}$$

$$= \frac{\text{cos. } (PZ \backsim PS) - \text{cos. } (z + z')}{\text{sin. } PZ \text{ sin. } PS}.$$

Now $PZ \backsim PS$, that is, the difference between the co-latitude and the co-declination is equal to Z, the meridian zenith distance, because the co-latitude P Z is always equal either to $PS + z$, or $PS - z$, or $z - PS$, the latter being the case when S is below the pole (see Fig. 26, at page 1078). Consequently

$$2\ \text{sin.}^2\tfrac{1}{2}\,\text{P}=\frac{\text{cos. z}-\text{cos. }(\text{z}+\text{z}')}{\text{sin. PZ sin. PS}}$$

$$=\frac{\text{cos. z}-\text{cos. z cos. z}'+\text{sin. z sin. z}'}{\text{sin. PZ sin. PS}}.$$

If the difference z′, between the meridian zenith distance and that actually observed, be so small that cos. z′ may be regarded as equal to 1, then we shall have

$$2\ \text{sin.}^2\tfrac{1}{2}\,\text{P}=\frac{\text{sin. z sin. z}'}{\text{sin. PZ sin. PS}}$$

$$\therefore\ \text{sin. z}'=2\ \text{sin. PZ sin. PS cosec. z sin.}^2\tfrac{1}{2}\,\text{P}.$$

The number of seconds in the arc z′ is very nearly equal to the number of times sin. z′ contains sin. 1″: consequently, No. of seconds in

$$\text{z}'=\frac{2}{\text{sin. }1''}\ \text{sin. PZ sin. PS cosec. z sin.}^2\tfrac{1}{2}\,\text{P}$$

$$=\frac{2}{\text{sin. }1''}\ \text{cos. lat. cos. dec. cosec. z sin.}^2\tfrac{1}{2}\ \text{hour-angle.}$$

To apply this formula, we must, of course, know z approximately: this is deduced from the latitude by account. By the aid of this approximate latitude and the small hour-angle P, we may, therefore, discover what correction z′ must be applied to the zenith distance actually observed, to reduce it to the meridian zenith distance, from which the corrected latitude is easily obtained, as in the examples already given.

A result still more perfect may in general be arrived at, by proceeding anew with this corrected latitude, writing it in the formula in place of the latitude by account, and thus getting a more accurate correction for the reduction of the observed, to the true meridian zenith distance. The additional work for this purpose will be but trifling.

The formula just deduced, furnishes the following rule for deriving the latitude by aid of the latitude by account, and from the observed altitude when near the meridian of a celestial object whose declination is known. The number 5·615455 is the logarithm of $\frac{2}{\text{sin. }1''}$.

LATITUDE FROM AN ALTITUDE NEAR THE MERIDIAN, THE DECLINATION, THE HOUR-ANGLE, AND THE LATITUDE BY ACCOUNT.—Rule 1. Take the declination of the object for the Greenwich time by account, and add it to the latitude by account when they are of different names; otherwise, take the difference of the two: the result is the meridian zenith distance by account.

2. If the object be the sun, the apparent time from noon is the hour-angle: for any other object, add the sun's right ascension to the apparent time, since preceding noon. The difference between this sum and the object's right ascension is the hour-angle.

3. Add together the following logarithms:—

The constant logarithm 5·615455,
log. cosine of the latitude by account,
log. cosine of the declination,
log. cosine of the mer. zenith dist., as deduced from the two latter,
twice log. sine of half the hour-angle.

The sum, rejecting the tens from the index, is the logarithm of a number of seconds, which, subtracted from the true zenith distance, deduced from the observation, gives the meridian zenith distance. If this and the declination are of the same name, their sum, otherwise their difference, is the latitude, of the same name as the greater.

Examples.

1. In latitude 48° 12′ N. by account, when the sun's declination was 16° 10′ S., at 0h. 16m. P.M., apparent time, the sun's true zenith distance was 64° 40′ N. Required the latitude.

Constant log.			5·615455
Latitude by acct.	48° 12′ N.	cos.	9·823821
Declination	16° 10′ S.	cos.	9·982477
∴ Mer. zen. dist. acct.	64° 22′	cosec.	10·044995
Half hour-angle in deg.	2° 0′	2 sin.	17·085638
			log. 2·552386
			60)357″

Reduction	— 5′ 57″
Zen. dist. from observation	64° 40′ 0″ N.
True mer. zen. dist.	64° 34′ 3″ N.
Declination	16° 10′ 0″ S.
Latitude	48° 24′ 3″ N.

This example is from Mr. Riddle's *Treatise on Navigation and Nautical Astronomy.* We shall now solve it anew by putting the latitude here deduced, in place of the latitude by account.

Constant log.			5·615455
Latitude	48° 24′ 3″ N.	cos.	9·822117
Declination	16° 10′ 0″ S.	cos.	9·982477
Mer. zen. dist.	64° 34′ 3″	cosec.	10·044268
Half hour-angle	2° 0′ 0″	2 sin.	17·085638
Reduction	355″	log.	2·549955

The difference between this and the former reduction is only 2″, so that the corrected latitude is 48° 24′ 5″ N.

It may here be remarked, that as fractions of a second are disregarded in the *Reduction,* the logarithms used in finding it, need be taken out of the table only to the nearest minute of each of the angular quantities.

If the formulæ marked (A), at page 1084, be applied to the preceding example, the work will be as follows:—

Referring to Fig. 27, at page 1084, in connection with the formulæ (A), we have

1. tan. P M = cos. hour ang. cotan. dec.

cos.	4° 0′	9·998941
cotan.	16° 10′	10·537758
tan. P M	73° 47′ 45″	10·536699
Z M	64° 36′ 20″	

138° 24′ 5″ = 90° + lat., since lat. and dec. have different names.
90°
48° 24′ 5″ = lat. N., the same as before.

2, cos. Z M = cos. P M cosec. dec. sin. alt.

cos.	73° 47′ 45″	9·445699
cosec.	16° 10′	10·555280
sin.	25° 20′	9·631326
cos. Z M	64° 36′ 20″	9·632305

In this example the latitude is north, and the declination south, so that P M, in the general investigation of the formulæ, is in this particular case P′ M, and therefore P′ M + Z M — 90° is the distance of Z above the equinoctial; that is, it is the latitude of the ship.

In finding the latitude by the above formulæ (A), it is of course necessary to ascertain on which side of Z the foot M of the perpendicular from S falls; that is, whether Z M is to be added to or subtracted from P M; but whether the correct co-latitude is P M — Z M or P M + Z M, can be matter of doubt only when Z M is so small as to make it of little consequence which be taken. But as the method by the rule is free from all ambiguity, it is to be preferred when the object is near the meridian.

2. In latitude 50° 50′ N. by account, when the sun's declination was 11° 41′ 58″ N. at 12m. 3s. from apparent noon, the sun's true altitude was 50° 52′ 29″. Required the latitude. Ans. Latitude, 50° 47′ 49″ N.

3. At 3h. 5m. 36s. apparent time, the sun's true alti-

tude was 35° 4′ 7″, and his declination 10° 54′ 26″ N. Required the latitude from the formulæ (A).

Ans. Latitude, 50° 48′ 23″ N.

4. At 18m. 45s. from apparent noon, in latitude 8° S. by account, the sun's true altitude was 74° 16′, and his declination 23° 27′ S. Required the latitude to the nearest minute. Ans. Latitude, 8° 23′ S.

5. In longitude 0° 45″ W., at 11h. 2m. 32s. apparent time, the observed altitude of the pole star was 51° 22′, the index correction being — 2′. For apparent noon at Greenwich, on the day of observation, the *Nautical Almanac* gave the following particulars :—

Sun's right ascension, 6h. 51m. 11⅓s.
Star's right ascension, 1h. 1m. 41s.
Star's declination, 88° 26′ 56″.

Required the latitude to the nearest minute by the formulæ (A). Ans. Latitude, 51° 47′ N.

ARTIFICIAL HORIZON.—The problem just discussed will be found very useful at sea, whenever the mariner, on account of cloudy weather coming on near noon, is disappointed of a meridian altitude. As the object may be obscured though the horizon may be clear and well defined, so, on the other hand, the celestial body may be visible and in a position well suited for observation, and yet a haze may obscure the horizon. In such a case an artificial horizon is employed: this is a shallow trough of quicksilver, protected from agitation from the air by a glass covering or roof.

The observer, placing himself at a convenient distance from this horizon, so that both the celestial object and its reflected image may be distinctly seen, measures with his sextant the angular distance between the two ; and as the real object is as much above the horizontal plane as the image is below it, he thus gets *double* the altitude, and has no correction to make for *dip:* the angle read off from the instrument, being corrected for the index error and divided by 2, gives the apparent altitude of the point observed.

To get a *meridian* altitude of the sun is one of the principal items in a "day's work" at sea, for correcting the latitude by the dead-reckoning ; if the weather interfere with this operation, then an observation off the meridian is sought for, and the latitude inferred by help of the apparent time at the ship, as explained in the preceding article. The reader will bear in remembrance that a ship carries the mean time at Greenwich with her : the ship's chronometer, when the known daily gain or loss is applied to it, supplies this important information. The *apparent* time is deduced therefrom, by means of the equation of time given in the *Nautical Almanac;* and the apparent time at the ship is ascertained by turning the longitude into time ; and thus the hour-angle of the object, observed from the meridian, is found. The longitude by account may be somewhat in error ; but the trifling inaccuracy in the resulting time at the ship, will have no important influence on the latitude deduced from it.

But valuable as the chronometer is, yet, like all human contrivances, it is subject to accidents and exposed to derangements from circumstances beyond our control. It is of great importance, therefore, to be able to find the position of a ship at sea, independently of its aid : this we have seen, as far as *latitude* is concerned, may be done by means of meridian altitudes. It may also be done by aid of *two* altitudes of the same celestial objects taken off the meridian. This is technically called the problem of *double altitudes:* we proceed now to investigate its principles.

LATITUDE FROM TWO ALTITUDES OF THE SUN, AND THE TIME BETWEEN THE OBSERVATIONS.—Scarcely any problem in nautical astronomy has received more attention from scientific men than the problem of *double altitudes* ; and, as the calculations involved in it are much longer than those for finding the latitude from a single altitude, various tables, to facilitate the operations, have been constructed. The determination of the latitude, by help of such tables, is what is called the *indirect* method of solution ; and, like all such methods, it is not so strictly correct as the direct method by trigonometry. Delambre carefully examined all the rules he was acquainted with for the solution of the present problem, and he came to the conclusion that the rigorous process by spherical trigonometry was to be preferred, as well for brevity as for accuracy of result. The investigation of the direct method is as follows :—

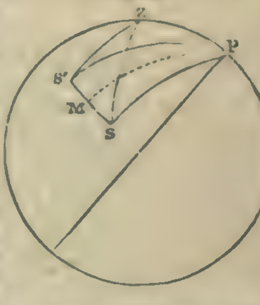
Let P (Fig. 28) be the elevated pole, Z the zenith of the ship, and therefore Z P its co-latitude. Let S, S′ be the two places of the sun when the altitudes are taken ; then, drawing the great circle arcs, as in the diagram, or in that of Fig. 27, we shall have the following quantities given, namely—

$$\left.\begin{array}{ll}\text{The co-declinations} & PS,\ PS' \\ \text{The co-altitudes} & ZS,\ ZS' \\ \text{The hour-angle} & SPS'\end{array}\right\}\ \text{To find } ZP.$$

There are three spherical triangles to consider, viz.—

1. The triangle P S S′, in which are given the two sides P S, P S′, and their included angle, to find the third side S S′, and one of the remaining angles, as, for instance, the angle P S S′.

Fig. 28.



2. The triangle Z S S′, in which are given the three sides, to find the angle S′ S Z ; from which, and the previously-found angle P S S′, the angle Z S P becomes known, so that we have,

3. The triangle Z S P, in which are given two sides and their included angle, to find the third side Z P.

Before proceeding to the solution of these triangles, the observed altitudes must, of course, be reduced to the true altitudes, as in the former examples ; and since the ship most probably sails on during the interval between the two observations, an additional correction becomes necessary, in order to reduce the first altitude to what it would have been, if taken at the place of the second observation. This correction for the ship's run will become known, provided we know the number of minutes the ship has sailed directly towards or directly from the sun, in the time between the two observations ; and they may be ascertained as follows ;—

Take the angle included between the ship's course and the sun's bearing at the first observation ; and considering this angle as a course, and the distance sailed as the corresponding distance, find by the traverse table, or by calculation, as in plane sailing, the difference of latitude ; this difference of latitude, expressed in minutes, will be the number of minutes by which the ship has approached to or receded from the sun, so that we shall know how many minutes must be added to or subtracted from the first altitude, to reduce it to what it would have been if taken by another observer, at the place of the second observation.

If the angle between the ship's track and the bearing of the sun be less than 90°, the ship will obviously be approaching towards the sun, in which case the correction of the altitude, determined as above, must be added ; but if the angle exceed 90°, it must be subtracted : if it be exactly 90°, no correction of the altitude will be necessary for the ship's change of place.

But a correction of the elapsed time may be requisite for the change of longitude ; this change, converted into time, must be added to the time elapsed between the two observations, if the ship have sailed eastward, and subtracted if she have sailed westward.

These are the corrections necessary to fit the three triangles above for trigonometrical calculation. And to simplify the work of finding S S′, without any material sacrifice of accuracy, we may regard the declinations of the sun at the times of observation, as both equal to the declination it has at the middle time between them ; the shorter this time is, the less will the supposition affect the precision of the result.

Regarding the above mentioned corrections to have been made, we shall now give an example of the trigonometrical operation.

Examples.

The two corrected zenith distances are,

Z S = 73° 54′ 13″, and Z S′ = 47° 42′ 51″;

the corresponding co-declinations of the sun are

P S = 81° 42′ N., and P S′ = 81° 45′ N.;

and the interval of time between the observations is three hours. Required the latitude.

For the more easy determination of S S′, let it be regarded as the base of an isosceles spherical triangle, of which each of the equal sides is ½ (P S + P S′) = 81° 43′ 30″, the vertical angle at P being 3h. or 45°; then if the perpendicular P M be drawn, the triangle P M S will be right-angled, and we shall have given

$$\text{P S} = 81°\,43'\,30'' \text{ and P} = \frac{4°}{2} = 22°\,30'$$

to find S M = ½ S S′ as follows :—

1. *In the triangle* P M S *to find* S M.

sin. P S,	81° 43′ 30″	. . .	9·9954547
sin. P,	22° 30′ 0″	. . :	9·5828397
sin. S M,	22° 15′ 11″·3	. . .	9·5782944
	2		
∴ S S′ =	44° 30′ 22″·6		

2. *In the triangle* P S S′ *to find the angle* P S S′.

sin. S S′,	44° 30′ 22″·6	Arith. Comp.	·1542898
sin. P S′,	81° 45′ 0″	„ „	9·9954822
sin. S P S′	45° 0′ 0″	„ „	9·8494850
sin. P S S′	86° 38′ 58″	„ „	9·9992570

3. *In the triangle* Z S S′ *to find the angle* Z S S′.

Z S′,	47° 45′ 51		
sin. Z S′,	73° 54′ 13″	Arith. Comp.	·0173686
sin. S S′,	44° 30′ 22″·6	„ „	·1542898
	2)166° 10′ 26″·6		
½ sum =	83° 5′ 13″·3		
sin. (½ sum − Z S),	9° 11′ 0″·3	. . .	9·2030206
sin. (½ sum − S S′),	38° 34′ 50″·7	. .	9·7949179
			2)19·1695969
sin. (½ Z S S′,	22° 36′ 26″·4	. . .	9·5847985

∴ Subtract

Z S S′ = 45° 12′ 52″·8

from P S S′ = 86° 38′ 58″

∴ P S Z′ = 41° 26′ 5″·2

4. *In the triangle* Z S P *to find* Z P. (See the following Investigation.)

tan. P S,	81° 42′ 0″	. . .	10·8359917
cos. P S Z,	41° 26′ 5″·2	. . .	9·8748930
cot. ω =	11° 0′ 41″·2	. . .	10·7108847
Z S =	73° 54′ 13″		
ω + Z S =	84° 54′ 54″·2		
cos. P S		. . . . .	9·1594354
sin. ω Ar. Comp.		. . .	·7189551
sin. (ω + Z S).		. . . .	9·9982874
sin. Z P,	48° 49′ 59″·7	. . .	9·8766779

Hence the latitude is 48° 50.′

As Z P is here found by a method not always given in works on Spherical Trigonometry, we shall subjoin the investigation of it. Representing, as usual, the three sides of a spherical triangle by *a*, *b*, *c*, and the angle included by the first two by C, we have, by the fundamental formula of Spherical Trigonometry (page 658),

$$\cos. c = \cos. a \cos. b + \sin. a \sin. b \cos. C.$$

$$\text{Or, since } \sin. a = \cos. a \frac{\sin. a}{\cos. a} = \cos. a \tan. a,$$

$$\cos. c = \cos. a\,(\cos. b + \tan. a \sin. b \cos. C).$$

Put cot. ω for tan. *a* cos. C; that is, let

$$\tan. a \cos. C = \cot. \omega = \frac{\cos. \omega}{\sin. \omega} \quad . \; . \; . \; . \; . \quad (1)$$

Then we shall have—

$$\cos. c = \cos. a \frac{\sin. \omega \cos. b + \sin. b \cos. \omega}{\sin. \omega}$$

$$\text{that is, } \cos. c = \frac{\cos\ a \sin. (\omega + b)}{\sin. \omega} \quad . \; . \; . \; . \; . \quad (2)$$

The expressions (1) and (2) are those already calculated. In the preceding solution more attention is paid to minute quantities than is at all necessary in actual practice at sea, where fractions of a second are of course disregarded. Yet in lengthy operations seconds themselves ought not to be entirely neglected, except in those confessedly approximative methods which the indirect processes, by peculiar *tables*, generally are. The only departure from strict mathematical rigour in the foregoing work, is in the first part of it, where the arc S S′ is supposed to be equal to an arc subtending the same angle at P, the sides of this angle being the mean between the two slightly differing co-declinations P S, P S′. It is plain, from the small amount of this difference, that the fictitious arc cannot vary in length from the real arc S S′ by a quantity deserving of any consideration, when the time between the observations is not unreasonably great.

By any one familiar with the practical solution of spherical triangles, the method here illustrated will be preferred to the indirect methods adverted to above; for the operation, though rather long, lays no burden upon the memory, and is, moreover, free from the inaccuracies —small inaccuracies, no doubt—which indirect methods are always affected with. A distinguished practical navigator, Captain Kater, after the example of Delambre, gives the preference to the direct process : the preceding Exercise is taken from the former writer; but the latter part of the solution is conducted differently.

2. On the 7th of February, 1846, in latitude by account 35° N., and longitude 47° W., at 8h. 9m. 4s. A.M. mean time, the altitude of the sun's lower limb was 36° 10′, and his bearing S. ¼ E.; after running N.E. 27 miles, the altitude of the lower limb, at 11h. 30m. 18s., was observed to be 41° 20′; the height of the eye was 20 feet. Required the latitude of the ship when the second observation was made.

From the *Naut. Alm.*	declination.		
	Feb. 7, noon	15° 19′ 32″ S.	Semi-diam. 16°14′.
	„ 8, .	15° 0′ 40″ S.	

1. *For the true altitude of sun's centre.*

First alt. sun's L. L.	. .	36° 10′ 0″
Dip . . . . −4′ 24″ Semi-di. . 16′ 14″	. .	+ 11′ 50″
App. alt.	. . . .	36° 21′ 50″
Refraction and par.	. . .	− 1′ 10″
True altitude	. . . .	36° 20′ 40″
Second alt. sun's L. L.	. .	41° 20′ 0″
Dip. and semi-diam.	. .	+ 11′ 50″
Apparent alt.	. . .	41° 31′ 50″
Refraction and par.	. .	— 58″
True altitude	. . .	41° 30′ 52″

The angle between the sun's bearing S. ¼ E. and the course N.E. is 11¾ points, so that the ship has sailed within 4¼ points of the direction opposite to the sun, a distance of 27 miles. With this distance and 4¼ points as a course, the Traverse Table gives 18′ for the corresponding difference of latitude, which is the number of minutes the ship has receded from the sun during the interval of the observations; hence these 18′ must be *subtracted* from the first true altitude, to reduce it to what it would have been if taken by another observer at the place of the second observation; consequently, the true altitudes at this second place, taken at the stated times, are 36° 2′ 40″ and 41° 30′ 52″

∴ Z S = 53° 57′ 20″ and Z S′ = 48° 29′ 8″.

2. *For the co-declinations* P S, P S′.

Ship's time, Feb. 6 . .		20h. 9m. 4s.
Long. in time . . .		3h. 8m. 0s. W.
Time at Greenwich . .		23h. 17m. 4s.
Dec., Feb. 6.	15° 38′ 0″	var. — 46″·5
	17′ 49″	23
Declination .	15° 20′ 20″ S.	1395
	90°	930
	P S = 105° 20′ 20″	6)106·95
		17·82

Ship's time, Feb. 6 . .		23h. 30m. 18s.
Long. in time . . .		3h. 8m. 0s.
Gr. time, Feb. 7 . .		2h. 38m. 18s.
Dec. Feb. 7 .	15° 19′ 32″	var. — 47″·2
	1′ 58″	2½
Declination .	15° 17′ 34″ S.	944
	90°	236
	P S′ = 105° 17′ 34″	6)11·80
		1·97

The decimal part of the minutes, in the correction for declination, is reduced to seconds by multiplying by 60.

3. *For the angle* S P S.′

Time of first observation . . .	8h. 9m. 4s.	3h.	= 45°
Time of second observation . .	11h. 30m. 18s.	21m.*	= 5° 15′
Interval of time	3h. 21m. 14s.	14s.	= 3′ 30″

∴ the angle S P S′, in degrees, = 50° 18′ 30″

Hence in the isosceles triangle P M S, we have for each of the equal sides ½ (P S + P S′) = 105° 18′ 57″, and for half the vertical angle, 25° 9′ 15″.

1. *In the triangle* P M S *to find* S M.

sin. P S,	105° 20′ 20″ . .	9·9842479
sin. P,	25° 9′ 15″ . .	9·6284454
sin. S M,	24° 11′ 58″ . .	9·6126934
	2	
S S′ =	48° 23′ 56″	

2. *In the triangle* P S S′ *to find the angle* P S S′.

sin. S S′,	48° 23′ 56″	Arith. Comp.	·1262231
sin. P S′,	105° 17′ 34″	” ”	9·9843431
sin. S P S′,	50° 18′ 30″	” ”	9·8862044
sin. P S S′,	83° 1′ 17″	” ”	9·9967706

3. *In the triangle* Z S S′, *find the angle* Z S S′.

Z S,	48° 29′ 8″		
sin. Z S,	53° 57′ 20″	Arith. Comp.	·0922566
sin. S S′,	48° 23′ 56″	” ”	·1262230
	2)150° 50′ 24″		
½ sum =	75° 25′ 12″		
sin. (½ sum − Z S),	21° 27′ 52″	” ”	9·5633906
sin. (½ sum − S S′),	27° 1′ 16″	” ”	9·6573607
			2)19·4392309
sin. ½ Z S S′	31° 37′ 27″	” ”	9·7196154

∴ Z S S′ = 63° 14′ 54″

P S S′ = 83° 1′ 17″

∴ P S Z = 19° 46′ 23″

4. *In the triangle* Z S P, *to find* Z P.

tan. P S	105° 20′ 20″ .	10·5617760
cos. P S Z	19° 46′ 23″ .	9·9736081
cot. ω	16° 15′ 2″ .	10·5353841
Z S =	53° 57′ 20″	
− ω + Z S =	37° 42′ 18″	

cos. P S . . .	9·4226245
sin. ω, Ar. Comp . .	·5530929
sin. (ω, + Z S) . .	9·7864647
sin. Z P, 35° 20′ . .	9·7621821

Hence the latitude is 35° 20′ N.

Note.—It *may* happen, in low latitudes, that the arc S S′, if prolonged, would cut the meridian P Z between P and Z, in which case the angle P S Z will not be the difference between the angles P S S′, Z S S′; and the sum of these angles must be taken instead. In cases of doubt, therefore, the last portion of the work should be modified on this second supposition, and that one of the two resulting latitudes taken which best agrees with the latitude by account. (See Fig. 27, page 1084).

It may be also noticed that the error of a few minutes in the estimated mean time at the ship will be of no consequence in deducing the declination; but as an error in the elapsed time, and therefore in the corresponding polar angle, is to be avoided, the elapsed time should be taken from the chronometer, or a good watch.

3. The two corrected altitudes of the sun are 42° 14′ and 16° 5′ 47″; the corresponding declinations are 8° 16′ 30″ N., and 8° 15′ N., and the time between the observations is three hours. Required the latitude of the place. Ans. Latitude, 48° 54′ 27″ N.

4. The two corrected zenith distances are 54° 39′ and 19° 59′; the corresponding declinations are 5° 31′ 6″ S. and 5° 28′ 54″ S., and the interval of time 2h. 20m. Required the N. latitude. Ans. Latitude, 1° 29′ 28″ N.

5. In latitude 29° 10′ S. by account, and longitude 124° W., the sun being obscured at noon, its altitude was taken at about 20m. past noon, the chronometer at the time showing 9h. 49m. 20s.: at 10h. 44m. 45s., by the same chronometer, the altitude was again taken. In the first observation the altitude of the upper limb was found to be 45° 33′; in the second, the altitude of the lower limb was 42° 8′ 30″, at which second observation the sun bore N. ½ E. The ship's course between the observations was N.W. ¾ W., and her run 6 miles; the allowance for dip was −4′ 30″, and the *Nautical Almanac* gave the following particulars for noon of the day at Greenwich:—

Sun's declination from *Naut. Alm.*, 16° 34′ 4″ N.; hourly var. 42″·8.

Semi-diameter from ditto, 15′ 52″.

Required the latitude of the ship, when the greater altitude was taken. Ans. Latitude, 28° 0′ S.

Note.—When, as in this last example, the latitude at the first observation is to be found, and the sun's bearing is taken at the second observation, the point *opposite* to that of the ship's course from the first position, is to be used in reducing the second altitude to what it would have been, if taken at the first position of the ship.

If the sun's true bearing, or *azimuth*, could be taken with precision at either place of observation, there would be no necessity for a second altitude, because in the spherical triangle Z P S, formed by the co-latitude Z P, the co-declination P S, and the co-altitude Z S, the angle

---

* Divide by 4, and reckon every unit of remainder as 15 *minutes*, if minutes be the dividend; or *seconds*, if seconds be the dividend.

Z would then be given; and this, together with Z S and P S, is sufficient for the determination of Z P.

It is more convenient to observe the bearing when the sun is low than when it is high, and the result can be the better depended upon; therefore, in the problem of double altitudes, the bearing of the sun is always taken when the less of the two altitudes is taken.

The method of finding the latitude here explained, may of course be applied to a star as well as to the sun, the interval between the observations being expressed in sidereal instead of in solar time; but as, in general, the horizon increases in obscurity as the star becomes more clearly visible, *two* observations of a star, with a sufficient interval of time between them, can seldom be accurately made. The following, therefore, is a more suitable problem for the purpose in view.

Latitude from the Altitudes of two Fixed Stars observed at the same time.—There are two advantages connected with this method of deducing the latitude: the first is, that as no allowance is to be made for change of place in the ship, all error arising from inaccuracies in the sun's bearing, and the course and distance steered, is avoided; the second is, that the risk of losing another observation, from unfavourable weather, is not incurred when both observations are made at the same time.

When the altitudes of the two stars are to be taken by one person, the mode of proceeding is this:—The altitude of one star is taken, and the time by the watch noted; the altitude of the other star is then taken, and the time noted; after a short interval, the altitude of the second star is again taken, and the time noted. Thus the change of altitude of the second star, in a known interval of time, will be found; and therefore the correction for the time, when the first star was observed, may be found by proportion.

As to the principles of solution, they are the same as in the former problem: the co-declinations or polar distances P S, P S′ of the two stars are given; the angle P between these is also given, this angle in time being the difference of the right ascensions of the two stars. We may hence compute the third side S S′ of the spherical triangle. As the co-declinations may differ considerably, this third side must not be calculated on the supposition that the mean of the co-declinations may be taken for each of the other two sides. It must be found from the distinct co-declinations themselves. The remaining part of the operation is the same as in the former problem.

Examples.

1. In north latitude 52° 30′ by account, the corrected zenith distances of Capella and Sirius were as follows:—

Capella, Z S = 29° 14′ 24″.
Pol. Dist., P S = 44° 11′ 39″.
Sirius, Z S′ = 72° 5′ 48″.
Pol. dist., P S′ = 106° 28′ 40″.

Difference of the two right ascensions, 1h. 33m. 45s. = 23° 26′ 11″ = P. Required the latitude of the ship.

1. *In the triangle* S P S′ *to find* S S′.

tan. P S,	44° 11′ 39″ . . .	9·9877822
cos. P,	23° 26′ 11″ . . .	9·9626072
cot. ω,	48° 15′ 56″ . . .	9·9503894
	106° 28′ 40″ . . .	
ω + P S′ =	154° 44′ 36″	

cos. P S	9·8555080
sin. ω Ar. Comp.	·1271225
sin. (ω + P S′)	9·6300961
cos. S S′, 65° 47′ 55″	9·6127266

2. *In the triangle* P S S′ *to find the angle* P S S′.

sin. S S′,	65° 47′ 55″	Arith Comp.	·0399527
sin. P S′,	106° 28′ 40″	„ „	9·9817868
sin. S P S′,	23° 26′ 11″	„ „	9·5995891
sin. P S S′,	24° 43′ 3″	„ „	9·6213286

3. *In the triangle* Z S S′ *to find the angle* Z S S′.

Z S′ = 72° 5′ 48″		
sin. Z S′ = 29° 14′ 24″	Arith. Comp.	·3111631
sin. S S′ = 65° 47′ 54″*	„ „	·0399536
2)167° 8′ 6″		
½ sum = 83° 34′ 3″		
sin. (½ sum − Z S) = 54° 19′ 39″	„ „	9·9097504
sin. (½ sum − S S′) = 17° 46′ 9″	„ „	9·4845601
		2)19·7454272
sin. ½ Z S S′ = 48° 14′ 29″	„ „	9·8727136

∴ Z S S′ = 96° 28′ 58″ } to be added
P S S′ = 24° 43′ 3″ }
121° 12′ 1″
supplement = 58° 47′ 59″ = P S Z.

3. *In the triangle* Z S P *to find* Z P.

tan. P S,	44° 11′ 39″ . . .	9·9877822
cos. P S Z,	58° 47′ 59″ . . .	9·7143559
cot. ω,	63° 16′ 3″ . . .	9·7021381
Z S =	29° 14′ 24″ . . .	
(ω + Z S) =	92° 30′ 27″	

cos. P S	9·8555030
sin. ω Ar. Comp.	·0490919
sin. (ω + Z S)	9·9995830
sin. Z P, 53° 19′ 23″	9·9041829

Hence the latitude is 53° 19′ 23″ N.

In connection with the foregoing method of solving the problem of double altitudes, there are some points of theoretical interest to which the learner should attend. In the second step of the work the object is to find the angle P S S′; the operation conducts us to the *sine* of this angle; and as the angle answering to a given sine may be either acute or obtuse, we have no right, independently of controlling conditions, to assume it to be the one any more than the other.

In the example just solved, we have arbitrarily taken it to be acute, simply for convenience, without examining into any overruling circumstances. Now, in the present problem we may always take a similar liberty; for although the proper angle may really be the supplement of that we put down, the subsequent step will not be affected by this circumstance: the angle P S Z, which it is the object of that step to find, will still be the sum or difference of Z S S′, P S S′ or the supplement of the sum.

But it is well to show how all doubt respecting the species of the angle P S S′ may be avoided.

The fundamental formula of spherical trigonometry, applied to the triangle P S S′, gives

$$\cos.\ PSS' = \frac{\cos.\ PS' - \cos.\ PS \cos.\ SS'}{\sin.\ PS \sin.\ SS'};$$

and as it is matter of indifference which of the two stars, or which of the two places of the sun we mark S or S′, we may always consider, in this formula, that cos. P S′ is *numerically greater* than cos. P S, in which case the numerator of the above fraction, and consequently the fraction itself (since its denominator is positive), will have the same sign as cos. P S′; hence *taking* P S′ *for that of the two co-declinations whose sine is the less, the opposite angle* P S S, *will always be of the same species as* P S′—that is, they will either be both acute or both obtuse.

In the example just solved, cos. P S′ is negative, and cos. P S, cos. S S′ are both positive; consequently the fraction is negative, and therefore the angle P S S′ is obtuse—namely, 155° 16′ 57″, instead of 24° 43′ 3″, as we have taken it above; and we see that by *subtracting* 96° 28′ 58″ we get the same result—namely, 58° 47′ 59″.

---

* A second is deducted from this arc, in order that there may be an even number of seconds in the sum of the three, so as that, in taking the half, fractions of a second may be avoided; the omission of a second can have no sensible influence on the result.

Whatever method of solving the problem of double altitudes be employed, there is always, in particular instances, a degree of uncertainty as to whether the sum or difference of a particular pair of arcs or angles is to be taken, and which uncertainty can be removed only by reference to the latitude by account.

The method proposed by Mr. Ivory, and which has been put in a very commodious form by Mr. Riddle, in his *Navigation and Nautical Astronomy*, is perhaps the shortest of the correct processes, when the object observed is the sun; but the investigation of it is very long and complicated, and the several steps of the work are far less easy of recollection than those above: it has the advantage, however, of deciding the ambiguity here mentioned in the case of the sun, with but very little trouble.

But in the case of a pair of stars, the uncertainty is not so easily removed: an amount of calculation, equivalent to a repetition of the work involved in the last step above, has to be gone through.

Now it occurs to us, that the best and most satisfactory way of coming at the proper value of the angle P S Z, is to directly compute this angle (in imitation of step 2 before) from the three sides of the triangle P S Z—namely the co-declination P S, the co-altitude Z S, and the co-latitude by account P Z. This extra work may be regarded as at least an approximate verification of the entire process up to the end of step 3; and, in executing it, seconds in the several arcs need not be attended to: it will be sufficient to take each side to the nearest minute.

The resulting value of the angle P S Z would be a safe guide to the value of it, which step 3 ought to give; and the concluding step might then be worked without any misgiving.

It may be further remarked here, in reference to a double altitude of the *sun*, that when the true co-latitude P Z is obtained, we may combine it with co-declination P S, and the co-altitude Z S, to determine the hour-angle Z P S, the apparent time from noon when the altitude furthest from the meridian was taken: the correction for the equation of time being applied, the result will be the mean time at the ship when S was observed. The chronometer, proper allowance being made for its daily loss or gain, will show the mean time at Greenwich; and the difference between the two will be the longitude in time.

But this important subject will be more fully discussed in the next chapter; we shall only add here, that an altitude near the meridian is not eligible for determining *time*, because, in that position, altitudes vary so slowly, that a small error in altitude may occasion a comparatively large error in time.

Example 2.—In latitude 58° N. by account, the true altitude of Capella was 69° 23′; and at the same time the true altitude of Sirius was 16° 19′; the following particulars were also given by the *Nautical Almanac*:—

Right Ascension of Capella 5h. 2m. 18s. Dec., 45° 47′ N.
" Sirius 6h. 36m. 33s. " 16° 27′ S.
Required the latitude. Ans. Latitude, 57° 8′ N.

THE DEVIATION OF THE COMPASS.—The mariner's compass is subject to two kinds of disturbance, which operate against its true north and south direction. One is a local disturbance attributable to the attractive influence of the iron in the ship, which, when unequally distributed in reference to the magnetic meridian, or the line along which the compass would otherwise settle, causes a deviation from that line. The effect of this local attraction is called the *deviation* of the compass. The amount of the angular disturbance or aberration is ascertained by experiment, before the ship proceeds on her voyage; and a table is then formed, which gives the proper correction for different positions of the ship's head. But Mr. Barlow, of the Royal Military Academy, Woolwich, has devised an apparatus for counteracting the effect of local attraction: a small iron plate is so placed near the compass, vertically and behind it, as that its influence upon it may neutralise the action of the iron in the ship; the proper situation for the plate being ascertained by experiment when the ship is in harbour. For an account of this contrivance, and the mode of applying it, the reader is referred to Barlow's *Essay on Magnetic Attractions*. It may be observed, however, that much care is requisite in fixing the plate; and that if the distribution of the iron in the ship be afterwards changed, the plate must be readjusted; but this inconvenience must attach to every method of estimating the deviation from the results of observations previously made, under particular conditions, as to the amount and position of the disturbing materials. Local deviation has sometimes been found to be so great, that, in a ship loaded with iron, the course by compass has been known to differ from the proper course by so much as 30°.*

THE VARIATION OF THE COMPASS.—The vertical plane passing through the direction of the horizontal needle at any place, marks out the *magnetic meridian* of that place, just as the vertical plane through the north and south points of the horizon marks out the geographical meridian of the place. The angle traced on the horizontal plane by the vertical planes just mentioned, measures the *variation of the compass* at the place. There are but very few places on the surface of the earth where the needle points directly to the north and south points of the horizon, or where the variation is zero. The line in which such places lie is called the line of no variation, and is a curve of very complicated form. It was not till probably some centuries after the discovery of the compass that the needle was suspected ever to lie out of the plane of the geographical meridian: it seems first to have been observed by Columbus, in 1492.

The variation of the compass is not only different at different places; but, what is more remarkable, it is not constant even at the same place. At London the variation was *eastward* till about the middle of the seventeenth century; in 1659 the needle pointed due north and south, the variation being zero, so that at that time the magnetic coincided with the geographical meridian. After this the variation became *westerly*, and it continued to increase till the year 1818, when it appears to have attained it greatest limit of westerly variation—namely, 24° 30′. Since then the variation has been slowly diminishing, and it is now about 23° *west*.

In order to ascertain the variation of the compass at any place, it is necessary that we find by computation, or, by some means independent of the compass, the *true bearing* of a celestial object; then observe the magnetic or compass bearing; the difference of the two will be the variation of the compass; including, however, the local deviation, unless this have been neutralised, as explained above.

There are two forms of the problem: the object whose bearing is observed may be either in the horizon or above it. In the former case it is the magnetic *amplitude* that is observed; in the latter case it is the *azimuth*: in both cases the latitude of the place is supposed to be known.

TO FIND THE VARIATION FROM AN OBSERVED AMPLITUDE.—It has already been seen that the angle which the equinoctial makes with the horizon of any place is the co-latitude of that place (page 1074). This angle is therefore given; and as the object observed is in the horizon, and its declination or distance from the equinoctial known, we have given the perpendicular (the declination) and the opposite angle (the co-altitude) of a right-angled spherical triangle to find the hypotenuse (the true amplitude); and the difference between this and the observed amplitude is the variation, including the local deviation when not previously counteracted. Refraction causes objects to appear in the horizon when, on an average, they are 33′ below it; consequently, the compass-amplitude should be taken when the sun's centre, or the star selected, is about 33′ *plus* the dip, above the sea-horizon; or, allowing 16′ for the sun's semi-diameter, the altitude of the sun's lower limb should be about 17′ + dip.

---

* This subject, and that of the Variation, is fully entered into in the section on Magnetism in this volume.—ED.

Examples.

1. In January, 1830, in latitude 27° 36′ N., the rising amplitude of Aldebaran was observed, by compass, to be E. 23° 30′ N. Required the variation of the compass.

By the *Nautical Almanac* the declination of Aldebaran was 16° 9′ 37″ N.; and since by right-angled triangles, we have

sin. declination = sin. amplitude × cos. latitude;

$$\text{therefore, sin. amplitude} = \frac{\text{sin. declination}}{\text{cos. latitude}}$$

so that the logarithmic computation is as follows:

		10
sin. declination	16° 9′ 37″ . . .	9·44455
cos. latitude	27° 36′ 0″ . . .	−9·94753
sin. amplitude	18° 18′ 16″ . . .	9·49702
Magnetic amplitude	23° 30′ 0″	
	5° 11′ 44″	

As the star is thus farther by 5° 11′ 44″ from the magnetic east towards the north than from the true east, the magnetic east has therefore receded thus much towards the south, and consequently the magnetic north towards the east, hence the variation of the compass is 5° 11′ 44″ E. But the following directions will serve for all cases.

When the object is rising, the true amplitude is always estimated from the east, and when it is setting, from the west, and towards the north or south, according as the declination is north or south.

If the true amplitude, and that by compass, be both north or both south, their difference will be the variation; but if one be north and the other south, their sum will be the variation, easterly when the true amplitude is to the right, and westerly when it is to the left of the observed amplitude.

2. On Feb. 15th, 1841, in latitude 43° 36′ N., and longitude 20° W., the setting amplitude of the sun's centre was observed to be W. 6° 45′ N., at 6h. 52m. P.M., apparent time. Required the variation of the compass.

Time at ship . . .	6h. 52m.
Long. in time . . .	1h. 20m. W.
Time at Greenwich .	8h. 12m.

Sun's dec. at noon, *Naut. Alm.*	12° 37′ 18″ S.
Correction for 8h. 12m. .	−6′ 49″
Sun's dec. at time of obs.	12° 30′ 29″ S.

		10
sin. declination	12° 30′ S. . .	9·33534
cos. latitude	43° 36′ . .	−9·85984
sin. amplitude W.	17° 23′ S. . .	9·47550
Magnetic amplitude W.	6° 45′ N.	

Variation . 24° 8′ West, the true amplitude being to the left of the magnetic.

The true amplitude is always of the same name—north or south, as the declination, as is obvious.

3. In latitude 21° 14′ N., when the sun's declination reduced to the time at ship, was 19° 18′ 6″ S., its magnetic amplitude at rising was E. 35° 20′ S. Required the variation of the compass.

Ans. Variation, 14° 34′ West.

4. In latitude 26° 32′ N., and longitude 79° W., the sun's centre was observed to set W. 4° 17′ S.; the time at the ship was about 6h. P.M.: the sun's declination at noon Greenwich time, was 30′, and the hourly increase of declination 1′. Required the variation of the compass.

Ans. Variation, 3° 31′ E.

5. In latitude 48° 20′ N. the star Rigel was observed to set 9° 50′ to the northward of the west point of the compass: the star's declination was 8° 25′ S. Required the variation of the compass.

Ans. Variation, 22° 33′ W.

VARIATION OF THE COMPASS FROM AN AZIMUTH.—The computation of the azimuth of a celestial object requires the solution of an oblique-angled spherical triangle, the three sides being given to find an angle. The three sides are the co-latitude, the co-declination, and the zenith distance, or co-altitude of the object: the azimuth is measured by the angle at the zenith, or that of which the sides are the co-latitude and the co-altitude; in other words, it is the angle at the zenith between the meridian and the vertical circle through the object, agreeably to the definitions (page 1074). In north latitude, the true azimuth is reckoned from the south point of the horizon; and in the south latitude, from the north point, towards the east, when the altitude is increasing, and towards the west when the altitude is decreasing.

The observed or magnetic azimuth being reckoned from the same point as the true azimuth, if both are east or both west, their difference will be the variation; but if one is east and the other west, their sum will be the variation. The variation is east or west, according as the true azimuth is to the right or to the left of the observed azimuth.

Examples.

1. On June 9, 1853, at about 5h. 50m. A.M., in latitude 50° 47′ N. and longitude 99° 45′ W., the bearing of the sun by compass was S. 92° 36′ E.; when the altitude of his lower limb was 18° 35′ 20″, the index correction was + 3′ 10″, and the height of eye 19 feet. Required the variation of the compass.

2. In latitude 48° 50′ N. the true altitude of the sun's centre was 22° 2′; the declination at the time of the observation was 10° 12′ S.; and the magnetic bearing S. 161° 32′ E. Required the variation of the compass.

Ans. Variation, 22° 40′ 40″ W.

3. November 19, 1835, in latitude 50° 22′ N., longitude 24° 30′ W., at about 9 o'clock in the morning, the altitude of the sun's lower limb was 8° 10′, and the bearing by compass S. 21° 18′ E.; also the height of the eye was 20 feet. Required the variation to the nearest minute.

Sun's dec. at noon, Nov. 19, G. T., 19° 23′ S. Semidiameter, 16′.

Variation of dec. in 1h. + 40″, so that 2′ must be subtracted for three hours before noon.

Ans. Variation, 24° 12′ West.

NOTE.—In the foregoing examples, if the local deviation of the compass remain uncorrected, what is named *variation* will be compounded of variation proper and deviation. Each result must then be regarded as the difference between the uncorrected compass-bearing and the true bearing.

It is proper to remark also, in concluding this division of our subject, that a single altitude or a single azimuth taken at sea is not considered so trustworthy as the mean of several; consequently, when all attainable accuracy is desired, the observations are repeated at short intervals of time (a minute or so), and the mean result of the set is taken for *the* observation employed in the calculation, the mean of the times being the corresponding time of that observation.

Attention to the local deviation of the compass is a matter of great practical importance; and Barlow's correcting plate is a valuable check to its influence. About a quarter of a century ago the *Thetis*, with a million of dollars and other treasure on board, sailed under the most favourable prospects from Rio Janeiro; the next day, in consequence of unfavourable wind, they tacked ship, in full confidence of being clear of land; the fatal mistake was first discovered by the jib-boom striking a high perpendicular cliff; all the three masts were at once sent over the side, and vessel and cargo were lost. In a paper in the *Phil. Trans.* for 1831, Mr. Barlow shows that the local deviation of the compass was exactly such as to be likely to occasion this great mistake in the ship's reckoning. The distance the vessel had run was about 80 miles; and assuming the local attraction to have been equal to that of the *Gloucester*—a similar ship—she would have passed five miles nearer to the scene of her destruction—Cape Frio—than she would have done had the compass been undisturbed by the attraction of the vessel, or had this disturbance been counteracted by any neutralising apparatus.

CHAPTER IV.

ON FINDING THE LONGITUDE AT SEA.

INTRODUCTION.—To determine the longitude of a ship at sea, is justly regarded as the greatest achievement of Nautical Astronomy; it is often considered, too, as the most important achievement; but since both the latitude and the longitude are equally necessary to enable the mariner to ascertain the position of his ship on the ocean, one of these determinations has, in fact, no claim to superior importance over the other, as respects its practical value to the navigator.

A higher degree of consequence has been attached to the problem of finding the longitude, solely because of the greater difficulties with which the solution of it is beset, and of the larger demand made upon the resources of science—both mechanical and astronomical—for the means of overcoming them.

We have seen, in the preceding Chapter, that there are several ways of determining latitude: of these the simplest is that wherein the data are the altitude and declination of a celestial object when on the meridian. So there are several methods of determining longitude; but in each of these we have two distinct problems to solve instead of one: the problems are, 1st, to find the time at the ship; and, 2nd, to find the time at Greenwich. The difference of the times is the longitude of the ship in time. The first of these problems is comparatively easy; the second has exercised the ingenuity and tasked the exertions of the greatest minds; and two very different forms of solution have resulted from these efforts.

As the great object to be accomplished is to discover, at any instant at the ship, what time it is at Greenwich, or at the meridian from which longitude is reckoned, it is natural that the problem of finding the longitude should have more especially engaged the attention of chronometer-makers; and, accordingly, when, in 1714, the first parliamentary reward was offered for the solution of this problem, within certain limits, a most laudable emulation was called forth among the more scientific of this class of artists. The pecuniary stimulus offered by government was this—namely, £10,000 for a method which should determine the longitude to within 60 miles of the truth; £15,000 if the method should give the longitude within 40 miles; and £20,000 if within 30 miles. The most successful competitor for these rewards was John Harrison, who, with indefatigable industry, applied himself to the construction of a chronometer that should keep time with sufficient accuracy to accomplish the last of these objects. In 1736 his first chronometer was subjected to trial in a voyage to Lisbon; and in 1739 a second, still more perfect, was produced; but in 1758 he completed a third, which he affirmed to be so accurate as to entitle him to the highest reward offered by the Commissioners of Longitude. In compliance with Mr. Harrison's request, the Admiralty directed the watch to be tried on a voyage to Jamaica, in the ship *Deptford*, which sailed from Portsmouth, November 18, 1761, and arrived at Port Royal, Jamaica, January 19, 1762. The time at Portsmouth—for the watch had been set to Portsmouth time—was found, on the 26th of the same month, to be 5h. 2m. 47s., as shown by the chronometer, at the instant of noon at Port Royal; and the exact difference of longitude, in time, between the same two places, as found by careful astronomical observations, was 5h. 2m. 51s.; differing from the determination of the chronometer by only 4s., which, in the parallel of Jamaica, is less than one nautical mile.

On January 28, 1762, the chronometer was sent back in the *Merlin*, which arrived at Portsmouth on March 26. On the passage, the ship encountered a violent storm, and the chronometer had to be removed to a place where it was likely to suffer from exposure. The time of mean noon, as shown by the chronometer, April 2, was 11h. 58m. 6s·5. Hence, from Nov. 6, 1761, to April 2, 1762, during which period the chronometer had passed through a variety of climates, and been subjected to violent agitations of the sea, its error was no more than 1m. 53s·5, or 28½ minutes of longitude in time, which, in the parallel of Portsmouth, does not amount to 18 nautical miles.

On this occasion Mr. Harrison received £5000; and another trial voyage was proposed—namely, from Portsmouth to Barbadoes—which was made in 1764, and which proved so satisfactory that an additional £5000 was ordered to be paid to him, and the remainder of the highest reward promised as soon as he had sufficiently explained the principles of his time-keeper to enable another artist to construct one as good. Mr. Harrison accordingly explained fully the whole of his mechanism to a properly qualified committee; and Mr. Kendal, a member of that committee, was directed to construct a chronometer on Harrison's principles. The instrument he produced was committed to the care of Mr. Wales, on his voyage round the world with Captain Cook, in the years 1772, 1773, and 1774; and it so fully justified Harrison's expectations in this severe trial, that the House of Commons ordered the remaining £10,000 to be paid to him.

Subsequently to this, chronometers were constructed by various persons, upon independent principles and of equal merit; those by Mudge, Arnold, and Earnshaw were considered to deserve special distinction, and accordingly £3000 were paid by government to each of these makers; but no parliamentary reward has since been given for chronometers.

At the present day, chronometers fully equal to any of those here adverted to are readily to be procured, and from the best makers; even superior time-keepers may at all times be obtained. The difference of longitude between Greenwich and New York, as recently determined by the chronometers of Mr. Dent, agreed with the results of astronomical observations, to within three-quarters of a mile!

Such, then, is the degree of perfection to which this department of mechanical art has been brought; so that the determination of the time at Greenwich, at any instant, in any part of the globe, would be an easy matter, provided only that a chronometer could be insured against all external interference with its action. But at sea, a piece of machinery so delicate is peculiarly exposed to deranging influences—changes of climate—the jerks and vibrations of the ship—local attraction, &c., &c., all have their influence; and however these ordinary hindrances to the correct performance of the watch may be provided against, yet an unavoidable accident may at any time render the machine useless. The safety of navigation requires, therefore, that—valuable as the chronometer is—other means of finding the longitude, independent of its aid, should be devised; and these are furnished by what are called the LUNAR OBSERVATIONS.

By aid of tables of the moon's motion—first supplied to the British Admiralty by Professor Mayer of Göttingen (1755—'62), and subsequently improved by Mason, Bradley, and others—the angular distances of the moon from the sun, and from the principal stars that lie near her path, are predicted for every three hours of time, and for several years in advance. These "Lunar Distances" are given in the *Nautical Almanac*. The motion of the moon in her orbit is so rapid—about 13° in 24 hours—that her advance to, or recession from a star in her path, is a measurable quantity even in the lapse of a few seconds of time: by means of the three-hourly distances computed in the *Nautical Almanac* for Greenwich time, her distance from any one of the selected stars, at any intermediate instant of Greenwich time, can be easily found by simple proportion; and, conversely, any intermediate distance being known, the corresponding Greenwich time can, in a similar manner, be found.

Like as in all the other angular measurements of Nautical Astronomy, the observer is considered to be situated at the centre of the earth: a lunar distance, therefore, being taken at sea, and reduced to this point, the mariner has only to turn to his *Almanac*, and from the distances there given, to compute, by proportion, the time at Greenwich, when the distance of the same objects was what he has found it to be. The Greenwich time at the instant of observation is thus discovered, and thence—his own time being known—the longitude of the ship is ascertained.

The heavens thus supply the navigator with an unerring chronometer—a time-piece that needs no winding up—that never gets out of repair, nor ever requires re-adjustment—that can neither be deranged by accident, nor be deteriorated by neglect. Placed beyond the reach of sublunary vicissitudes, heat and cold, storm and tempest affect it not: these, indeed, may temporarily cloud and obscure its face, but they can neither disturb its mechanism nor alter its rate; and we know that it will run down only when our concerns with TIME are at an end.

From these introductory remarks, the student will readily anticipate the business that is now before us. Whether we consult a chronometer, or take a lunar distance, for the purpose of finding the time at Greenwich, the time at the ship is an indispensable element in the determination of the longitude; the problem first to be solved, therefore, is *to find the local time.*

ON FINDING THE TIME AT SEA.—At first sight it would appear that the time at the ship, most easily determined, is the time of *noon*, or when the sun comes to the meridian; but, for a minute or two before and after the sun's transit, the change in altitude is so small, except in very low latitudes, that it is not possible at sea to detect the instant of the meridian passage; and the same may of course be said in reference to any other celestial object.*

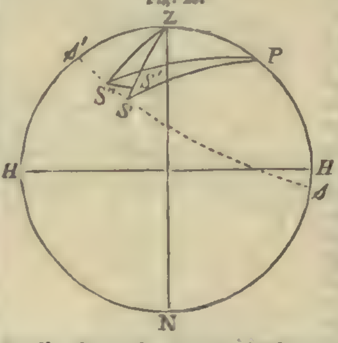
In determining the *latitude* by a meridian observation, the error of a minute or so in the time of apparent noon is of no consequence; for, as just remarked, the altitude of the object—which is all that the latitude is concerned with—is pretty nearly constant for a few minutes in the neighbourhood of the meridian; but, as respects the *longitude*, the error of a single minute in the time would occasion an error of fifteen minutes of longitude. It is obvious, therefore, that when time is to be deduced from altitude, with a view to the determination of the longitude, the position of the celestial object to be observed should be so chosen—when circumstances are such as to permit of a change of position—as that a small error in the altitude may have the least effect possible on the hour-angle, or time from noon. It is of importance, therefore, to consider the following preliminary problem:—

To determine upon what vertical a Celestial Object must be, in order that a small error in the Altitude may have the least effect on the Time.

Let S (Fig. 29) be the place of the celestial object observed; but by a small error in taking the altitude, let it be referred to S'. Draw $S' S''$ parallel to the horizon, and meeting the parallel of declination $s s'$, in the point S''.

Then, when the object is at S'' it will really have the co-altitude $Z S''$ equal to its supposed co-altitude $Z S'$, when it was actually not at S', but at S; so that in the determination of the hour-angle P from the co-latitude $P Z$, the co-declination $P S''$, and the erroneous co-altitude $Z S''$, the small angle $S P S''$ will measure the amount of error in the time.

Fig. 29.



As the triangle $S S' S''$ is of course exceedingly small, since the error of observation is not purposely made, it may be regarded as a rectilinear triangle, right-angled at S'; therefore $S S' = S S'' \sin. S''$, and $S S'' = \sin. PS \angle S P S''$, for $S S''$, the distance passed over by the object, may be compared to the distance sailed on a parallel of latitude by a ship, making the difference of longitude $S P S''$; and we know that in this case (page 1056),

$$\text{cos. lat.} : 1 :: \text{dist.} : \text{diff. long.} \therefore \text{dist.} = \text{cos. lat.} \times \text{diff. long.}, \therefore S S' = \sin. PS \angle S P S''.$$

$$\text{Hence } S S' = \sin. S'' \sin. PS \angle S P S'' \therefore S P S'' = \frac{S S'}{\sin. S'' \sin. PS} \quad . \quad . \quad . \quad (1)$$

Now the angle S'', that is, the angle $S' S'' S$, is equal to the angle Z S P, because S′ being a right angle, S′ S S′ is the complement of each; and therefore, from the relation between the sides and angles of a spherical triangle, we have

---

* It may be remarked, moreover, that the altitude of the sun, the moon, or a planet, is not necessarily always the greatest when on the mid-day meridian of the place of observation; nor necessarily the least, when on the midnight meridian: the body's change of declination may be such as to prevent this.

$$\text{sin. } S' : \text{sin. } SZP :: \text{sin. } PZ : \text{sin. } PS$$

$$\therefore \text{sin. } S' \text{ sin. } PS = \text{sin. } PZ \text{ sin. } SPZ \quad . \; . \; . \; (2)$$

Substituting the second member of (2) in (1), we therefore have

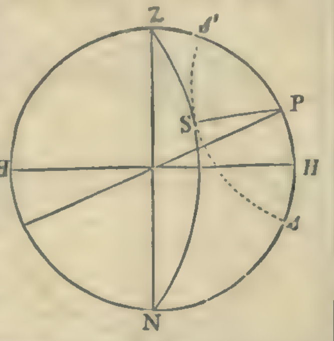
$$SPS' = \frac{SS}{\text{sin. } PZ \text{ sin. } SZP} = \frac{\text{error in altitude}}{\text{cos. lat. sin. azimuth}} \; . \; . \; . \; (3)$$

This expression for the error in time will obviously be the least possible, when the sine of the azimuth is the greatest possible; hence, if the co-declination be sufficiently great, or the co-latitude sufficiently small for the object to cross the prime vertical Z N, above the horizon, in its progress towards the meridian or towards the horizon, the most favourable time for an observation of the altitude will be when the prime vertical is reached—that is, when the object is due east or due west—the azimuth being then 90°. If other circumstances—weather, proximity to the horizon, &c.—be unfavourable, then the nearer the position of the object to the prime vertical the better.

But if the co-latitude P Z exceed the co-declination P s′, then the object cannot arrive at the prime vertical; the azimuth P Z N will then be the greatest, and have the greatest sine, when the object is at S, the point in which the azimuth circle Z S N *touches* the parallel of declination s s′. It is plain that in this position the apparent motion of the object is nearly perpendicular to the horizon. (See Fig. 30).

The triangle P S Z (Fig. 29) is right-angled at S, for P S is the shortest arc from P to Z N, and is, therefore, at right angles to Z N; in this triangle the two sides P S, P Z, the co-declination and the co-latitude, are supposed to be given: we may, therefore, find the angle Z, or the bearing the object ought to have, so that the error in altitude may affect the time as little as possible; or we may find the angle P, the time from apparent noon, when the observation should be made. If it be not practicable to take the altitude when the object is in the most favourable position, then a position as near to it as possible should be chosen; and it must be remembered that, throughout the interval between the best position and the meridian, the nearer the object is to the meridian, the more unfavourably is it situated for the purpose of computing the time from an altitude; the formula (3) sufficiently shows this.

Fig. 30.



This formula (3) will of course serve for determining the error in the time consequent upon any assumed error in the altitude, at any observed azimuth; but as the angle S P S′ is expressed in minutes of the equinoctial, as appears from (1) above, it is necessary to divide by 15, to bring the measure into minutes of time: so that

$$\text{Error of app. time in minutes} = \frac{1}{15^{\circ}} \frac{\text{error of altitude}}{\text{cos. lat. sin. azimuth}}$$

For example. Suppose the latitude to be 51’ 31′ N.’ the azimuth of the object S. 48° 10′ E., and that the error of altitude is estimated at 10′. Required the error in the apparent time.

The above formula, put into logarithms, is,

$$\text{log. error of time} = \text{log. error of alt.} - \text{log. cos. lat.} - \text{log. sin. azimuth} - \text{log. } 15 + 20.$$

10	1·0000
cos. 51° 31′ Arith. Comp.	·2060
sin. 48° 10′ Arith. Comp.	·1278
15 Arith. Comp.	8·8239
1′·438	·1577

Hence the error in time is 1′·438 = 1′ 26″

It will, of course, be observed that if the latitude and azimuth remain the same, as also the error in altitude, the error in time will remain the same, however the altitude may vary.

TIME AT SHIP DEDUCED FROM A SINGLE ALTITUDE.—If the object observed be the sun, the hour-angle which its circle of declination, at the instant of observation, makes with the meridian, is the apparent time from that meridian. By applying the equation of time, given in the *Nautical Almanac*, and reduced by means of the longitude by account, to the estimated instant of observation, the apparent may be converted into mean time.

If the object be a star, the hour-angle its circle of declination makes with the meridian is a portion of sidereal time; it is the difference between the right ascension of the star, and the right ascension of the meridian. When the star is to the west of the meridian, its R. A. (right ascension) must be increased by the hour-angle; when it is to the east, its R. A. must be diminished by the hour-angle: the result is the R. A. of the meridian; and the difference between this and the sun's R. A. at the time of observation, is the time from the same meridian, and which is apparent, or mean time, according as the sun's R. A. is taken from p. 1 or p. 2 of the *Naut. Alm.*

If the object be the moon or a planet, the apparent and mean time are obtained just as in the case of a star.

To determine the hour-angle P from which the mean time at the ship is thus deduced, there are given in the spherical triangle P Z S, the co-latitude P Z, the co-declination P S, and the co-altitude Z S; hence, putting *s* for half the sum of these three sides, we have for cos. ½ P.

$$\text{cos. } \tfrac{1}{2} P = \sqrt{\frac{\text{sin. } s \text{ sin. } (s - ZS)}{\text{sin. } PZ \text{ sin. } PS}} \quad \text{(TRIGONOMETRY, p. 658).}$$

The co-altitude Z S, used in working this formula, is usually deduced from a set of altitudes taken within a minute or two of each other, as in the following examples:—

Examples.

1. *Time deduced from the Sun.*—On September 23, 1845, in latitude 50° 30′ N., and longitude by account 110° W., a set of altitudes of the sun were taken as below; the index correction was — 3′ 20″, and the height of the eye 20 feet. Required the mean time at the ship.

NOTE.—Besides a chronometer or two a ship always carries a good common watch, marking seconds, by which, what may be called the time at ship *by account*, or the estimated time, is kept. This may be regulated by the meridian altitudes, or by the double altitudes, or, as already noticed, by means of the chronometer and estimated longitude. For the purposes to which the watch is applied, an error of a few minutes is of no consequence; in the present problem the estimated time is used to get the declination and equation of time. The times recorded below are the mean times at the ship, as shown by the *watch*.

Altitudes of the Sun.	*Times per Watch.*

	2		
∴ P =	72° 1′ 34″		

Equation of Time.
Sep. 23 7m. 42s. var. 0″·858,*
Cor. for 12h., + 10s.
7m. 52s.

In time =	4h. 48m. 6s.	Apparent time
Equation of time	− 7m. 52s.	at ship.
	4h. 40m. 14s.	Mean time at ship.

In this result a quarter of a second has been disregarded, and we conclude that the watch is about 5m. *fast.*

It is of importance in discussing operations of this kind, the results of which are required to be brought out with the utmost attainable accuracy, that the student's confidence in such results be not shaken by the fact that certain of the data with which he works are confessedly erroneous, and are never more than approximations to the truth ; the estimated longitude, and the estimated time at the ship are, of course, more or less affected with error. He must take notice that these two elements do not enter directly into the trigonometrical process : they merely affect the preparatory reductions for declination and equation of time ; quantities that vary so little, even in a large interval of time, that a considerable error in the estimation of this interval, occasions but an inconsiderable error in the proper corrections. Hence, with but ordinary care in the dead-reckoning, and the proper accuracy in taking the altitude, the time at sea, determined as above, may be depended upon as correct, not only to the nearest *minute,* but even to the nearest *second* notwithstanding the acknowledged fact that certain of the data are only approximately true.

To illustrate this, let us modify the foregoing operation by applying the above correction to the watch, or by putting it back 5m. ; then the mean time at Greenwich, when the observed altitude of the sun at the ship was 11° 0′ 50″, will be 12h. The correction for declination will therefore be $58'' \frac{1}{2} \times 12 = 11' 42''$; hence, subtracting 5″ from the above value of P S, we shall have, for the more correct value, P S = 90° 18′ 38″ ; and the work, modified in accordance with this change in the co-declination of the sun, will stand as follows :—

Z S,	78° 55′ 34″		
sin. P Z,	39° 30′ 0″	Arith. Comp.	·1964895
sin. P S,	90° 18′ 38″	Arith. Comp.	·0000064
	2)208° 44′ 12″		
sin. s,	104° 22′ 6″		9·9861985
sin. (− Z S)	25° 26′ 32″		9·6330650
			2)19·8157594
cos. $\frac{1}{2}$ P,	36° 0′ 51″		9·9078797
	2		
∴ P =	72° 1′ 42″		

In time = 4h. 48m. 6s. $\frac{3}{4}$ } ∴ 4h. 40m. 14s. $\frac{3}{4}$, is
Equation of time — 7m. 52s. } the correct mean time at the ship.

The time, according to the former result, was 4h. 40m. 14s. $\frac{1}{4}$; for, as stated above, the fraction of a second was suppressed : we see, therefore, that the error of 5m. in the *estimated* time occasions an error of only half a second in the *correct* time. Suppose now that not only the estimated time, but that the estimated longitude is also affected with an error equivalent to 5m. of time—that is, an error of $1\frac{1}{4}$° in longitude, which is a large error ; and suppose that both errors conspire, making the mean time at Greenwich 12h. 10m. The correction for declination will then be $58\frac{1}{2}'' \times 12\frac{1}{6}$ = less than 11′ 52″ ; then P S will be 90° 18′ 48″, and the modified work will be as follows :—

Z S,	78° 55′ 34″		
sin. P Z,	39° 30′ 0″	Arith. Comp.	·1964895
sin. P S,	90° 18′ 48″	Arith. Comp.	·0000065
	2)208° 44′ 22″		
sin. s,	104° 22′ 11″		9·9861958
sin. (s − Z S),	25° 26′ 37″		9·6330871
			2)19·8157789
cos. $\frac{1}{2}$ P,	36° 0′ 45″		9·9078894
	2		
∴ P =	72° 1′ 30″		

In time = 4h. 48m. 6s. } ∴ 4h. 40m. 14s., is the
Equation of time − 7m. 52s. } mean time at the ship.

Hence, notwithstanding the above errors in the estimated time and longitude, the time at the ship is correctly deduced to within three-quarters of a second of the truth. Whenever there is a very considerable difference between the time per watch, and the calculated time at the ship, it will be prudent to repeat the work with the corrected time, as in the second of the foregoing operations.

2. *Time deduced from a Star.*—On June 3, 1842, at 12h. 9m. P.M., nearly (mean time) in latitude 50° 48′ N., and longitude by account 1° 6′ 3″ W., the observed altitude (or the mean of a set of altitudes) of *a* Bootis, west of the meridian, was 89° 53′ 30″, with the artificial horizon : the index correction was — 10″. Required the mean time at the ship.

As the artificial horizon was used, there will be no correction for dip (page 1076) : the angle shown by the instrument, when corrected for index error, is double the altitude from the rational horizon.

---

* This is the variation of the equation of time in one hour, as given in the *Nautical Almanac.*

Angle by Instrument . . .	89° 53′ 30″
Index correction	— 10
	2)89 53 20
App. alt. of star	44 56 40
Refraction	— 58
True alt.	44 55 42
	90
∴ Z S =	45 4 18

Estimated time . . .	12h. 9m.
Long. 1° 6′ W. . . .	4m.
Mean time at Greenwich .	12h. 13m.
Sun's R. A. at noon, or the sidereal time . . .	4h. 46m. 7s.·1
Correction for 12h. 13m. .	+ 2m. 0s.·4
Sun's R. A. at time of obs. .	4h. 48m. 7s.·5

Stars R. A. 14h. 8m. 30s.·5, Dec. 20° 0′ 15″ N., ∴ P S = 69° 59′ 45″. Also P Z = 39° 12′.

Z S, 45° 4′ 18″		
sin. P Z, 39 12 0	Arith. Comp.	·1992628
sin. P S, 69 59 45	Arith. Comp.	·0270256
2)154 16 3		
sin. s, 77 8 2	. .	9·9889570
sin. (s — Z S), 32 3 44	. .	9·7249635
		2)19·9402089
cos. ½P, 21 1 1½	. .	9·9701044

∴ P = 42 2 3 or 2h. 48m. 8s·2 of sid. time.

Star's R. A. . .	14h. 8m. 30s.·5
R. A. of meridian .	16h. 56m. 38s.·7
R. A. of sun . .	4h. 48m. 7s.·5
Mean time at ship .	12h. 8m. 31s.·2

It will be observed here that the hour-angle P is expressed in sidereal time; and in like manner the right ascensions of the star, the meridian, and the mean sun, are all expressed in sidereal time: hence, 12h. 8m. 31s.·2 is the distance of the mean sun from the meridian in sidereal time; and this time in reference to the *mean* sun is mean time.

Examples for Exercise.

1. On January 12th, 1840, in latitude 30° 55′ N. and longitude 14° W., by account, the mean of a set of altitudes of the sun's lower limb was 22° 55′ 33″; the corresponding time by watch was 9h. 31′ 33″ A.M.; the index correction was + 4′ 30″, and the height of the eye 30 feet. Also the *Nautical Almanac* gave the following particulars, namely—

Sun's dec., Jan. 11th . .	21° 54′ 30″ S.
Hourly variation . . .	— 23″·42
Equa. of time, Jan. 11th .	8′ 3″
Hourly variation . . .	+ 0′ 1″
Sun's semi-diameter . .	16′ 16″

Required the mean time at the place of observation.

Ans. 9h. 41′ 24″ A.M.

2. On April 18th, 1844, in latitude 50° 48′ N., and longitude by account 1° 0′ W., the mean of a set of altitudes of the sun's lower limb (with artificial horizon) was 76° 16′ 46″; the corresponding time by watch was 9h. 18m. A.M.; the index correction was — 3′ 46″; and the *Nautical Almanac* gave the following particulars, namely—

Sun's dec., April 17th . .	10° 36′ 49″ N.
Hourly variation . . .	52″ 38
Equa. of time, April 17th .	0′ 31″·3
Hourly variation . . .	0′ 0″·573
Sun's semi-diameter . .	15′ 56″.

Required the mean time at the place of observation.

Ans. 9h. 18m. 16s. A.M.

3. On April 26th, 1840, in latitude 29° 47′ 45″ S., and longitude by account 31° 7′ E., at 2h. 19m. 41s. A.M. by watch, the true altitude of the star Altair was 25° 14′ 20″ to the east and north. Required the mean time at the place of observation.

R. A. of Altair 19h. 43m. Decli. 8° 26′ 47″ N. Sun's R. A., or sidereal time at mean noon, 2h. 18m. 21s.·1.

Ans. 1h. 45m. 11s. A.M.

NOTE.—As remarked at page 1093, the time may be found in a similar way when the object is the moon instead of the sun or a star; but, on account of the rapidity of the moon's motion in right ascension and declination, this body is the least eligible for the purpose of discovering the time at sea. The approximate time and the approximate longitude which, as we have seen in the case of the sun (page 1095), may be employed with safety, may lead to considerable uncertainty when the object is the moon, of which the declination changes sometimes more than 2′ in 10m. of time.

TIME DEDUCED FROM EQUAL ALTITUDES.—There is another way of determining the time, which ought to be briefly noticed. It is called the method of *equal altitudes:* the following exposition of it is principally from Lieut. Raper's *Practice of Navigation and Nautical Astronomy*—a work which well deserves the attention of the practical seaman.

Since the altitude of a body which does not change its declination, varies exactly at the same rate while rising on the E. side of the meridian, as while falling on the W. side, the same altitude occurs at the same hour-angle on each side of the meridian, and the middle point of time, between the instants of two equal altitudes, is the instant at which the body passes the meridian.

In the case of the sun, the middle point of time, or the mean of the observed times of equal altitudes, A.M. and P.M., is apparent noon. In the case of a star, or other body, the mean of these times corresponds to the R. A. of the star when upon the meridian, or the sidereal time, which may easily be converted into apparent time, or mean time.

Since the sun changes his declination sensibly in large intervals of time, two equal altitudes, A.M. and P.M., do not correspond to equal hour-angles; and it therefore becomes necessary to apply to the mean of the observed times a correction which is called the *Equation of Equal Altitudes.* A table of the equation of equal altitudes is to be found in all nautical tables. Also at sea, the change of place of the ship, in the intervals between the altitudes, will generally render another correction necessary. When the course made good is true E. or W., the ship changes in her longitude only, by the portion of time which she gains or loses on the sun in intervals. This change, provided it is made good equally on both sides of the meridian, introduces no correction; and the only question is, the time by watch when the interval is half expired.

But when the ship changes her latitude, the same altitude no longer corresponds to the same time from noon, and the correction adverted to becomes necessary.

This method has some advantages:—it is independent of the terrestrial refraction, provided this remains unchanged in the interval employed; and the correction, when necessary, requires the latitude and altitude to be but roughly known. Within the tropics, the interval may in general be very small, on account of the rapid change of the altitude; and the correction for change of latitude may, in such cases, be omitted. In high latitudes, however, the ship's change of latitude considerably alters the time from noon, at which the second altitude (equal to the first) is taken; hence, in such high latitudes the method is less useful.

The general mode of proceeding is this:—Observe the sun's altitude shortly before noon, and note the time. Note the instant of the same altitude in the afternoon. For great accuracy, several pairs of equal altitudes should be obtained. Take the mean of the A.M. and P.M. times by watch: this, when the ship does not change her latitude, is the time by watch of apparent noon. To render any correction for change of latitude unnecessary, it would be desirable to alter the course of the ship, so as to preclude this change, when the interval between the observations is but short, as it should be to warrant the dispensing with correction for change of declination.

On account of the constancy of its declination, a star is the best suited for the purpose of the present problem; but a change in the state of the atmosphere, during the interval of the observations, may interfere with the precision of the result, especially in the case of low altitudes; attention to the indications of the barometer and thermometer is therefore necessary to the attainment of accuracy. But the observations, to be free from all source of error, should be made on shore; for if the interval be large, there is, at sea, some uncertainty as to the correction for change of latitude; and if the interval be small, there is some uncertainty as to the altitudes, especially in high latitudes, on account of the slowness with which altitude changes near the meridian.

ON FINDING THE LONGITUDE BY A CHRONOMETER.—From what is shown in the preceding articles, it appears that the time at the ship can be accurately obtained by means of altitudes of the sun or fixed stars, assisted by the longitude, by dead-reckoning, and the time by estimation; and therefore all that is necessary for the determination of the ship's longitude is, that we know also the time at Greenwich at the same instant. If we can only discover what o'clock it is at the same instant at two different places on the globe, however distant, we may at once infer the difference of longitude of those places. We have only to convert the difference of time into degrees, at the rate of 15° to one hour, to effect this object. To find the time at Greenwich at any instant is therefore to solve the problem of the longitude; and as noticed at page 1092, it is to supply this important information that so much skill and perseverance have been bestowed on the *chronometer.*

It is not necessary to the perfection of this instrument that it should show the exact time at Greenwich, which, in fact, a chronometer never does; what is required is, that its action be uniform and regular. The difference between Greenwich mean time at any instant and the time shown by the chronometer, is the *error* of the chronometer at that instant; and its average gain or loss in 24 hours is its *mean daily rate.* There is a depôt established at the Royal Observatory, Greenwich, for the reception of such chronometers as the makers choose to send, and where their errors and rates are determined by the Astronomer Royal; and few persons would now purchase a chronometer for use at sea, without the proper official certificate of these particulars. If the original error on Greenwich mean time be allowed for, and the proper correction be made for the accumulated daily rate, the Greenwich time at any instant will of course be correctly obtained, provided that nothing has disturbed the action of the chronometer after it left the observatory.

It will have been observed in the foregoing articles, that the estimated longitude and time at the ship have been employed solely for the purpose of getting the Greenwich time when the altitude was taken, with sufficient accuracy to enable us to get the co-declination or polar distance of the object observed; and we have seen that even a considerable error in the estimated quantities will not sensibly affect the precision of the result. But if the chronometer can at all be depended upon, the Greenwich time of the observation will become known at once, and, unless great derangement of the chronometer have taken place, with more accuracy than it can be found by the estimated longitude and time at the ship. The problem just disposed of may therefore be correctly solved by aid of even an indifferent chronometer; but if the time at Greenwich, after the corrections for error and rate, be not correctly furnished by the instrument, there will of course be a proportionate error in the longitude inferred from it.

We are anxious that the student should clearly understand how it happens that, from erroneous data, we obtain accurate results, even in a matter of so much delicacy as the determination of the time at sea. The errors referred to can affect only two elements of the calculation—the declination and the equation of time; and from the slowness with which these vary, a few minutes, more or less, can have no sensible influence.

ON FINDING THE RATE OF A CHRONOMETER.—It is evident that if the rate of a chronometer remained invariable, the time at Greenwich could always be accurately deduced from it; but a sudden jerk or concussion, change of climate, local attraction, and even the motion of transporting it from the observatory to the ship, may cause the rate to vary. The scientific navigator, therefore, avails himself of every favourable opportunity of ascertaining the rate of his chronometer. This is best done when the ship is in harbour, and in the neighbourhood of a fixed observatory, at which the rate may be ascertained like as it was at Greenwich. For this purpose the chronometer need not be carried on shore. The time may be taken from it by a good seconds-watch, and the watch then carried to the observatory and compared with the mean-time clock—the error of the chronometer, on the mean time at that place, will thus be seen; and this comparison being repeated day after day, the daily deviation from the exact amount of the error will be discovered, and hence the mean daily rate. The ship then sails afresh with the time at the new meridian, and therefore—the longitude of that meridian being known—with the Greenwich time.

Or, without resorting to a fixed observatory, the rate may be ascertained, when the ship is in harbour, by finding the mean time at the place, as explained in last problem. A comparison of this with the mean time shown by the chronometer will, in like manner, show the error on mean time at the place; and the observations being repeated day after day, the rate will become known. The altitudes may in general be obtained with greater precision by taking them on shore, by means of an artificial horizon, the chronometer time being carried there by the watch.

Every attention should be paid on ship-board to circumstances likely to interfere with the rate of the chronometer: it should be kept as much as possible out of the influence of changes of temperature, and its horizontal position should remain undisturbed: to secure this permanence of position, it is frequently suspended on gimbals, like the compass. It should be wound up by the action of the key alone, the chronometer itself being kept steady; if the instrument be turned as well as the key, the motion of the balance-wheel will be affected, and the rate disturbed. We have hitherto spoken of *the* chronometer, as if ships in general carried only one; but in long voyages, or in voyages undertaken for scientific purposes, ships usually take several chronometers as checks to one another, and to provide against accident. Captain Fitzroy, in his surveys of the coast of South America, took so many as twenty-two chronometers. The apartment in which the chronometers are kept is called the chronometer-room, and the temperature of it is sometimes regulated by lamps, with the aid of the thermometer. This should be the permanent depository of the time-keepers, and they should be meddled with only for the purpose of winding them up, which should be at the same regular interval; and, of course, they should not be allowed to run down.

The error and rate of a chronometer being found, as explained above, the longitude is determined, as in the following example, from Captain Kater's article in the *Encyclopædia Metropolitana.*

Examples.

1. On the 2nd of June, 1823, the true altitude of the sun's centre was 30° 2′, when the chronometer showed 5h. 1m. 0s.; the latitude was 40° 5 N.; and the sun's

declination at the time of observation, 22° 9′ 17″ N. The chronometer on the 20th of May preceding was 45s. slow for Greenwich time: its daily rate was 2s.·1 losing. Required the longitude of the ship.

Examples for Exercise.

1. On September 23rd, 1845, in the afternoon, and in latitude 50° 30′ N., the observed altitude of the sun's lower limb was 11° 0′ 50″, the index correction being— 3′ 20″, and the height of the eye 20 feet. The chronometer showed 11h. 59m. 30s.; it was fast on Greenwich mean time 45s. ·5 on August 21st, and its daily rate was 5s. ·7 losing; the sun's declination at the time of observation being 0° 18′ 41″ S., and the equation of time 7m. 52s. ·3; also the sun's semi-diameter was 15′ 58″. Required the longitude. Ans. Long. 110° 18′ 10″ W.

2. In the afternoon of October 18th, 1841, in latitude 15° 46′ N., the observed altitude of the sun's lower limb was 12° 40′: the chronometer showed 11h. 12m. 42s. Greenwich time of October 17th: its error August 12th, at noon, was 5m. 26s. slow, and its daily rate was 12s. ·5 gaining. Required the longitude, the index correction being + 2′ 30″, the height of the eye 16 feet, and the following particulars being furnished by the *Nautical Almanac*, namely—

Sun's dec. October 17th, 9° 18′ 8″ S. Hourly diff. + 54″·81. Eq. of time 14m. 34s. ·3. Hourly diff. + 0″·483. Sun's diameter 16′ 5″. Ans. Long. 83° 51′ 45″ E.

3. On September 10th, 1844, in latitude 48° 20′ N., an afternoon altitude of Arcturus was observed to be 31° 5′ 40″, the star west of the meridian: the chronometer showed 5h. 1m. 28s.: its rate August 25th, was 4s. ·3 gaining, and it was 2m. 40s. slow on Greenwich mean time. The index correction was — 4′ 10″, and the height of the eye 20 feet: also the sun's R. A. at the time of observation was 11h. 19m. 18s.; the star's R. A. 14h. 8m. 34s. ·65, and its declination 14° 59′ 44″ N. Required the longitude. Ans. Long. 32° 8′ 20″ E.

ON FINDING THE LONGITUDE AT SEA BY LUNAR OBSERVATIONS.—The reader has sufficiently seen that the difference of longitude between two places on the surface of the earth, is virtually the same as the difference of time between those two places at the same absolute instant. Suppose, for example, that a rocket could be projected so high, and give out light of such intensity, as to be seen at the instant of explosion by two observers thirty or forty miles apart: the explosion takes place, of course, at a certain instant of absolute time: the mean-time clock at Greenwich might mark this instant—in the local reckoning of that place—as 3h. 20m.: an observer to the east of Greenwich might find the time at *his* place to be 3h. 22m.: the difference in the local reckoning would thus give a difference of 2m. in the time, although both observers saw the flash at the same absolute instant; and we should conclude that the easterly place of observation had half a degree, or 30 nautical miles of east longitude. It is the same in reference to any other phenomenon: let only the time at Greenwich be noted which marks the instant of its occurrence, and also the time at any other locality which marks the same instant; the difference of the times thus noted will be the longitude, in time, of that other locality from Greenwich.*

The heavenly bodies furnish signals in abundance analogous to the rocket-signal here imagined, and astronomers have only to make their selections suitably to the circumstances of the observers: what are called *the lunar observations* are the best adapted to determine the longitude at *sea*. Certain stars, lying in or very near to the moon's path, are chosen, and the distance of the moon from each of these, as also from the sun at noon (Greenwich time), and at every interval of three hours, is predicted and recorded in the *Nautical Almanac* for every day in the year. An observer at sea measures one of these distances, and refers to the *Nautical Almanac* for the Greenwich time when the same phenomenon happened; he finds, most likely, that *his* distance is intermediate between a certain *pair* of the three-hourly distances; he knows, therefore, that the Greenwich time is intermediate between the recorded hours; and, just as in the case of any other varying quantity—given in the *Almanac* for regular intervals of time—he calculates the intermediate time corresponding to the intermediate distance, by proportion. The motion of the moon is found to be sufficiently uniform, for a period of three hours, to justify an intermediate position being inferred in this way, and it is sufficiently rapid to render her change of place sensible even in two or three seconds of time; a trifling correction for variable motion will, however, be noticed hereafter.

The lunar observations thus enable the mariner to discover the time at Greenwich independently of the chronometer, and thence to determine the error of his time-keeper; and, therefore, by taking the difference between this error and that last recorded, to apply the proper correction to the mean daily rate. The lunar observations *alone* will not enable the navigator to find his longitude; but they enable him to find what o'clock it is at Greenwich at the instant the lunar distance was taken, and thus to correct his chronometer.

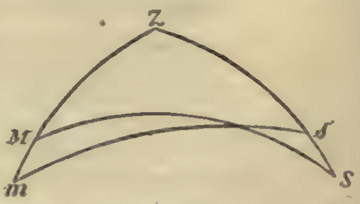
Knowing, in this way, the time at Greenwich, we can very accurately compute the declination of the sun at the time of observation, or its right ascension, if the distance be that between the moon and a star, and thence, by means of the latitude of the place, supposed to be already known, we can find, as explained at page 1094, *et seq.*, the time at that place, and thence the longitude.

It must be remarked that the *observed* distance between two celestial objects is not the *true* distance, any more than their observed altitudes are the true altitudes; these latter—the true altitudes—it is necessary to find, in order, from the observed, to compute the true distance; for it is the true distance, as measured from the centre of the earth, that is predicted in the *Nautical Almanac*: in other words, it is the observed distance cleared from the effects of parallax and refraction. Such being the case, the reader will perceive that the deduction of the Greenwich time, from an observed distance, is not wholly independent of all local information to be afforded by the ship's account: the estimated time at the ship, and the estimated longitude, are evidently useful for the purpose of enabling us to get the semi-diameter and horizontal parallax of the *moon* with greater precision; for these quantities, especially the latter, sensibly vary from noon to midnight, and they are elements which necessarily enter the calculations for reducing the moon's observed altitude to the true altitude.

We shall now investigate formulæ for computing the true distance of the moon's centre from that of the sun, or from a fixed star, by means of the apparent and true altitudes of the two objects, and their apparent distance—that is, the observed distance corrected for semi-diameter.

INVESTIGATION OF FORMULA FOR CLEARING THE LUNAR DISTANCE.—In the annexed diagram (Fig. 31), let Z represent the zenith of the place of observation, and Z M, Z S the two verticals on which the objects are observed. Let *m*, *s* be the observed places of the moon and sun, or of the moon and a fixed star, and let M, S be their true places. As the moon is depressed by parallax more than it is elevated by refraction, M will be above *m*; but the sun, on the contrary, being more elevated by refraction than depressed by parallax, S will be below *s*.

Fig. 31.



The corrections for dip, index error, and semi-diameter being applied, observation gives the apparent zenith distances, Z *m*, Z *s*, and the apparent distance *m s* of the objects themselves; and the proper corrections for parallax and refraction being applied to the apparent altitudes, we get the true zenith distances Z M, Z S, and the object of the present investigation is to determine the true distance M S by computation.

Let d stand for the apparent distance
D . . . true distance
a, a' . . . apparent altitudes
A, A' . . . true altitudes

By Spherical Trigonometry (page 658), the triangle M Z S gives for cos. Z, the following expression, namely:—

$$\text{ocs. Z} = \frac{\text{cos. D} - \text{sin. A sin. A}'}{\text{cos. A cos. A}'}$$

and the triangle *m* Z *s* gives in like manner

$$\text{cos. Z} = \frac{\text{cos. } d - \text{sin. } a \text{ sin. } a'}{\text{cos. } a \text{ cos. } a'}$$

Hence, for the determination of D we have the equation

$$\frac{\text{cos. D} - \text{sin. A sin. A}}{\text{cos. A cos. A}'} = \frac{\text{cos. } d - \text{sin. } a \text{ sin. } a'}{\text{cos. } a \text{ cos. } a'}$$

from which we have for cos. D the expression

$$\text{cos. D} = \frac{\text{cos. } d - \text{sin. } a \text{ sin. } a'}{\text{cos. } a \text{ cos. } a'} \text{cos. A cos. A}' + \text{sin. A sin. A}.$$

But since cos. $(a + a') = \text{cos. } a \text{ cos. } a' - \text{sin. } a \text{ sin. } a'$, this is the same as

$$\text{cos. D} = \frac{\text{cos. } d + \text{cos. } (a + a') - \text{cos. } a \text{ cos. } a'}{\text{cos. } a \text{ cos. } a'}$$

$$\text{cos. A cos. A}' + \text{sin. A sin. A}'$$

$$= \left\{ \frac{\text{cos. } d + \text{cos. } (a + a)}{\text{cos. } a \text{ cos. } a'} - 1 \right\} \text{cos. A cos. A}' + \text{sin. A sin. A}'.$$

If the -1 within the braces be suppressed, we may restore it by adding cos. A cos. A' at the end, as is obvious. Hence

$$\text{cos. D} = \frac{\text{cos. } d + \text{cos. } (a + a')}{\text{cos. } a \text{ cos. } a'} \text{cos. A cos. A}' - \text{cos. } (\text{A} + \text{A}')$$

The numerator of the fraction in this expression being

---

[*] The electric telegraph has been largely used on similar principles throughout Europe during the last few years, for accurately determining the longitudes of various stations.—ED.

the sum of two cosines, we may replace it by a product from the formula (page 628), namely :—

$$\cos.\ \theta + \cos.\ \phi = 2 \cos.\ \tfrac{1}{2}(\theta + \phi) \cos.\ \tfrac{1}{2}(\theta \backsim \phi)$$

so that we have

$$\cos.\ D = \frac{2 \cos.\ \frac{1}{2}\left\{(a + a') + d\right\} \cos.\ \frac{1}{2}\left\{(a + a') \backsim d\right\}}{\cos.\ a \cos.\ a'}$$

$$\cos.\ A \cos.\ A' - \cos.\ (A + A')$$

Subtract each side of this equation from 1, then since by Trigonometry (page 628),

$$1 - \cos.\ D = 2 \sin.^2 \tfrac{1}{2} D, \text{ and } 1 + \cos.\ (A + A') = 2 \cos.^2 \tfrac{1}{2}(A + A')$$

the equation after division by 2 becomes

$$\sin.^2 \tfrac{1}{2} D = \cos.^2 \tfrac{1}{2}(A + A')$$

$$- \frac{\cos.\ \frac{1}{2}\left\{(a + a') + d\right\} \cos.\ \frac{1}{2}\left\{(a + a') \backsim d\right\} \cos.\ A \cos\ A'}{\cos.\ a \cos.\ a'}$$

$$= \cos.^2 \tfrac{1}{2}(A + A')$$

$$\left\{1 - \frac{\cos.\ \frac{1}{2}\left\{(a + a') + d\right\} \cos.\ \frac{1}{2}\left\{(a + a') \backsim d\right\} \cos.\ A \cos.\ A'}{\cos.\ a \cos.\ a' \cos.^2 \frac{1}{2}(A + A')}\right\}$$

Or, calling the second of these factors $1 - \sin.^2 \theta$, that is, $\cos.^2 \theta$, we have

$$\sin.^2 \tfrac{1}{2} D = \cos.^2 \tfrac{1}{2}(A + A') \cos.^2 \theta$$

$$\therefore \sin.\ \tfrac{1}{2} D = \cos.\ \tfrac{1}{2}(A + A') \cos.\ \theta$$

which is known by the name of the formula of Borda. This formula consists, we see, of two parts: the first part determines the arc θ, and the second by means of θ computes D. The working model is therefore this, namely :—

$$\left.\begin{array}{l} \sin.\ \theta = \sqrt{\dfrac{\cos.\ \frac{1}{2}\left\{(a + a') + d\right\} \cos.\ \frac{1}{2}\left\{(a + a') \backsim d\right\} \cos.\ A \cos.\ A'}{\cos.\ a \cos.\ a' \cos.^2 \frac{1}{2}(A + A')}} \\ \sin.\ \frac{1}{2} D = \cos.\ \frac{1}{2}(A + A') \cos.\ \theta \end{array}\right\} (1)$$

from which we see that the entire work for determining the true distance D may be conducted by logarithms.

It may be worth while to remark, that we were fully justified in assuming that the fraction in the foregoing expression for $\sin.^2 \frac{1}{2} D$ could be represented by $\sin.^2 \theta$; for this was only assuming that the fraction must be less than unity, or that the expression within the braces is positive, which it necessarily is, because $\sin.^2 \frac{1}{2} D$ is necessarily positive. A desirable feature in this method of clearing the lunar distance is, that sines and cosines are the only trigonometrical quantities employed in it; a circumstance which not only affords relief to the memory, but, at the same time, facilitates reference to the tables.

Rule for Clearing the Lunar Distance.—The steps for calculating D from the formula just established may be described in words as follows :—

Rule.—1. Add together the apparent distance and the apparent altitudes; take the difference between half their sum and the apparent distance, and underneath the result write the true altitudes; and, leaving a gap for two lines, then write half the sum of the true altitudes: the *whole* sum may be interposed in the space thus left.

2. These directions having been complied with, it will be found that *nine* arcs have been written down, the apparent distance being the first. Then, disregarding the first arc, as also the fourth arc, which is the sum of the preceding three, write opposite to each of the other *seven*, towards the right, the word *cosine*, prefixing, however, "*complement*" to the first two. Refer to the table of sines and cosines for the quantities thus indicated, putting a *plus* mark after the last cosine, and a *minus* mark in front of it.

3. Add up the first six of the numbers thus placed in column, divide the sum by 2, and subtract the cosine previously marked with the *minus*; the remainder will be sin. θ

[These three precepts conduct us, therefore, to the value of the first of the two expressions in the formula (1) above: the fourth precept, following, enables us to compute the second expression].

4. Take out cos. θ, putting a *plus* mark after it, and add it to the cosine with the + after it; the sum will be sin. $\frac{1}{2}$ D; taking, therefore, the corresponding arc $\frac{1}{2}$ D, out of the tables, and multiplying it by 2, we have the true distance sought.

Examples.

1. Suppose the apparent distance between the centres of the sun and moon to be 83° 57′ 33″; the apparent altitude of the moon's centre 27° 34′ 5″; the apparent altitude of the sun's centre 48° 27′ 32″; the true altitude of the moon's centre 28° 20′ 48″; and the true altitude of the sun's centre 48° 26′ 49″. Required the true distance.

Here $d = 83° 57' 33''$, $a = 27° 34' 5''$, $a' = 48° 27' 32''$
$A = 28° 20' 48''$, $A' = 48° 26' 49''$;

and proceeding by the rule, the work will stand thus :—

d	83°	57′	33″			
a	27	34	5	comp. cos.	·0523390	
a'	48	27	32	comp. cos.	·1783835	
2)	159	59	10			
½ sum	79	59	35	cos.	9·2399686	
½ sum ∽ d	3	57	58	cos.	9·9989587	
A	28	20	48	cos.	9.9445275	
A′	48	26	49	cos.	9·8217187	
A + A′	76	47	37		2)39·2358960	
					19·6179480	
½ (A + A′)	38	23	48½	−cos.	9·8941654 +	These two being added together
θ	31	57	53½	sin.	9 7237826	
θ	.	.	,	cos.	9·9285870 +	
½ D	41	40	27	sin.	9·8227524	= their sum.
∴ D =	83	20	54			

In the foregoing operation more attention is paid to minute quantities than is necessary in actual practice. Fractions of a second are of course always disregarded at sea: seconds themselves are, indeed, very frequently neglected; but this negligence in problems like the present is by no means to be commended. A table of sines and cosines computed to every ten seconds—such as the *Tables Portatives* of Callet—will enable the computer to take account of his seconds, without entailing upon him any extra work worth mentioning. Tables of logarithmic sines and cosines, computed to every ten seconds, will also be found in the *Nautical Tables* of Inman and Mackay.

The reader will have observed that, agreeably to what is recommended at page 1048 of the Introduction, the preceding rule directs that the table employed should not be applied to, till the work can be advanced no further without its aid; and that when it is once in hand, all the extracts from it, previously to the determination of θ, should be made before it is laid down. As a and A are always pretty close together, cos. A may be taken out of the table immediately after comp. cos. a; and as a' is, in like manner, in close neighbourhood to A′, cos. A′ may be taken out immediately after comp. cos. a'.

The above is, of course, a rigorous method of clearing the lunar distance from the effects of parallax and refraction, and provided only that the data furnished by the observations be correct, is perfectly accurate. By help of an auxiliary table, like that which forms Table XLII., in the second volume of Dr. Mackay's *Treatise on the Longitude*, the operation may be shortened. The table alluded to supplies the value of the expression log. $\frac{\cos.\ A \cos.\ A'}{\cos.\ a \cos.\ a'}$, which is called the *Logarithmic Difference*, and unlike some of the subsidiary tables, for abridging the calculations required in the direct methods of working the present problem, it may always be used with confidence; this part of the trigonometrical operation may therefore be shortened without any sacrifice of accuracy. In general, however, the indirect methods of clearing the lunar distance, though often shorter than the direct methods, are proportionately deficient in precision. The author conceives that the strict accuracy of the results, and the unhesitating confidence that may consequently be always placed in the conclusions of the direct methods, by Spherical Trigonometry, produce a degree of satisfaction which more than compensates for the trouble of a few additional references to those common tables, with which every calculator may reasonably be expected to be abundantly familiar.

It will, no doubt, occur to the reader, that instead of comp. cos., secant may be used; observing to reject the index 10 from each secant.

2. The apparent distance of the moon's centre from the star Regulus was 63° 35′ 14″; the apparent altitude of the moon's centre 24° 29′ 44″; the apparent altitude of the star 45° 9′ 12″; the true altitude of the moon's centre 25° 17′ 45″; and the true altitude of the star 45° 8′ 15″. Required the true distance.

d 63° 35′ 14″			
a 24 29 44	comp. cos.	·0409617	
a' 45 9 12	comp. cos.	·1516803	
2)133 14 10			
½ sum 66 37 5	cos.	9·5986359

A + A′ 70 26 0		2)39·5953332	
		19·7976666	
½(A + A′) 35 13 0	− cos.	9·9122099+	These two being added together
θ 50 11 23	sin.	9·8854567	
θ . . .	cos.	9·8063479+	
½ D 31 32 17½	sin.	9·7185578 = their sum.	
∴ D = 63 4 35			

On Making the Observations.—In taking a lunar distance at sea, it is desirable that there should be *three* observers; one of these measures the distance between the limbs of the sun and moon, or between the limb of the moon and the selected star, and the other two take the altitudes of the objects, at the instant the distance is obtained. A single distance, and a single corresponding pair of altitudes, are not in general considered as sufficient; but a set of distances, and a set of corresponding altitudes, are usually taken, allowing as little time as possible to intervene between each observation: the mean of the distance, and the corresponding means of the altitudes, are then employed in the calculation.

If, however, there be but one observer, it will be necessary that he have the aid of an assistant, to note by the watch intervals of time, the observer proceeding as follows. 1, Let the altitude of the sun or star be taken; 2, then the altitude of the moon; 3, a set of distances; 4, another altitude of the moon; 5, another altitude of the sun or star; the times of each observation being noted. Then let the means of the distances and times of observing them be taken; and reduce the altitudes to the mean time thus found by proportion. These are the directions given by Norie; but Lieut. Raper, an experienced practical navigator, recommends as follows:—When the observer is alone, he will first observe the altitude of the object farthest from the meridian, then that of the other object, and then the distance, concluding with the altitudes in the reverse order; the reason of this order is, that the outer object preserves uniformity in its change of altitude for a longer time than the other, and consequently its altitude may be reduced, by simple proportion, to an intermediate time, with less error than the altitude of the other object; we may add, however, that it is desirable that the outer object should not be the moon.

When the ship has much motion, the observer fixes himself in a corner, or lies on his back on the deck, to take the distance, in order to remove, as much as possible, the sense of bodily effort and inconvenience which disturbs the eye and the attention. Three or five distances, at least, should be taken; less precision is necessary in taking the altitudes than in observing the distance, so that one altitude of each object, taken with ordinary care, will in general suffice, when the time at the ship is not to be deduced as well as the true distance.

Other Methods of Clearing the Distance.—As the problem of deducing the true lunar distance from the observed distance is one of such note and importance in Nautical Astronomy, we shall present the reader with some other methods, all, like that of Borda just given, conducted by the rigorous principles of Spherical Trigonometry, and requiring only the common logarithmic and trigonometrical tables; that is, only the logarithms of numbers, and the natural and logarithmic sines and cosines.

The first of these additional methods which we shall offer is that of Delambre, the formula for which occurs in the investigation of the method given at page 1100; namely—cos. D

$$= \frac{2 \cos. \tfrac{1}{2}\{(a + a') + d\} \cos. \tfrac{1}{2}\{(a + a') \backsim d\} \cos. A \cos. A}{\cos. a \cos. a'}$$

$$- \cos. (A + A').$$

The logarithm of the first expression in this formula is calculated as in the method of Borda; then the natural number answering to that logarithm is taken out of the table, and the natural cosine of (A + A′) subtracted from it; the remainder is the natural cosine of the true distance. As this is a sort of mixed method, requiring reference to both logarithmic and natural cosines, attention must be paid to the change of radius in passing from one to the other: the expression which it is here proposed to find the common logarithm of, will supply four additive logarithms and two subtractive ones; hence two tens, or 20, must be suppressed in the result (page 1038); but if the arithmetical complements of log. cos. a, log. cos. a', be *added*, then four tens, or 40, must be suppressed; and the result will then be, the ordinary logarithm of the expression; and from the number answering thereto, the nat. cos. (A + A′) is to be subtracted, as the formula indicates.

Taking the example at page 1100, in which

$$d = 83° 57' 33'', \ a = 27° 34' 5'', \ a' = 48° 27' 32''$$
$$A = 28° 20' 48'', \ A' = 48° 26' 49''$$

The operation by the above method of Delambre will stand arranged as follows:—

d 83° 57′ 33″ . .	comp. cos.	·0523390
a 27 34 5 . .	comp. cos.	·1783835
a' 48 27 32 . .	log. 2	·3010300
2)159 59 10		
½ sum 79 59 35 . .	cos.	9·2399686
½ sum ∽ d 3 57 58 . .	cos.	9·9989587
A 28 20 48 . .	cos.	9·9445275
A′ 48 26 49 . .	cos.	9·8217187
	log.	·3442921 = $\bar{1}$·5369260 (40 suppressed).
A + A′ 76 47 37	nat. cos.	·2284595
D 83 20 54	nat. cos.	·1158326

Other formulæ may be investigated as follows:—

Referring to the two expressions for cos. Z at page 1099, we have

$$1 + \cos. Z = \frac{\cos. D + \cos. A \cos. A' - \sin. A \sin. A'}{\cos. A \cos. A'}$$

$$= \frac{\cos. D + \cos. (A + A}{\cos. A \cos. A'}$$

$$1 + \cos. Z = \frac{\cos. d + \cos. a \cos. a' - \sin. a \sin. a}{\cos. a \cos. a'}$$

$$= \frac{\cos. d + \cos. (a + a')}{\cos. a \cos. a'}$$

$$\therefore \frac{\cos. D. + \cos. (A + A')}{\cos. A \cos. A'} = \frac{\cos. d + (\cos. a + a')}{\cos. a \cos. a'}$$

$$\therefore \cos. D = \left\{ \cos. d + \cos. (a + a') \right\} \frac{\cos. A \cos. A'}{\cos. a \cos. a'}$$

$$- \cos. (A + A') \quad . \quad . \quad . \quad (1)$$

From the same two expressions for cos. Z, we also have

$$1 - \cos. Z = \frac{\cos. A \cos. A' + \sin. A \sin. A' - \cos. D}{\cos. A \cos. A'}$$

$$= \frac{\cos. (A \backsim A') - \cos. D}{\cos. A \cos. A'}$$

$$1 - \cos. Z = \frac{\cos. a \cos. a' + \sin. a \sin. a' - \cos. d}{\cos. a \cos. a'}$$

$$= \frac{\cos. (a \backsim a') - \cos. d}{\cos. a \cos. a'}$$

$$\therefore \frac{\cos. (A \backsim A') - \cos. D}{\cos. A \cos. A'} = \frac{\cos. (a \backsim a') - \cos. d}{\cos. a \cos. a'}$$

$$\therefore \cos. D = \left\{ \cos. d - \cos. (a \backsim a') \right\} \frac{\cos. A \cos. A'}{\cos. a \cos. a'}$$

$$+ \cos. (A \backsim A') \quad . \quad . \quad . \quad . \quad (2)$$

The formula marked (1) and (2) are tolerably commodious by help of the common logarithmic tables; as an exemplification of their advantages, we shall solve the example at page 1101 by each. In this example the following quantities are given, namely—

$$d = 63° 35' 14'', \; a = 24° 29' 44'' \; a' = 45° 9' 12''$$
$$A = 25° 17' 45'', \; A' = 45° 8' 15''.$$

Determination of D *by formula* (1).

			Logarithms.
d 63° 35′ 14″ nat. cos.	·4448349	+	
a 24 29 44	.	.	comp. cos. ·0409617
a′ 45 9 12	.	.	comp. cos. ·1516803
a + *a*′ 69 38 56 nat. cos.	·3477722	+	
natural number	·7926071	.	$\bar{1}$·8990579
A 25 17 45	.	.	cos. 9·9562230
A′ 45 8 15	.	.	cos. 9·8484402
natural number	·7877042	.	$\bar{1}$·8963631
A+A′ 70 26 0 nat. cos.	·3349034	—	
D 63° 4′ 35″ nat. cos.	·4528008		

With the exception of the middle logarithm in the column on the right, the sum of the numbers in that column may be found at once by a table of the Logarithmic Difference, as already noticed at page 1100. Of all the auxiliary tables employed in Nautical Astronomy, or at least in that part of it with which we are here occupied, the table alluded to is perhaps the most useful; the element it furnishes enters into nearly all the methods of clearing the lunar distance.

As far as the author knows, the method just given is new; but rules for clearing the distance are so numerous, that it is more than probable it has appeared elsewhere. In working by this method, it is best to take the formula itself as a guide, and to attend to the algebraic sign of the factor $\left\{ \cos. d + \cos. (a + a') \right\}$: if this should be negative, the first natural number above, is still to be treated as positive; the second natural number, which is the product of the two factors in the formula, will then, however, be negative, and from this negative number the nat. cos. (A + A′) is to be subtracted as above.

Determination of D *by formula* (2).

d 63° 35′ 14″ nat. cos.	·4448349	+	
a 24 29 44	.	.	comp. cos. ·0409617
a′ 45 9 12	.	.	comp. cos. ·1516803
a ∽ *a*′ 20 39 28 nat. cos.	·9357042	—	
natural number	·4908693	.	$\bar{1}$·6909659
A 25° 17′ 45″	.	.	cos. 9·9562230
A′ 45 8 15	.	.	cos. 9·8484402
natural number	·4878329	.	$\bar{1}$·6882711
A ∽ A′ 19 50 30 nat. cos.	·9406341	+	
D 63 4 35 nat. cos.	·4528012		

The first of the preceding natural numbers is, by the formula, negative, though treated as positive. In consequence of this, the second natural number—which is the product of the two factors in the formula—is also negative, so that cos. D is the *difference* between the last nat. number and cos. (A ∽ A′).

This last method of clearing the distance is the same as that proposed by Mr. Keith, in his *Treatise on Trigonometry*, and, like the one previously given, is capable of abridgment by means of the table of "Logarithmic Differences."

The reader will observe that the natural cosine of D, arrived at above, differs by four units in the seventh place of decimals, from the natural cosine of D in the former method, although the resulting arcs differ only by a fraction of a second. Occasional insignificant discrepancies of this kind must be expected in working the same example by different methods with tables. In looking at the "differences" in tables, it will be seen that, in some parts, the difference between two consecutive numbers is large, and in other parts small. In proportioning for an intermediate number, in the former case a comparatively large difference will have but small influence, while in the latter case a comparatively small difference may have a very sensible effect. But a discrepancy in the seventh place of decimals is of no moment even in working to seconds.

All the preceding methods of clearing the lunar distance are independent of subsidiary tables; a large collection of compendious rules for working the problem by special tables will be found in Dr. Mackay's valuable *Treatise on the Longitude;* and a very short form of operation is also given by Mr. Woodhouse in the *Appendix* to White's *Ephemeris*, 1855.

Before leaving the present problem, it may be useful to observe that the altitudes of the objects are not required to that precision with which the distance should be taken: this is a desirable circumstance, because, from the frequent obscurity of the sea horizon, it is more difficult to get the altitudes accurately than the distance. If reference be made to any of the formulæ given in the preceding pages, it will be seen that *d* remaining the same, a small alteration in the values of *a*, *a*′, and the same alteration in those of A, A′, cannot produce any sensible effect upon the value of D: the factor $\frac{\cos. A \cos. A'}{\cos. a \cos a'}$, the logarithm of which is, in nautical tables, called the Logarithmic Difference, is always very nearly equal to unit, as is obvious; and this is the principal reason why a small error in the altitudes does not sensibly affect the distance. It is of importance, however, that the proper corrections be carefully applied to the observed altitudes to obtain the true altitudes, even though the former should not have been taken with precision—the *relative* values of the observed and true altitudes must still be preserved. With a view to the determination of the longitude from the lunar distance, accuracy in these corrections is of much importance; and the neglect even of those depending upon the state of the atmosphere, as indicated by the barometer and thermometer, will sometimes occasion an error of more than thirty minutes of longitude.

From what is here said, the learner will perceive that a few seconds may always be safely added to or subtracted from the observed altitudes, if such a modification be found to facilitate the calculation; the seconds may, for instance, be always made a multiple of 10. The observed altitudes may, indeed, without occasioning any appreciable error in the result, be taken to the nearest minute; and even an imperfect altitude, that may err from the truth by so much as two or three minutes, may still be employed with safety, provided the time is not to be computed as well as the distance. In most cases an error of altitude to the extent of 10 minutes will affect the resulting distance by less than that number of seconds. It is also worthy of notice that the apparent distance itself may be so modified as to be rendered free from seconds, provided that when D is deduced, the seconds of error, whether in defect or excess, be applied the reverse way to D.

But except in the merely approximative methods of solution, seconds cannot be wholly dispensed with throughout the work: the corrections for deducing the observed altitudes to the true will always introduce them. By means, however, of the tables already referred to, in which the trigonometrical quantities are computed to every ten seconds of the arcs or angle, the proper allowance for the odd seconds may always be made with but comparatively little trouble.

Examples for Exercise.

1. The apparent distance between the moon's centre and a star is 64° 36′ 40″; the apparent altitude of the moon's centre 44° 33′; the apparent altitude of the star 11° 51′; the true altitude of the moon's centre 45° 15′ 38″; and the true altitude of the star 11° 46′ 33″. Required the true distance. Ans. D = 64° 46′ 14″.

2. The apparent distance between the centres of the sun and moon is 108° 14′ 34″; the apparent altitude of the moon's centre 24° 50′; the apparent altitude of the sun's centre 36° 25′; the true altitude of the moon's centre 25° 41′ 39″; and the true altitude of the sun's centre 36′ 23′ 50″. Required the true distance. Ans. D = 107° 32′ 1″.

3. The apparent distance between the centre of the moon and a star is 51° 28′ 30″; the apparent altitude of the moon's centre 12° 30′ 4″; the apparent altitude of the star 24° 48′ 17″; the true altitude of the moon's centre 13° 20′ 40″; and the true altitude of the star 24° 46′ 14″. Required the true distance. Ans. D = 51° 9′ 48″.

4. The apparent distance between the moon's centre and a star is 31° 13′ 26″; the apparent altitude of the moon's centre 8° 26′ 13″; the apparent altitude of the star 35° 40′; the true altitude of the moon's centre 9° 20′ 45″; and the true altitude of the star 35° 38′ 49″. Required the true distance. Ans. D = 30° 23′ 56″.

5. The apparent distance of the centres of the sun and moon is 90° 21′ 17″; the apparent altitude of the moon's centre 5° 17′ 9″; the apparent altitude of the sun's centre 84° 7′ 20″; the true altitude of the moon's centre 6° 9′ 14″; and the true altitude of the sun's centre 84° 7′ 15″. Required the true distance. Ans. D = 89° 29′ 18″.

NOTE.—The method of finding the true distance between the centre of the moon and a star, is the same as that for the distance between the moon's centre and a planet: in the case of a star, the true altitude is deduced from the apparent altitude, by applying the correction for refraction merely; but in the case of a planet, a correction may be necessary for the parallax in altitude. But in general this correction may be neglected, as it is usually too small to be of much importance.

ON COMPUTING THE ALTITUDES.—It sometimes happens that, though circumstances may be favourable for taking a lunar distance, yet the obscurity of the horizon may present an obstacle to the observations for altitude; in such a case the true altitudes will have to be computed, and from these the apparent altitudes may be deduced, by applying the corrections the contrary way. To compute an altitude it is necessary to know the hour-angle, or angular distance, of the object from the meridian. If the object be the sun, this angle is the apparent time for the meridian; and as the altitude, as already remarked, is not required with precision, the estimated time at the ship will answer for the purpose. If the object be the moon or a star, the sun's right ascension, at the instant, must be increased or diminished by the apparent time, according as this time is P.M. or A.M., to get the right ascension of the meridian; the difference between this and the right ascension of the object, is the hour-angle or the meridian distance of the object. The hour-angle being thus found, a formula for the altitude may be investigated as follows:—

Let P be the hour-angle, l the co-latitude, z the co-altitude, and p the polar distance or co-declination. Then the fundamental formula of spherical trigonometry gives,

$$\cos. \mathrm{P} = \frac{\cos. z - \cos. l \cos. p}{\sin. l \sin. p}$$

$$\therefore \cos. z = \cos. l \cos. p + \sin l \sin. p \cos. \mathrm{P};$$

$$\text{but } \cos. \mathrm{P} = 1 - 2 \sin.^2 \tfrac{1}{2} \mathrm{P}$$

$$\therefore \cos. z = \cos. l \cos. p + \sin. l \sin. p - 2 \sin. l \sin. p \sin.^2 \tfrac{1}{2} \mathrm{P}$$

$$\therefore \cos. z = \cos. (l \backsim p) - 2 \sin. l \sin. p \sin.^2 \tfrac{1}{2} \mathrm{P} \quad \ldots (1)$$

By means of these tables of natural and logarithmic sines and cosines, the co-altitude z may be obtained from this formula; but to adapt it wholly to logarithms, let 1 be added to each side of the equation; then remembering that $1 + \cos. \mathrm{A} = 2 \cos.^2 \tfrac{1}{2} \mathrm{A}$, we have, upon dividing by 2,

$$\begin{aligned} \cos.^2 \tfrac{1}{2} z &= \cos.^2 \tfrac{1}{2} (l \backsim p) - \sin. l \sin. p \sin.^2 \tfrac{1}{2} \mathrm{P} \\ &= \cos.^2 \tfrac{1}{2} (l \backsim p) \left\{ 1 - \sin. l \sin. p \sin.^2 \tfrac{1}{2} \mathrm{P} \times \sec.^2 \tfrac{1}{2} (l \backsim p) \right\} \end{aligned}$$

Put $\cos.^2 \mathrm{M}$ for the expression within the braces; then for computing the altitude a, that is, the complement of z, we have the following formula—namely,

$$\left. \begin{aligned} \sin. \mathrm{M} &= \sin. \tfrac{1}{2} \mathrm{P} \sec. \tfrac{1}{2} (l \backsim p) \sqrt{\sin. l \sin. p} \\ \sin. \tfrac{1}{2} (a + 90^\circ) &= \cos. \tfrac{1}{2} (l \backsim p) \cos. \mathrm{M} \end{aligned} \right\}$$

or, which is perhaps a little more convenient,

$$\left. \begin{aligned} \sin. \mathrm{M} &= \frac{\sin. \tfrac{1}{2} \mathrm{P}}{\cos. \tfrac{1}{2}(l \backsim p)} \sqrt{\sin. l \sin. p} \\ \sin. \tfrac{1}{2}(a + 90^\circ) &= \cos. \tfrac{1}{2} (l \backsim p) \cos. \mathrm{M} \end{aligned} \right\} \quad \ldots\ldots (2)$$

Suppose, for example, that by means of the estimated time at the ship, and the longitude by account, the moon's angular distance from the meridian is found to be 33° 30′, at the time of taking a lunar distance in latitude 38° 14′, the moon's co-declination reduced to the time, being 64° 13′ 13″. Required the apparent altitude by computation, the obscurity of the horizon preventing an observation. Working by the formula (2) the operation is as follows, where P = 33° 30′ p = 64° 13′ l = 51° 46′:

l	51° 46′	½ sin.	4·947572		
p	64° 13′	½ sin.	4·977228		
½ P	16° 45′	sin.	9·459688		
½($l \backsim p$)	6° 13½′	comp. cos.	·002568	cos.	9·997432
		sin.	9·387056	cos.	9·986683
½(a + 90°) = 74° 36′				sin.	9·984115
	2				

∴ a = 59° 12′ the true altitude

cor. for par. and refraction — 28′

58° 44′ the apparent alt.

It is obvious, that in strictness, the correction for parallax and refraction should be taken out of the tables in accordance with the *apparent* altitude, not the true altitude: the correction above, therefore, belongs to an altitude somewhat too great, so that only an approximate apparent altitude is in reality deduced from the true altitude. The proper correction may, however, be found by again entering the table with this approximate apparent altitude; we shall thus get 27′ 54″ for the correction, instead of 28″, so that the correct apparent altitude is 58° 44′ 6″.

Unless the time at the ship is to be deduced, precision is not necessary in computing the true altitude:—seconds may always be disregarded, and the result found to the nearest minute as above. But seconds should not be neglected in the corrections.

It is of importance that the practical navigator have a due appreciation of the value of small quantities in the computation of the true lunar distance: it is only in the apparent altitudes that precision can be dispensed with. In finding *latitude*, if the result be brought out to the nearest minute, the demands of practice will be fully satisfied, as the error cannot exceed half a mile; but an error of only twenty-two seconds in the lunar distance will, on the average, occasion an error of ten minutes of longitude, which, except in high latitudes, is equivalent to seven or eight miles; and within 36° of latitude the error would range from eight to ten miles. Too much pains and caution cannot therefore be exercised in observing a lunar distance: the instrument should be of the very best description, and the observer should have a well-disciplined eye; but the corresponding altitudes may be safely taken by a less skilful person.

An interesting incident is related by the late Captain Basil Hall, an officer who was highly accomplished in the science of his profession. He once sailed from San Blas, on the west coast of Mexico; and after a voyage of eight thousand miles, occupying eighty-nine days, he arrived off Rio Janeiro, having in this interval passed through the Pacific Ocean, rounded Cape Horn, and crossed the South Atlantic, without making any land, or even seeing a single sail, with the exception of an American whaler off Cape Horn. When within about a week's sail of Rio, he set seriously about determining, by lunar observations, the longitude of his ship, and then steered his course accordingly by those common principles of navigation which may be safely employed for short distances between one known position and another.

Having arrived to within what he considered, from his computations, to be about fifteen or twenty miles of the coast, he hove to, at four o'clock in the morning, to await the break of day, and then bore up, proceeding cautiously onward on account of a thick fog which enveloped the ship. As this cleared away, the people on board had the satisfaction of seeing the great Sugar-loaf Rock, which stands on one side of the harbour's mouth, so nearly right a-head that they had not to alter their course above a point, in order to hit the entrance of the harbour! This was the first land they had seen for three months, after crossing so many seas, and being set backwards and forwards by innumerable currents and foul winds. The effect on all on board was electric, and the admiration of the sailors was unbounded.

Something in this remarkable case may have been due to a compensation of small errors; but it is only fair to conclude, that the accuracy with which the ship's position was ascertained, was almost entirely attributable to the precision with which the lunar distances were taken, and the care with which the computations were executed.

To Determine the Longitude from the Lunar Observations.—In the preceding articles, we have shown at considerable length how the true distance between the moon and the sun, or a fixed star, as seen from the centre of the earth, may be determined from the observed distance taken from the surface. It was also shown, by means of the altitude of a celestial object whose declination is known, and the latitude of the place where the altitude is taken, how the time at that place may be found.

The determination of a lunar distance necessitates the determination of the altitudes of the objects whose distance is observed, so that the data for finding the true lunar distance, involves likewise the data for finding the time when that distance had place. But, as already remarked, if these two objects be sought to be accomplished, the altitude employed for the purpose of ascertaining the time at the ship, must be taken with a degree of precision which is not indispensable in "working the lunar:" much more care and accuracy is requisite in observations of altitude for *time* than for either latitude or lunar distance; and on this account the time at ship is, in general, determined independently by one or other of the methods explained at page 1094, *et seq.*, either shortly before or shortly after the distance is taken. By means of the chronometer or watch, the interval between the time thus found, and the instant of taking the distance, is known, and the proper correction for change of longitude in that interval being made, we get the time corresponding to the distance.

We have just said that the altitude—or rather the set of altitudes—for determining the time, are taken *shortly* before or after the observations for the distance, whenever these observations are not themselves sufficiently accurate for the purpose. It is desirable that the interval should not be large, because the difference of longitude in that interval may be large too, and our estimation of its amount is, therefore, liable to a larger error. But as it is important to get the altitude as precise as possible, the situation of the object should be as near the prime vertical; that is, as nearly due east or due west as possible (page 1093). There is thus room for the exercise of some judgment: the object selected for the determination of the time at ship should be near the prime vertical, and it should reach this position shortly before or shortly after the observation for the lunar distance. Whenever the weather is so favourable as to render all risk of losing the anticipated observation but very small, it is prudent to wait till these conditions are fulfilled, provided other circumstances are such as to allow of the delay. In general, the object best suited to the determination of the time at sea is the sun, as its declination, though varying with the time, changes so slowly, as to be deducible accurately enough for the purpose from the estimated time, or time by account, as sufficiently shown at page 1095. A fixed star, however, is very suitable for the purpose, whenever it is nearly due east or west, and the horizon clearly enough defined to admit of an accurate observation of its altitude.

The object of the lunar distance is to find the time at Greenwich at the instant that distance has place; and the object of the other, or extra observation, is to find the time at the same instant at the ship. The difference of the two times gives the longitude in time. The Greenwich time is obtained by comparing the true distance, deduced from the observation, with the nearest predicted distance, supplied by the *Nautical Almanac*, in the way that will be explained presently. It may be well, however, first to show what will be the average effect on the inferred longitude of a given error, in the determination of the lunar distance.

Effect on the Longitude of an Error in the Lunar Distance.—The mean diurnal motion of the moon in her orbit is 13°·1764: at certain times it is about 2° slower, and at other times 2° quicker; but this is her average rate of motion; so that, on the average, 360° of longitude (or 24h. of time) correspond to 13°·1764 of the moon's progress. Hence, to find the error in longitude produced by an error of a seconds in the distance between the moon and a fixed star in her path, we have the proportion

$$13^\circ{\cdot}1764 : 360^\circ :: a : \frac{360a}{13{\cdot}1764} = 27{\cdot}322a\,;$$

which show that the error in the longitude is 27·322 times the error in the distance. Thus an error of 10″ in the lunar distance, causes, on the average, an error of 273″·22 in the resulting longitude, or 4′ 33″·22; and an error of 1′ in the distance, causes, on the average, an error of 27′ 19″·3 in the longitude.

The more rapidly the moon moves, the less is the effect upon the longitude of a given error in the lunar distance: the most rapid change in three hours is very nearly 1° 48′, or 1°·8; so that for any error a in the distance, the corresponding error in longitude, in the most favourable case is $\frac{45a}{1{\cdot}8} = 25a$. Hence, in the most favourable case, the error in longitude corresponding to an error of 10″ in the lunar distance, is 250″ = 4′ 10″; and the error in longitude caused by an error of 1′ in the lunar distance, is 25′. As every inaccuracy in the distance becomes thus increased twenty-five fold in the longitude deduced from it, even in the most favourable case, the reader will at once perceive the importance of securing precision in this element. Several distances ought to be carefully observed, and the mean of them all employed; and scrupulous attention should be paid to the *corrections* of the altitudes; though, as already remarked, the altitudes themselves need not be taken with the utmost nicety.

To obtain the time at Greenwich, corresponding to the true distance determined at sea, requires an operation in simple proportion. To facilitate this operation, Dr. Maskelyne—to whom, indeed, navigators are indebted for originating the *Nautical Almanac*—contrived the table of *Proportional Logarithms*, to be found in every collection of nautical tables. As Proportional Logarithms have not as yet been alluded to in the present section, it will be necessary to say a word or two about them here.

Proportional Logarithms.—These logarithms are derived from the logarithms in common use, thus:— From the logarithm of 10800, the number of seconds in 3 hours, subtract the logarithm of a, any portion of time, in seconds, less than 3 hours: the remainder is called the proportional logarithm of a; in other words,

$$\text{Prop. log. } a = \text{common log. } \frac{10800}{a}$$

If $a = 10800$, then Prop. log. a = com. log. $1 = 0$; so that proportional logarithms are, in fact, complements of the ordinary logarithms to the number log. 10800; just as the arithmetical complements of log. sines and log. cosines, are complements to 10.

As already remarked, the lunar distances, given in the *Nautical Almanac*, are calculated for every three hours of interval. Suppose a distance is determined at sea, at some Greenwich time within one of these intervals; we seek in the *Almanac* for the nearest distance, preceding, in order of time, the given distance, and take the difference between it and the given distance: call this d, and the difference between the two three-hourly distances, intermediate to which the given distance occurs, call D: then, by proportion, we should have for the time x^h, corresponding to the given distance,

$$D : d : : 3^h : x^h ;$$

and therefore, in common logarithms, we should have

$$\text{log. } x^h = \text{log. } 3^h + \text{log. } d - \text{log. D.}$$

But since $3^h = 10800''$, the proportional logarithm of which is 1, we should have, in proportional logarithms,

$$\text{Prop. log. } x^h = \text{Prop. log. } d - \text{Prop. log. D.}$$

In the *Nautical Almanac*, Prop. log. D is inserted between the distances there given, at the beginning and end of every three hours; so that by subtracting this given proportional logarithm from the proportional logarithm of d taken out of the table, we get a proportional logarithm, answering to which, in the table, is the portion of time to be added to the hour of the earliest distance: the result is the Greenwich mean time corresponding to the given distance.

For example—Suppose it were required to find the Greenwich mean time, at which the true distance between the Moon and Pollux was 32° 30′ 25″, on January 14, 1846.

By inspecting the distances in the *Nautical Almanac* for that year, we find against January 14, and opposite the name of the proposed star, Pollux, the following row of lunar distances:—

Midnight.	Pr. log.	xv$^{h.}$	Pr. log.	xviii$^{h.}$	Pr. log.	xxi$^{h.}$	Pr. log.
31° 49′ 25″	3368	33° 12′ 18″	3342	34° 35′ 41″	3319	35° 59′ 31″	3298

From which it appears that the time at Greenwich corresponding to the given lunar distance was between midnight and XV hours; the nearest distance preceding, in order of time, the given distance, is therefore the distance at midnight: we therefore proceed as follows:—

Distance at midnight 31° 49′ 25″ Prop. log. of diff. 3368 –
Given distance 32 30 25
Difference 0 41 0 . . Prop. log. 6425
Portion of time after midnight } 1h. 29m. 2s. . . Prop. log. 3057

Hence the Greenwich mean time, when the distance was as stated above, was 13h. 29m. 2s.

If the distance increased with perfect uniformity during the interval within which the given distance is found, the Greenwich time corresponding to that given distance, determined as above, would be strictly correct, but, as such is not the case, a correction should be applied to the time so found, for the variation of the differences of the distances. A table for obtaining such corrections of the approximate interval of time as found above, is given in the *Nautical Almanac*. In the example above, the correction comes out 8s. additive, so that the correct Greenwich mean time is 13h. 29m. 10s.; the neglect of this correction would, however, occasion an error of only 2′ in the longitude; but in extreme, and therefore, of course, unusual cases, the error in longitude, from a neglect of this correction, might amount to so much as 12′ in the longitude.

Besides the use of proportional logarithms in connection with the lunar problem, they also serve to point out the star which is most favourably circumstanced for accurate observation; that star being to be preferred which has the *least* proportional logarithm opposite to it: for, as already shown (page 1104), the greater the velocity of the moon from or towards a star, the greater is the reliance to be placed on an observation of the distance; in other words, the less is the effect of a small error in the distance upon the longitude. It is a property of proportional logarithms, to decrease as the natural numbers answering to them increase; a smaller proportional logarithm, therefore, indicates a greater velocity of the moon, or greater variation of distance in the interval, upon which the value of the observation depends.

We shall add another example or two of finding the Greenwich mean time, corresponding to a given lunar distance on a given day.

2. On August 2nd, 1836, the distance of the moon from the planet Mars was found, from an observation at sea, to be 56° 30′ 8″: the *Nautical Almanac* gave,

Aug. 2, at 3h. distance 57° 43′ 59″ Pr. log of diff. 2948 –
Given distance . . 56 30 8
Difference . . . . 1 13 51 Pr. log. . . 3869
Portion of time aft. 3h., 2h. 25m. 36s. Pr. log. . 921

Hence the mean time at Greenwich was 5h. 25m. 36s.

3. On April 7, 1831, the true distance between the sun and moon was found to be 65° 54′ 48″: the *Nautical Almanac* gave,

April 7 at noon, Dist. 67° 0′ 8″ P. L. of diff. 3051 –
Given distance . . . 65 54 48
Difference . . . . . 1 5 10 P. L. . . 4412
Portion of time aft. n., 2h. 11m. 35s. P. L. . . 1361

Hence the Greenwich mean time was 2h. 11m. 35s.

4. On November 22, 1853, the true distance of Saturn from the moon was found to be 77° 52′ 45″: the *Nautical Almanac* gave,

Nov. 22, at 3h. Distance, 77° 14′ 40″, and P. L. = 6745.

Required the Greenwich mean time.

Ans. 4h. 13m. 55s.

The proportional logarithms annexed to the Lunar Distances in the *Nautical Almanac*, and most of the tables of them inserted in books on Navigation, are limited to four places of figures; in certain parts of the table, this number of places is too few to show any difference for two, or even three consecutive *arguments;* thus the proportional logarithms of 2h. 41m., 2h. 41m. 1s., 2h. 41m. 2s., are all the same—namely, 484: this is a defect. In Dr. Inman's *Nautical Tables*, the proportional logarithms are given to five places of figures, so that the logarithms of consecutive quantities are not confounded. If five-figure proportional logarithms are used in finding the Greenwich mean time, corresponding to a lunar distance, then the proportional logarithm of the difference between the consecutive lunar distances in the *Almanac* must be sought for in the table, as the *Almanac* gives it to only four places of figures. Thus, taking the example just given,

Given distance .	77° 52′ 45″	
Nov. 22, at 3h Dist.	77 14 40	from *Naut. Alm.*
,, 6h. ,,	78 47 24	
Diff. of dist. in *Alm.*	1 32 44 .	Prop. log. 28804—
Diff. of given dist. and that at 3h.	0 38 5 .	Prop. log. 67454
Time after 3 hours,	1h. 13m. 55s. .	Prop. log. 38650

Hence the Greenwich mean time was 1h. 13m. 55s.

Examples of Determining the Longitude from Lunar Observations.

The foregoing articles contain all that is necessary for the determination of the time at the ship, and the time at Greenwich, at the same absolute instant; and it has been sufficiently explained how these two determinations lead immediately to the discovery of the longitude, as in the following examples :—

Example 1.—On the 1st of September, 1846, the true distance of the star Antares from the moon's centre was 39° 48′ 20″, the mean time at the ship being 8h. 14m. 12s. Required the longitude.

The time at the ship at the instant the lunar distance was taken being known, we have merely to find the Greenwich time corresponding to that distance. We seek, therefore, among the predicted lunar distances in the *Nautical Almanac*, for that one preceding it in order of time, which is the nearest to it, and take the difference between the two. The proportional logarithm, annexed to the distance extracted from the *Nautical Almanac*, subtracted from the proportional logarithm of this difference, will give the proportional logarithm corresponding to a portion of time, to be added to the time at which the distance taken from the *Almanac* had place. The result will be the time at Greenwich corresponding to the given time at the ship. Thus :—

Sept. 1, at 6h., dist. (*Naut. Alm.*)	38° 50′ 28″	P.L. 2287 –
Given distance . . .	39 48 20	
Difference	0 57 52	P.L. 4928
Time after 6h. .	1h. 37m. 59s.	P.L. 2641
∴ Time at Greenwich	7h. 37m. 59s.	
Time at ship . .	8h. 14m. 12s.	
Long. E. in time	0h. 36m. 13s.	
Then, page 1104, 36′ in time =	9° 0′ 0′	In Longitude.
,, 13″ ,, =	3 15	
∴ Longitude	9 3 15	East.

In this example the mean time at the ship is supposed to have been determined by one or other of the methods already explained, and the true lunar distance to have been deduced from the observed, as shown in the preceding pages. But it will be instructive to exhibit, in a connected form, the operations necessary for ascertaining the longitude from the ship's account, in combination with the astronomical observations: we shall, therefore, proceed to an illustration or two of this kind, conducting the process by the following steps :—

1. The first object will be to get, from the ship's account, the approximate time at Greenwich when the observations are made.

By help of this approximate Greenwich date, we shall find semi diameter, horizontal parallax, declination, &c., at the instant of observation, sufficiently near the truth for our ultimate purpose; because, as already seen, these elements vary so slowly, that even a large error in the time can never affect their values, except in a very trifling degree.

2. The next thing will be to apply the necessary corrections to the observed, in order to obtain the apparent and true altitudes, and the apparent distance. Sufficient data will thus be obtained for deducing both the time at ship and the time at Greenwich; and it is matter of indifference which of these requisites is determined first, when the time at the ship is deduced from either the sun or a star.

An error in the ship's account will but very slightly affect the time at ship when the observation is made, unless this time be determined from the moon (page 1105); but the altitude employed must be taken with care.

An error in the ship's account will, in like manner, but very slightly affect the lunar distance, and thence the time at Greenwich; for the moon's semi-diameter, though dependent on the time, varies too slowly to cause its approximate value, deduced from the estimated Greenwich time, to differ from its true value, at the instant of taking the distance, by any appreciable amount; and as far as the *altitude* is concerned, it has been seen that this difference is of no moment.

Example 2.—On February 12, 1848, at 2h. 36m. P.M., mean time by estimation, in latitude 53° 30′ S., and longitude by account 15° 30′ E., the following lunar observation was taken :—

Obs. alt. sun's L. L.	29° 17′ 26″	Obs. alt. moon's L. L.	25° 40′ 20″
Index cor.	—2 10	Ind. cor.	—1 10
	29 15 16		25 39 10

Obs. dist. nearest limbs.	99° 27′ 30″
Ind. cor.	— 50
	99 26 40

The height of the eye above the sea was 20 feet. Required the longitude.

Ship time, Feb. 12 . . .	2h. 36m.
Longitude E. in time . . .	1h. 3m.
Approximate Greenwich time .	1h. 33m.

Referring now to the *Nautical Almanac*, we take out the two semi-diameters for noon of Feb. 12: the approximate Greenwich time differs too little from noon to render any correction necessary; the sun's declination and the moon's horizontal parallax are taken out at the same time: we thus have—

From the Nautical Almanac.

As it is proposed to deduce the time from the sun, the co-altitude of the moon is not wanted.

*For the Time at the Ship.**

To compute the time, we have the co-altitude Z S = 60° 34′ 30″, the co-latitude P Z = 36° 30′, and the co-declination, or polar distance, P S = 76° 8′ 59″; therefore, page 1095, the work is as follows:—

Z S,	60° 34′ 30″		
sin. P Z,	36 30 0	Arith. Comp.	·2256124
sin. P S,	76 9 0	Arith. Comp.	·0128140

App. time at ship	3h. 55′ 21″	∴ Mean time 4h. 9′ 54″.	
Equation of time	14 33		
Mean time at ship	4h. 9 54		

From this result it appears that the ship's account must be very considerably in error. It may be advisable therefore, as recommended at page 1095, to repeat the foregoing operation with the corrected time here determined. Whether or not this repetition be absolutely necessary, we shall be able to ascertain after finding the mean time at Greenwich, as follows:—

For the Time at Greenwich.

Longitude E. 39 19 45

It appears from this result, that although the ship's longitude by the dead-reckoning is nearly 24° in error, yet the error in the estimated time happens to be such, that the supposed time at Greenwich, namely, 1h. 33m., is so nearly equal to the correct time there, that the operation for the time at the ship need not be repeated with the corrected data. We may safely conclude from what has just been done, that the mean time at the ship at the instant of observation, is 4h. 9m. 54s. P.M., and that the longitude is 39° 19′ 45″ east. Such a large error as the above, as well in the estimated time as in the longitude, could arise only from a long continuance of foul weather, which, preventing observations of the heavenly bodies, left the ship entirely dependent upon the dead-reckoning. And without taking into consideration the effect of unknown currents, leeway, &c., even the deviation of the compass alone, from the magnetic action of the vessel, might in a few weeks lead a ship astray to the above extent.*

---

* See *ante*, Fig. 29, p. 1093.

Under the circumstances here imagined, it would be better to take the Greenwich time at once from the chronometer, if this can at all be depended on, as already recommended at page 1097; for the longitude and time by account are employed, only as subsidiary, to finding an approximation to the time at Greenwich when the observations are made. If the Greenwich time, as determined from the lunar distance, differ considerably from the chronometer time, the operation for the time at the ship should be repeated with the more correct Greenwich time thus obtained, and thence the longitude accurately deduced.

2. On June 2, 1849, at 10h. 17m. P.M., mean time by estimation, in latitude 50° 51′ N., and longitude by account 41° W., the following observations were taken:—

Regulus W. of meridian.

For the Time at Greenwich.

In computing the true lunar distance in this example, we shall adopt the recommendation at the bottom of page 1103, and so modify the observed, or rather the apparent altitudes, that the seconds in each altitude may be a multiple of 10: whatever be added or subtracted in this way, must of course be in like manner applied to the true altitudes. We shall also introduce a similar modification into the apparent distance, and apply the necessary correction to the true distance: the object of these changes is to reduce the work of computing for odd seconds.

---

* In iron ships, propelled by steam, the local attraction is subject to great and frequent changes, and the compass is so powerfully acted upon by this fluctuating influence—the effect of which is often unsuspected—that the most fearful consequences sometimes result—the true course of the vessel being, from this cause, widely different from that indicated. At the conclusion of the next Chapter, we shall give a brief abstract of Dr. Scoresby's researches and suggestions in reference to this very important subject. If science fail to apply a remedy to counteract the ever-changing influence of iron steamers on the compass, this useful instrument had almost as well be abandoned in such ships. The mere heeling of the vessel will greatly affect the local deviation, and the continual strain and vibration to which a vessel under steam is subjected, so influences its magnetic condition, as to render the compass a dangerous guide. The ship *Tayleur*, which was wrecked in the Irish Channel in January, 1854, was led out of her proper course by these unsuspected influences. The captain relied upon his helm compass, and 290 persons perished. The original deviation in this iron steamer was so great as 60°, and this was subjected to changes that might amount to as much as between 40 and 50 degrees. It is easy to conceive that, in the open ocean, a ship misguided in this way, and precluded from adjusting her position by astronomical observations, through a long continuance of bad weather, might err even to the extent supposed in the above example.

Obs. dist.	72° 27′ 20″

17m. " = 4° 15′ "
58s. " = 14′ 30″ "

Longitude W. 34° 29′ 30″

In each of the foregoing examples the mean time at the ship is obtained from an altitude of the sun or a star, and, as remarked at page 1106, it is matter of indifference, when such is the case, whether the time at the ship or the time at Greenwich is determined first; but as the moon's right ascension and declination change very rapidly, comparatively to the sun's in a given interval, if the estimated time at ship be much in error, it is plain that the elements just referred to, computed to this estimated time, may differ so much from the truth as to very sensibly affect the accuracy of the ship's time, and thence of the longitude. We would, therefore, recommend when, in consequence of the other object, the sun or a star, being too near the meridian for the purpose of finding from it the time, the moon's altitude must be employed, that the time at Greenwich be found before that at the ship is computed, as in the following example:—

3. On May 22nd, 1844, at 11h. 15m. A.M. mean time nearly, in latitude 50° 48′ N., and longitude by account 1° W., the following lunar observation was taken when the moon was E. of the meridian:—

Having thus determined the time at Greenwich when the lunar distance was taken, we can compute the right ascension and declination of the moon to greater precision than the time by account could be expected to give. It so happens that, in this particular example, the time, by account, is very nearly the same as that deduced from the observations; but yet there would be a sensible difference in the resulting longitude, if the computation of the ship time had preceded that for the Greenwich time.

It is only in reference to the moon that much accuracy in the time and longitude, by account, is of any consequence.

For the Mean Time at the Ship.

Sun's R.A.		Moon's R.A.	
21st . .	3h. 56m. 53·8s.	23h. . .	7h. 55m. 24s.

4h. 50m.
1m. 50s.

Moon's hour-angle in time . . . . } 4h. 51m. 50s. east of the merid.
Moon's R.A. 7h. 55m. 40s.

R.A. of meridian 3h. 3m. 50s.
Sun's R.A. 4h. 0m. 41s.

Sun's hour-angle with meridian . . . } 0h. 56m. 51s. { before noon of the 22nd.
24h.

Mean time at ship 23h. 3m. 9s. May 21st.
Mean time at Greenwich 23h. 7m. 45s.

Longitude W. in time 0h. 4m. 36s. ∴ Long. W. 1° 9′.

Although the Greenwich time, by account, differs by only a few minutes from the Greenwich time as determined by the observation, yet the longitude would have differed by more than 4′ from the result here arrived at, if the ship time had been determined before the Greenwich time. It thus appears, that it is in all cases more prudent to compute the time at Greenwich before that at the ship, when the latter is to be deduced from the *moon*.

Examples for Exercise.

1. On March 25, 1847, at 3h. 30m. P.M., mean time nearly, in latitude 52° N., and longitude by account 33° W., the following lunar observation was taken:—

Obs. alt. sun's L.L.	Obs. alt. moon's L.L.
23° 10′ 20″	23° 50′ 10″
Index cor. − 6 10	Index cor. + 5 0

Obs. dist. nearest limbs.
112° 56′ 30″
Index cor. − 4 20

The height of the eye was 20 feet, and the following particulars were furnished by the *Nautical Almanac:* namely,

	Sun's dec.	Equa. of time.
Mar. 25,	1° 40′ 56″ N.	6m. 13·8s. *additive.*
26,	2° 4′ 29″ N.	5m. 55·2s. ,,

Moon's semi.	Hor. par.	Sun's semi.
noon 25th, 14′ 59″	noon 54′ 59″	16′ 3″
midnight 14′ 55″	mid. 54′ 44″	

Also distance at 3h., 111° 33′ 34″; at 6h., 112° 57′ 16″. Required the longitude of the ship. Ans. 32° 59½′ W.

2. On January 9, 1851, at 7h. 50m. P.M., mean time nearly, in latitude 49° 40′ N., and longitude by account 10° E., the following lunar observation was taken:—

Obs. alt. of Pollux E. of merid.	Obs. alt. moon's L.L.
37° 10′ 10″	31° 50′ 10″
Index cor. − 1′ 10″	Index cor. + 1′ 20″

Obs. dist. farthest limb.
103° 20′ 0″
Index cor. + 1′ 30″

The height of the eye was 18 feet, and the following particulars were supplied by the *Nautical Almanac:* namely,

Right ascen. mean sun.	Moon's semi.	Hor. par.
Jan. 9, 19h. 13m. 42·27s.	noon 14′ 55·8″	54′ 47·2″
	mid. 15′ 0·2″	55′ 3·6″

The star's R.A. was 7h. 36m. 12s., and its dec. 28° 22′ 46″ S. Also, the distance at 6h. was 103° 8′ 4″, and at 9h., 101° 37′ 51″. Required the longitude of the ship.

Ans. 10° 19′ 15″ E.*

The examples now given will, we think, sufficiently illustrate the practical operations for determining the longitude at sea by a lunar observation. In the *Nautical Almanac*, the lunar distances are given for the planets Mars, Venus, Jupiter, and Saturn, as well as for the fixed stars near the moon's path. The calculations for the true distance are, of course, the same for a planet as for a fixed star; and, in deducing the time at ship from the planet, we must proceed exactly as in deducing the time from the moon; that is to say, we must find the planet's hour-angle, and thence, by means of its right ascension, taken from the *Nautical Almanac*, we must find the right ascension of the meridian: the difference between this and the right ascension of the mean sun will—as in last example—be the sun's hour-angle with the meridian of the place; that is to say, the time at the ship.

If either of the celestial objects observed be near the horizon, where the refraction is subject to considerable irregularities, the *mean* refraction, which is that generally employed, should be modified according to the state of the atmosphere, as shown by the barometer and thermometer. A table for properly correcting the mean refraction is to be found in every collection of nautical tables. A neglect of this correction, when one of the objects observed is not more than 8 or 9 degrees above the horizon, may occasion an error of 1′ in the lunar distance; and this error may be sufficient to introduce one of upwards of 30′ in in the longitude.

Longitude from Occultations and Eclipses of Jupiter's Satellites.—What has now been mentioned, comprehends all the essentials for finding the latitude and longitude at sea. Other celestial phenomena besides those here dwelt upon, may be occasionally made available for determining the longitude; as, for instance, an eclipse, or an occultation of a fixed star or planet by the moon. Eclipses are of too infrequent occurrence to be of much service to the navigator; but the passage of the moon over the stars and planets, in her path, is continually occurring; and this occultation of the object by the moon would furnish a very convenient means of finding the Greenwich time, and thence the longitude, if the motion of the ship did not, in general, preclude the possibility of keeping the telescope steadily directed to the moon's edge.

It is plain that at the instant of the occultation, that is, at the instant of the disappearance of the star or planet by the interposition of the moon—called the *immersion*—the apparent right ascension of the moon's occulting limb must be the same as the right ascension of the occulted star. By removing the effect of parallax, the moon's true right ascension at the instant of the star's immersion may therefore be found, and the Greenwich time corresponding to this right ascension may thence be deduced.

The eclipses of Jupiter's satellites answer a similar purpose, since the entrance of a satellite into the shadow of the planet, is a phenomenon which takes place at the same absolute instant, wherever on the surface of the earth the immersion be observed; and so likewise does the reappearance of the satellite, or its emersion.

The Greenwich time, when these immersions and emersions are predicted to happen, are given in the *Nautical Almanac;* so that if the ship time, when any such phenomenon occurs, be known, the longitude may be at once obtained.

But here again, as in the case of occultations of the stars by the moon, the frequent impracticability of keeping a telescope sufficiently steady for the accurate observation of the phenomena at sea, renders this short and otherwise convenient method of finding the longitude of but very limited application. In a calm sea, or in harbour, a telescope of sufficient magnifying power may, of course, be used without inconvenience. Of the four satellites, the *first*, or that which is at the least distance from the planet, is the best adapted for the purpose of determining the longitude, on account of its more rapid motion; it revolves round Jupiter, and is eclipsed by the shadow of the planet once in every forty-two hours: and the instants of immersion and emersion are capable, in general, of being much more accurately noted, than the instants of contact of the earth's shadow with the moon's limb.

CHAPTER V.

NAUTICAL INSTRUMENTS.

The Quadrant and Sextant.—These two instruments are the same in principle—both are equally employed to measure angular distances; but as the distance between a celestial object and the horizon, for the purpose of determining the latitude at sea, is a measurement more frequently made than any other, the former of the two above-mentioned instruments—the quadrant—is constructed with exclusive reference to this purpose, and, being less elaborate in its fittings and workmanship, is by far the cheaper instrument of the two.

The arc of the sea quadrant is the eighth part of an entire circumference, or 45°. This arc is therefore, strictly speaking, not a quadrant, but an *octant;* but as it is capable of measuring all altitudes from the horizon to the zenith—as will presently be explained—a greater extent of arc is unnecessary.

The sextant is a more delicate instrument. Its arc is the sixth part of an entire circumference, or 60°, and it is capable of measuring angular distances up to 120°. The arc of the more common quadrants is divided—and that by means of an auxiliary scale attached to the index-limb—into minutes only: those of a superior kind are thus divided into half minutes; but the arc of a sextant is frequently subdivided—by aid of the Vernier scale just alluded to, and hereafter explained—to every 10″.†

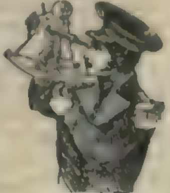
Artists generally extend the arc of a quadrant to a few degrees beyond 45°, and the arc of a sextant to a few

---

* For more examples, see Mr. Jean's *Navigation and Nautical Astronomy*, whence the above have been taken.

† Subdivisions of less extent than this must be estimated by the eye. A skilful observer can usually make this estimate within two or three seconds of the truth. Such an error, in the measurement of a lunar distance, would not occasion an error of more than about a mile in the resulting longitude. (See *Astronomical Instruments*, page 980, *et seq.*)

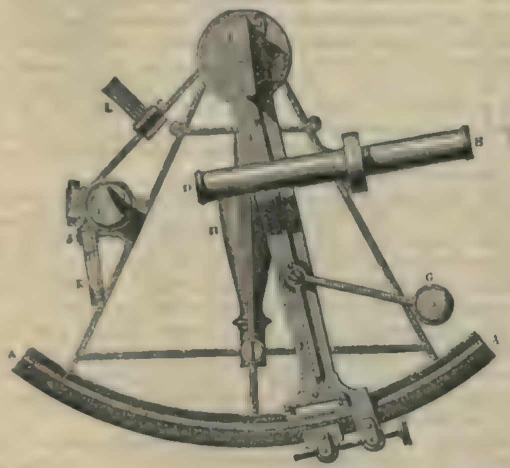
Fig. 32.



degrees beyond 60°. With either of these instruments an altitude may be taken; but usually with more precision with the sextant than with the quadrant, on account of the more minute subdivisions of the arc. The manner of holding the instrument in taking an altitude is figured in the margin. (See Fig. 32).

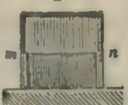
The sextant, however, is almost exclusively used for taking a lunar distance. All the essential parts of this valuable instrument are represented in the accompanying figure. H (Fig. 33) is the handle by which the sextant is held while taking the angular distance; D E is a small telescope fixed to the frame of the instrument, and directed towards the plane reflector or mirror, C. This reflector is immovable; the other plane reflector or speculum, B, is fixed to the movable radius, or movable limb, F, at the extremity of which is the index for pointing out the angle measured on the graduated limb, A A.

Fig. 33.



The two reflectors, B C, are perpendicular to the plane of the instrument—that is, to the plane in which the arc, or graduated limb, lies. The immovable reflector, C, is called *the horizon glass*; the upper half of it is transparent and unsilvered; and it is through this part that the horizon is viewed in taking an altitude; the lower half only, strictly speaking, is a reflector, being the only part coated with quicksilver (Fig. 34). The movable reflector, B, is called *the index glass*; it turns with the radius, or limb carrying the index, round the centre of the graduated limb.

Fig. 34.



Suppose this radius to be turned into such a position that the planes of the two reflectors, B, C, may be exactly parallel to one another: in this position of the index limb, the point on the graduated arc shown by the index is to be marked 0. It is the perfection of the instrument that, when the index points to 0, the two reflectors should be accurately parallel to one another. And here we pause for a moment to explain the cause of what the learner may have hitherto considered as the result of indifferent workmanship in the instruments employed in the preceding problems of Nautical Astronomy. We have repeatedly spoken of the *index error*, or the *error of the instrument*.

These terms do not imply faulty workmanship; all instruments whatever—the most elaborately-finished specimens in the most richly-furnished observatories—have, without exception, their *instrumental errors*, which are very different things, however, from errors of workmanship.

In the section on Mathematics (Commentary on Euclid), the reader has been frequently reminded, that it is beyond the reach of art to draw a line of a prescribed length *accurately*; to raise a perpendicular; or to draw a pair of lines that shall be accurately parallel. The perfect perpendicularity and parallelism, therefore, of the reflectors, B, C, are things that cannot be practically brought about; some minute departure from strict geometrical precision always exists, and hence, what is called "the index error." How this index error may be discovered and allowed for, will be seen presently; it is always furnished to the purchaser by the maker of the instrument.

In reference to this subject, it may not be unprofitable to the learner, to add to the present digression the following observations of Sir John Herschel:—

"Astronomical instrument-making may be justly regarded as the most refined of the mechanical arts, and that in which the nearest approach to geometrical precision is required, and has been attained.

"It may be thought an easy thing, by one unacquainted with the niceties required, to turn a circle in metal, to divide its circumference into 360 equal parts, and these again into smaller subdivisions—to place it accurately on its centre, and to adjust it in a given position; but, practically, it is found to be one of the most difficult. Nor will this appear extraordinary when it is considered that, owing to the application of telescopes to the purposes of angular measurement, every imperfection of structure or division becomes magnified by the whole optical power of that instrument, and that thus, not only direct errors of workmanship, arising from unsteadiness of hand or imperfection of tools, but those inaccuracies which originate in far more uncontrollable causes, such as the unequal expansion and contraction of metallic masses, by a change of temperature, and their unavoidable flexure or bending by their own weight, become perceptible and measurable.

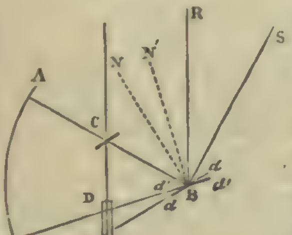
"An angle of one minute occupies, on the circumference of a circle of ten inches in radius, only about $\frac{1}{350}$th part of an inch—a quantity too small to be *certainly* dealt with without the use of magnifying glasses; yet one minute is a gross quantity in the astronomical measurement of an angle. With the instruments now employed in observatories, a single second, or the 60th part of a minute, is rendered a distinctly visible and appreciable quantity. Now the arc of a circle, subtended by one second, is less than the 200,000th part of the radius; so that on a circle of six feet in diameter, it would occupy no greater linear extent than $\frac{1}{5700}$th part of an inch—a quantity requiring a powerful microscope to be *discerned* at all.

"Let any one figure to himself, therefore, the difficulty of placing on the circumference of a metallic circle of such dimensions (supposing the difficulty of its construction surmounted), 360 marks, dots, or cognisable divisions, which shall be true to their places within such minute limits, to say nothing of the subdivision of the degrees so marked off into minutes, and of these again into seconds. Such a work has probably baffled, and will probably for ever continue to baffle, the utmost stretch of human skill and industry; nor, if executed, could it endure. The ever-varying fluctuations of heat and cold have a tendency to produce not merely temporary and transient, but permanent, uncompensated changes of form in all considerable masses of those metals which alone are applicable to such uses; and their own weight, however symmetrically formed, must always be unequally sustained, since it is impossible to apply the sustaining power to *every part* separately: even could this be done, at all events force must be used to move and to fix them, which can never be done without producing temporary, and risking permanent, change of form. It is true, by dividing them on their centres, and in the identical places they are destined to occupy, and by a thousand ingenious and delicate contrivances, wonders have been accomplished in this department of art, and a degree of perfection has been given, not merely to *chefs-d'œuvre*, but to instruments of moderate prices and dimensions, and in ordinary use, which, on due consideration, must appear very surprising. But though we are entitled to look for *wonders* at the hands of scientific artists, we are not to expect *miracles*. The demands of the astronomer will always surpass the power of the artist; and it must, therefore, be constantly the aim of the former to make himself, as far as possible, independent of the imperfections incident to every work the latter can place in his hands. He must, therefore, endeavour so to combine his observations, so to choose his opportunities, and so to familiarise himself with all the causes which may produce instrumental derangement, and with all the peculiarities of structure and material of each instrument he possesses, as not to allow himself to be misled by their errors, but to extract from their indications, as far as possible, all that is *true*, and reject all that is erroneous. It is in this that the art of the practical astronomer consists—an art of itself of a curious and intricate nature, and of which we can here only notice some of the leading and general features." (See Herschel's *Astronomy*, Lardner's *Cyclopædia.*)*

Returning now to the sextant:—To understand the way in which an angular distance is measured by this instrument, we must first assent to the following simple optical principle—that is, when a ray of light from a luminous body falls upon a reflecting surface, and is thence received by the eye, the *incident* ray—or that direct from the object to the reflector—makes, with the perpendicular to the surface of the reflector, drawn from the point where it impinges on it, an angle equal to the angle made with the same perpendicular and the *reflected* ray, or that received by the eye. This property is briefly expressed thus:—the angle of incidence is equal to the angle of reflection. It is the same with an elastic sphere striking a smooth hard surface, as, for instance, a common marble, shot against a smooth wall; if the marble be shot perpendicularly, it will rebound along the same path, and return to the hand, the angle of incidence and the angle of reflection being *nothing;* but if the marble be projected obliquely, it will rebound on the other side of the perpendicular; and the oblique incident path, and the oblique reflected path, will make equal angles with that perpendicular.

This principle being admitted, conceive the limb F to be moved so that the attached index points to zero on the graduated arc (the point A on the right in the figure 33). In this position of the index and of the reflector B, if the eye at E look through the upper or unsilvered part of the horizon glass at C, and perceive a celestial object, such as a star, it will at the same time also perceive the *image* of that star reflected from the silvered part of C. For as the reflectors are, by hypothesis, parallel, and the star so distant that two rays from it falling, the one on the glass B and the other on C, must differ only insensibly from parallelism, it follows that the ray from the star, reflected at B and thence proceeding to C, from which it is again reflected at E, must proceed to the eye E in the same direction as the direct ray from the star through the unsilvered part of C. But this will be better illustrated by a distinct diagram.

Fig. 35.



Let *d d* (Fig. 35) be the position of the index glass when the index points to zero, which in the diagram is marked by the letter *e*. By hypothesis, the surface of the half-silvered glass C is parallel to that of *d d*. An object, R, so remote as one of the heavenly bodies, would be equally seen to an eye at E in the direction of E D, parallel to B R, as to an eye at B, in the direction B R. If the dotted line B N be perpendicular to *d d*, R B N will be the angle of incidence, and C B N the angle of reflection: the reflected ray B C is now incident on C—a surface *parallel* to *d d*; therefore the reflected ray C D must be parallel to R B, so that an eye at E will see the object directly through the transparent part of C, and the image of it, after two reflections, in the same direction; or rather the object and its image would become confounded and superposed. Suppose now, while the eye is still looking at the object R through the telescope E D, the index-limb be moved from *e* to *e′*; the reflector *d d* turning round with this limb will take the new position *d′ d′*, and the *image* of R will disappear, and that of some other object S, in reference to a ray from which, B C will still be the reflection, will take its place.

In this way, two luminous points, R, S, as, for instance, two stars, or a star and an edge of the moon, or the edges of the sun and moon, may be brought together; one of the two, R, being seen by direct vision; the other, S, after two reflections at the mirrors.

The movement of the index from *e* to *e′*, necessary to bring the two objects R, S into contact, moves the reflector *d d* into the position *d′ d′*, and the perpendicular B N into the position B N′. Now B N, by the above-mentioned optical principle, bisects the angle R B C, and B N′, in like manner, bisects the angle S B C. Hence

$$\mathrm{NBN'} = \tfrac{1}{2}\,(\mathrm{SBC} - \mathrm{RBC}) = \tfrac{1}{2}\,\mathrm{SBR}.$$

And since the angles N B N′, *e* B *e′*, measured by the arc *e e′*, are obviously equal, it follows that the arc *e e′* measures half the angle S B R, formed by the two incident rays S B, R B; that is to say, it measures half the angular distance of the two objects S, R.

If, therefore, the arc A A, supposed to be 60°, be divided into twice that number—that is, 120 equal parts—then, by considering each part as a whole degree, the index at *e′* will show the number of degrees in the angular distance of S and R. In like manner, the degrees and minutes will be shown if each division be subdivided into 60 equal parts. This is the important principle in the construction of the sextant.

Besides the two reflectors, B and C, in figure 33, several other glasses—called *screens* or *shades*—are attached to the framework of the instrument, as shown at K and L. These are merely stained or coloured glasses to be interposed in the path of the rays from luminous objects, as the sun, and sometimes the moon, to reduce the intensity of the glare, which might be too strong for the sight, and, in the case of the sun, could not be endured with a clear sky. The principal use of these glasses, therefore, is to screen the eye; but they also serve to distinguish the object from its image by difference of colour. The movable glass, G, is a microscope, supported by a slip of metal turning about its extremity *a*, so as to allow of its being brought over the divisions of the *Vernier*—a small and important scale attached to the index, for the purpose of marking subdivisions too minute to be engraved on the circular limb of the instrument. We shall explain the Vernier presently.

To Use the Instrument.—The plane of the quadrant or sextant must always be held in the plane of the two objects, of which the angular distance is to be taken; it is grasped by the handle H, usually with the right hand (see Fig. 33, page 1112), the other hand being employed in moving and adjusting the index: when, as in common quadrants, there is no handle, the instrument is held by the framework itself. If the sun's altitude is to be taken, the instrument is to be held in a vertical position, the index set to 0 on the limb, and the eye applied to the telescope, or—removing this—to the sight-vane, which supplies its place, and directed through the horizon glass to that part of the horizon which is vertically under the sun. The index is now to be moved forward till the limb of the image of the sun, which we shall see to be gradually descending, just touches the horizon: the observed altitude of that limb will thus be obtained.

The sight-vane may now be turned down and the telescope introduced, which, by magnifying the image, will render the contact more distinct. It is, in general, more easy to get a contact, though with less precision, without the telescope than with it, as the telescope greatly limits the field of view; but after the index is adjusted to the approximate contact, the telescope, previously set to distinct vision, will at once show the object more clearly defined, and give the contact more accurately; of course, whatever shades may be necessary to protect the eye, and to distinguish the object from the image, are to be put in front.

---

* The reader may refer, on this subject, to the remarks on individual errors of observation, &c., in the section on Astronomy, as another source of error, independent of the instrument.—Ed.

If the altitude of a star is to be taken, the operation is just the same, care being taken to keep the star's image in view during the whole of its descent to the horizon, to avoid the mistake of bringing down the wrong star. The moon's altitude is taken in the same way as the sun's, using such shades as may be found necessary.

When a lunar distance is to be observed, the plane of the sextant must be held so that both objects may lie in that plane, and the sight is to be directed, through the horizon glass, to the fainter of the two, so that when the brighter object is to the left, the instrument must be held face downwards.

The practical management of the instrument, in making observations at sea, can be efficiently acquired only on ship-board; the movements of the body must be accommodated to the motion of the vessel, and peculiar attitudes and positions will be necessary in peculiar circumstances: the observer sometimes stands erect, sometimes reclines against a support, and sometimes lies on his back on the deck, when taking a lunar distance. It is plain that nothing but experience can dictate to him the best way of handling his instrument on the various occasions that may require its use. Supposing the observation to have been made, it remains to *read off* the angular measure; this is done by aid of the *Vernier*, a contrivance so called from the name of its inventor.

THE VERNIER.—This is a small scale attached to the index-limb, F, Fig. 33, of the instrument; it is slightly inclined to the face of the divided limb A A, and moves, with the index-limb, in close contact with the divided arc A A. It is attached to many other scales—as, for instance, to those of the barometer and thermometer—as well as to the scales of the quadrant and sextant, and is, in fact, an appendage to many astronomical instruments used for angular measurement; its object and utility may be explained as follows:—

Let C D (Fig. 36) represent any graduated scale, and A B a line which we wish to measure by it; the scale and line must of course be of the same character—both straight or both circular. If, upon applying the scale to the line, as in the following figure, we find the extremity B to fall accurately upon one of the divisions of the scale, we, of course, obtain the measure without any fractional parts of a division: we may, for illustration, call the divisions degrees, and we shall conclude the measure to be so many degrees exactly.

Fig. 36.

But if, as would be most likely, the extremity, B, of the line project beyond the boundary of a division without reaching the next, the length would be so many degrees and some fractional parts of a degree, which the scale affords us no efficient means of measuring. In the figure, the measure of A B is eight degrees, with a fractional part, *a* B, of the ninth degree, the exact amount of which can only be guessed at. The object of the Vernier is to make known the value of this fractional part.

Imagine a second scale, B E (Fig. 37), with its commencement placed in contact with the extremity, B, of the proposed line, to be applied to the scale C D: suppose the whole length of this second scale to be 8 degrees, but that it is divided, as in the figure, into 9 equal parts; and let us assume, moreover, that *a* B may be expressed in tenths of degrees.

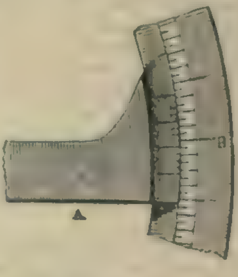
Fig 37.

Among the divisional marks of the second scale B E, thus placed, there will necessarily be found one which exactly corresponds to a divisional mark on the first scale, C D: in the figure below it is the *fourth* mark; and we accordingly conclude that *a* B measures four-tenths of a degree, so that the whole measure of A B is $8\frac{4}{10}$. That such is the case will be readily seen from considering that one of the divisions of B E is only $\frac{9}{10}$ths of one of the divisions of C D, so that one of the latter divisions exceeds one of the former by $\frac{1}{10}$th of a degree, two of the latter exceed two of the former by $\frac{2}{10}$ths, and so on.

Now from 4 to B, on B E, there are four divisions; and from *b* to *f*, on C D, there are also four divisions; the latter four, in their whole length, exceed the former four by $\frac{4}{10}$ths of a degree; but this excess is the length *a* B, consequently *a* B = $\frac{4}{10}$ths. It follows, therefore, that if *a* B be only an exact number of tenths of a degree; we shall be able to measure those tenths by this contrivance; and the error of measurement, if *a* B be not an exact number of tenths, and therefore the mark 4 not strictly the continuation of the mark *b*, must be less than $\frac{1}{10}$th. In like manner, if the scale B E had the length of 19 degrees of C D, and were divided into 20 equal parts, *a* B could have been measured accurately to within $\frac{1}{20}$th of a degree, and so on. The scale B E is the *Vernier*.

The annexed figure (Fig. 38) will give an idea how the Vernier, attached to the index-limb of the quadrant or sextant, adapts itself to the circular graduated limb of the instrument. The point marked *a* on the Vernier is the *index* of the graduated arc of the limb, and is that which marks out the integral part of the measure of the angle, the fractional part being indicated by the Vernier divisions, as already explained. It is the mark *a* which ought to correspond with the mark 0 on the graduated limb, when the index and horizon glasses of the instrument are parallel: it is common, however, to speak of the whole movable limb A as the *index*.

Fig. [illegible]



Suppose each of the divisions on the graduated limb to denote n minutes, and let m be the number of those divisions which make up the whole extent of the Vernier scale, then the Vernier will contain $m\,n$ of the minutes of the graduated limb. If this extent be divided into $m + 1$ equal parts, then the difference between one division on the graduated limb and one division on the Vernier, will be

$$n - \frac{m\,n}{m+1} = \frac{n}{m+1}$$

If $n = 20'$, and $m = 19'$, $\therefore \frac{n}{m+1} = 1'$. If $n = 10'$, and $m = 59'$, then $\frac{n}{m+1} = 10''$, &c.

THE INDEX ERROR.—If when the index and horizon glasses are parallel, the beginning *a* of the divisions on the Vernier does not coincide with the mark 0 on the graduated limb, the distance between them is the *index error*—subtractive when the Vernier mark is to the left of the 0, and additive when it is to the right. To discover the amount of index error, move the index till a point of the horizon, or some more distant object, coincides with its image: the distance of the index mark *a*, from 0 on the graduated limb, is the amount of index error.

The sextant just described is only a modification of the quadrant; both instruments are in principle the same. The first published description of the quadrant appeared in the *Philosophical Transactions*, No. 420, for the year 1738, the paper communicating it having been laid before the Society in May, 1731. It was the production of John Hadley, and the instrument he described was consequently called Hadley's Quadrant; there is little reason to suspect that the invention was not his own. But a similar instrument had long previously been invented by Newton, and communicated to Halley, who kept the contrivance to himself. "The description of the instrument was found, after the death of Halley, among his papers, in Newton's own handwriting, by his executor, who communicated his papers to the Royal Society, twenty-five years after Newton's death, and eleven after the publication of Hadley's invention, which might be, and probably was, independent of any knowledge of Newton's, though Hutton insinuates the contrary." "But," adds Sir John Herschel, "the priority of invention belongs undoubtedly to Newton, whose claims to the gratitude of the navigator are thus doubled, by his having furnished at once the only theory by which his vessel can be securely guided, and the only instrument which has ever been found to avail in applying that theory to its nautical uses."

CHARTS.—A chart is a map upon a plane surface of a portion of the sea, including whatever within its limits it may be useful to the mariner to have exhibited, such as rocks, shoals, &c.; and in some, the directions of currents, and the variations of the compass. Charts are of two kinds—the Plane Chart and Mercator's Chart. As in the former the meridians are all parallel lines, and the degrees of latitude all of equal length, the proper relations of latitude and longitude are grossly violated, and such charts are of no use except for mere coasting purposes. At sea, the only charts of any use are those constructed on Mercator's principles, described at page 1062, the degrees of longitude remaining invariable; while those of latitude are enlarged more and more from the equator to the pole, agreeably to the law investigated and explained at the page referred to.

The accompanying map is a representation of the globe projected upon Mercator's plan, but on a scale far too minute, of course, to serve any other purpose than mere illustration, for which alone it is here introduced. On the actual sea chart, representations of the compass are placed at intervals, for the purpose of setting off courses.

The meridians which limit the chart employed at sea are graduated, as also the parallel of latitude which bounds the extent of the chart north or south. A point on the chart being marked, we find its latitude by simply observing where the edge of a straight ruler applied to the point, and held parallel to any parallel of latitude, cuts the graduated meridian; and the longitude is found by placing the edge, while on the point parallel to any of the meridians, and observing where the edge cuts the graduated parallel.

To find the course between two places on the chart, apply the edge of a parallel ruler to the two places, and, holding it there, move the other part of the ruler till an edge passes through the centre of one of the compasses; the course will thus be indicated.

To lay down on the chart the position of the ship by dead-reckoning—that is, from her course and distance from a given point of departure, as the preceding noon—place the ruler on the point of departure, and parallel to the given course: from the graduated meridian at the side of the chart, and in the latitude of the ship, take the distance, in degrees, &c., by the compasses: this distance, applied from the point of departure along the edge of the ruler in the direction of the course, will mark out the position of the ship by dead-reckoning. To lay down the position as given by the latitude and longitude is sufficiently obvious: the intersection of two pencil lines, through the given points of latitude and longitude, and parallel to the boundaries of the chart, will be the position sought.

It will be perceived by the reader who has gone over what has been stated in the Navigation respecting Mercator's sailing, that although positions are correctly exhibited on the chart, as regards latitude, longitude, and course, yet *distances* are exaggerated. Distances which are the same on the globe, become more and more elongated on the chart as we approach the pole.

THE SHIP'S JOURNAL.—A Sea Journal is a record of the daily transactions and occurrences in connection with the navigation of the ship, including whatever observations and remarks that may be necessary to give a brief but connected professional history of the voyage.

The entries in the Journal are made hourly after the departure is taken: the ship shapes her course towards a definite point; and to do this, either a chart is consulted, or the angle determined by computation; allowance then being made for the variation of the compass, and the local deviation, the compass or steering course for the first stage is obtained. The ship, however, is usually considered to depart from the point of land or other conspicuous object last seen; and the bearing opposite to that, of this point of departure, is regarded as the first course, and the distance of it as the first distance. The ship is not, however, considered as having fairly commenced her voyage till her final departure has been taken.

Time is generally recorded as in the affairs of civil life, and not according to astronomical reckoning: noon and midnight equally divide the twenty-four hours, as on land. From the hourly registry of the course and distance, the leeway and the variation of the compass being properly allowed for, the ship's position is determined every day at *noon*. If no astronomical observations have been made, the position thus determined is the place of the ship by *dead-reckoning;* but if the latitude or longitude, one or both, have been computed from observations, a distinct entry to that effect is made, although the day's account by dead-reckoning is still preserved.

This clearing up the ship's account every day at noon, so as to enable her to take a fresh departure daily at that hour from a known position, just as she took her departure at first, is called a *day's work*. As noon is the time invariably fixed upon for ascertaining the resultant of all the preceding twenty-four hours' sailings, whatever latitude or longitude may have been determined by astronomical observations in the interval, is brought up to that hour by help of the dead-reckoning. Hence the entries, "Latitude by Observation," and "Longitude by Observation," frequently inserted in the noon results, are in general made up in some small part of the latitude and longitude by account.

In keeping the ship's reckoning, the position departed from at each noon, is considered to be that which nautical astronomy assigns; so that when observations have been made in the interim, the dead-reckoning commences afresh, and is not a continuation of the yesterday's account. The record is then carried uninterruptedly on till a noon arrives, immediately before which, the true position of the ship has again been settled by observations, and so on. The meridian observation for latitude is of course recorded for the noon on which it is made.

The working of a day's work may always be effected by the Traverse Table, after the manner shown at page 1055; and as the twenty-four hours' sailings should be regarded only as furnishing data for finding the position of the ship at the end of that time approximately, it is not considered as in general necessary to attend to minutes in the courses. "It is mere waste of time," observes Lieut. Raper, "to work the course nearer than to the whole degree; for if even the compass could be depended upon, as it cannot be, to 1°, the ship cannot be steered to twice that quantity." We shall now give a very short specimen of a Ship's Journal: there is no settled and uniform plan of arranging all the entries; but there are certain prominent features in which all sea journals are alike. The specimen here offered is, with some slight modification, extracted from that given by Mr. Riddle in the work before referred to.

The reader is already aware that the principal entries in the Journal are, in the first instance, written in chalk on the black board called the *log-board*, from which they are afterwards transferred to the *log-book*. The correction of the several courses for leeway and variation being made, and the position of the ship at noon, as deduced from the sailings, and as determined by observation when observations are taken, completes the day's work, and renders the log-book a *journal*.

EXTRACT FROM A JOURNAL OF A VOYAGE FROM ST. MICHAEL TOWARDS ENGLAND.

H	K	F	Courses.	Winds.	Lee-way.	Remarks, Sunday, Sept. 11, 18—.

Course.	Dist.	Lat. acc.	Lat. obs.	Long. acct.	Long. obs.	Bearing and dist. at noon, Lizard.
N. 69 E.	Dist. 63m.	38° 43′ N.	38° 46′ N.	22° 56′ W.	22° 45′ W.	N. 48¾° E. Dist. 1013m.

From what has already been said as to the unavoidable imperfections in even the most careful measurements of a ship's course and distance, the difficulty of making the proper allowances for the leeway, &c., and of estimating the effects of squalls, currents, &c., it will readily be inferred that a ship's journal would soon become so erroneous, as a registry of actual facts, as to be quite valueless, unless repeatedly rectified by astronomical observations. In the absence of these, such a journal would describe little other than the imaginary route of an imaginary ship, which, after a voyage of any length, might terminate at almost any point of the globe as likely as at the real point reached by the real ship. No opportunity, therefore, should be lost to check this increasing tendency to error in the dead-reckoning, by carefully determining the position of the ship from the safe principles of nautical astronomy; and the ship's account should be regarded as of value, only in so far as it can be made auxiliary to the application of those principles.

The letters H, K, F, at the heads of the first three columns in the preceding specimen of a journal, stand for hours, knots, and fathoms, or tenths of a nautical mile. The entries between noon and midnight are marked P.M. (*post meridiem*), and those between midnight and noon are marked A.M. (*ante meridiem*).

The result of each day's work is inserted at the bottom of the page; the courses being corrected for leeway and variation, the result exhibits the true course and distance from the point of departure; together with the diff. lat. and diff. long. made in the twenty-four hours, or rather the latitude and longitude reached.

In reference to the two preceding days' work, it will be observed, that as the variation of the compass is westerly, it must be allowed to the left of the compass courses; and, therefore, when the ship makes leeway on the larboard tack, the difference between the leeway and variation is the correction to be applied to the course—to the *left*, if the variation be greater; but to the *right* if the leeway be the greater.

When the ship makes leeway on the starboard tack, the allowance for it, as well as that for variation, being to the left, their sum will be the correction to be applied to the compass course; and when no leeway is made, the only correction is for the variation. Now E. N. E., the opposite point to the bearing of the land from which the departure is taken, is the first course; and this, and the drift, being corrected for variation, and the other courses for both variation and leeway (when there is any), and the distances on each of these courses added up, we have the following Traverse Table for the first day's work:—

TRAVERSE TABLE.

Courses.	Dist.	Diff. Lat.		Departure.	
		N.	S.	E.	W.
N.E. ¼ E.	18	12·1		13·3	
N.E. ¾ E.	16·9	10·1		13·6	
N.E. *b.* E. ¾ E.	8·3	3·5		7·5	
E.S.E. ¾ E.	11·4		2·8	11·1	
S.E. ¼ E.	7·0		4·7	5·2	
S.E. ¾ E.	8·1		4·8	6·5	
N.N.W.	4·3	4·0			1·6
N. *b.* W. ¾ W.	8·5	8·0			2·9
N. *b.* W. ¼ W.	9·7	9·4			2·4
N. ¾ W.	4·2	4·2			·6
N. ¼ W.	9·6	9·6			·5
S. ¼ W.	18·0		18·0		·9
		60·9	30·3	57·2	8·9
		30·3		8·9	
Course, N. 58° E. Distance, 57 miles.		30·6		48·3	

Lat. left . . 37° 48′ Mer. parts . . 2453
Diff. lat. . . 31′
Lat. in. . . 38° 19′ 2492
M. diff. . . 39

Hence, by Mercator's sailing, page 1061, the difference of longitude is 1° 2′ E.:—

Long. left . . .	25° 13′ W.
Diff. long. . . .	1 2 E.
	24 11 W.

Therefore the ship's place, by account, is

Lat. 38° 19′ N. Long. 24° 11′ W.

From 11 A.M. till noon, the ship's true course was N. ¼ W., 5 miles nearly: hence the difference of latitude also is 5 miles nearly; and this added to the latitude, as determined by double altitudes, at 11 A.M., gives 38° 20′ N. for the latitude by observation at noon.

With this latitude and the longitude by account, the bearing and distance of the Lizard are found to be N. 49° ½ E., 1074 miles.

The courses for the second day's work, being first corrected for leeway only, as the variation is given degrees, we have the following traverse table.

TRAVERSE TABLE.

Courses,	Dist.	Diff. Lat.		Departure.	
		N.	S.	E.	W.
N. ¾ E.	9·6	9·5		1·4	
N. *b.* E. ¼ E.	23·0	22·3		5·6	
S.E. *b.* E.	11·5		6·4	9·6	
S.E. *b.* E. ½ E.	10·3		4·8	9·1	
E.S.E.	12·0		4·6	11·1	
S.E. ¾ E.	11 6		6·9	9 3	
S.E. *b.* E.	15·7		8·7	13·0	
E. ½ N.	14·1	1·4		14·0	
E.	7·3			7·3	
E. ½ S.	6·8		·7	6·8	
W. (swell).	24·0				24
		33·2	32·1	87·2	24
		32·1		24·0	
Compass Co., N. 89° E. Distance, 63 miles.		1·1		63·2	

Compass course . . .	N. 89° E.
Variation	20° W.
True course . . .	N. 69° E.
Distance	63 miles.

With this course and distance, 63 miles, found from the Traverse Table, the diff. lat. and departure are found to be 22·8 N. and 58·8 E.

Lat. left	38° 20′ N.
Diff. lat.	23 N.
Lat. by account . .	38 43 N.
Long. left	24 11 W.
Diff. long.	1 15 E.
Long. by account . .	22 56 W.

The departure made, from 9 A.M. till noon, is nearly 14 miles, with which, and the mid-latitude, about 38½°, the difference of longitude is found to be 17 miles; which, taken from 23° 2′, the longitude by the chronometer at 9 A.M., gives 22° 45′ for the longitude by the chronometer at noon.

CONCLUSION.—In here terminating this section on the Principles of Navigation and Nautical Astronomy, we would remind the reader of the objects proposed in undertaking it, as sufficiently declared in the INTRODUCTION. This object was twofold: first, to furnish to the mathematical student a convincing proof of the great practical value of the abstract sciences which he cultivates; and, second, to supply the professional navigator with the theoretical principles on which his rules of operation are founded. It did not enter into our plan to go into all the practical details of navigating a ship, nor to dwell upon those facilitating expedients which could be rendered intelligible only by the aid of extensive nautical tables. The present treatise is offered to the notice of the mariner, more in the character of a companion or supplement to the books of rules and tables in every-day use at sea, and as serving to show him the scientific theory on which his practice is based. But as far as could be done, without special tables, we have fully gone into the calculations necessary for determining the position of a ship on the ocean; and have shown that all the practical demands of navigation may be amply satisfied by help of only the common logarithmic tables, and that knowledge of turning them to account, which the elementary principles of plane and spherical trigonometry supplies.

We shall now add a few general remarks by way of comment, subjoining some interesting and valuable information respecting the action of iron ships on the compass.

It cannot fail to strike an attentive reader, that the subject of Navigation presents a forcible example of the value of abstract science, even in circumstances where the practical application of its principles would seem to be almost precluded, on account of the unavoidable imperfections of our observations and experiments; of the instruments with which we work, and of the materials upon which we operate.

The mechanical tools or implements of the navigator, are the log, the compass, the chronometer, and the sextant; these are to furnish him with the materials upon which his science is to work, and from which he is to extract all his information in situations where no external aid can reach him, and where to err may involve life and property in sudden destruction. Yet the mechanical means upon which he thus depends for guidance and safety, are all confessedly imperfect; he can measure with accuracy neither the rate at which he sails, nor the course upon which he steers; and even if the log and compass were perfect, hidden and unsuspected agencies may vitiate, and falsify the indications of both. The sextant, fortunately, is beyond the operation of these disturbing causes; it is, moreover, the least imperfect of all his nautical appliances, and accomplishes the important end of rectifying and adjusting, to a very close approach to accuracy, what the other instruments may have done amiss. It is among the most valuable gifts that science has ever presented to man to aid him in his necessities. Nautical Astronomy could not exist without it: and to say that it is not perfect, is only to repeat what has been applied to every work of man's hands. The best sextants, however, are subdivided to no smaller arc than 10″, so that fewer seconds than 10 must be estimated, by help of the microscope, entirely by the eye.*

As just noticed, the sextant—including, of course, in this term the quadrant—is of the utmost use in correcting the results of the dead-reckoning. But the ship's account continuously accumulates, and its errors must run on till the weather and the sky furnish opportunities for celestial observations. In the interim, the vessel is trusted almost entirely to the guidance of the compass; and it most unfortunately happens that, from the local attraction, the ship may often be said rather to direct the compass than the compass to direct the ship. It is most important, therefore, that the intervals between observations at sea be shortened as much as possible by seizing every occasion that offers for making them. From what is taught in the preceding pages, the reader will easily perceive how it happens, that even very gross errors in the dead-reckoning become comparatively inoperative in the results deduced from astronomical observation, although the calculations founded upon these observations virtually involve the data furnished by the ship's account. These data, however, do not directly enter into the work; it is the *time* which corresponds to them that is employed; and, fortunately, the astronomical elements, taken from the *Nautical Almanac*, in reference to this time—semi-diameter—declination—right ascension—horizontal parallax, &c., vary so little, even in a large interval, that an error in the ship's place to the extent of a quarter of the globe, would not, in general, entail an error of a quarter of a degree in the adjustment of that place by the lunar observations, provided, at least, that the time be not deduced from the moon.

As already remarked at page 553, in the MATHEMATICAL SECTION, the reasonings of pure geometry tolerate no errors in the premises; but practice can never satisfy these rigorous conditions; and in proportion as they are departed from, will be the geometrical shortcoming of our conclusions. At first sight, therefore, it would seem chimerical to hope for any close approach to accuracy from data so widely erroneous; but when it is considered that these data connect themselves with other dependent data, which are incapable of error beyond a very limited range, we at once perceive that these latter may be very near the truth, though the former may greatly depart from it; and that if the inquiry involve the dependent data only, and not in a direct manner the original, the inaccuracies of *these* need give us but comparatively little concern.

It is thus that a very close approximation may be made to the true position of a ship, though the dead-reckoning may displace her many degrees, and though, at the same time, we employ this reckoning in the operation, as if it involved no error at all. But in the intervals between these adjusting observations, the safety of the ship is often wholly dependent on the trustworthiness of the compasses; and, of late, much mischief has arisen from placing too implicit a confidence in them in certain circumstances.

Since the prevalence of iron vessels, the disturbances of the compass have been seriously forced upon the attention of scientific men; and the subject of local deviation, still involved in considerable obscurity, is becoming more and more a matter of anxious scrutiny and investigation. The importance of the inquiry was strongly urged by Dr. Scoresby, at the meeting of the British Association, at Liverpool, in 1854. "There were certain principles," observes the Rev. Dr., "connected with the navigation of iron ships, which were universally admitted. Those principles were, that iron, being more especially disposed to the magnetic condition, was a material, of course, calculated above all others to disturb the action of the compass on board the ship. Again, it was admitted that there were difficulties in the navigation of iron ships, arising, not merely out of the original or primarily magnetic condition and disturbing influence of the iron, but also in respect of certain changes which had been held as mysterious—changes which took place not unfrequently in regard to ships whose magnetic condition had been supposed to be very well ascertained." Dr. Scoresby then adverts to the circumstances connected with the melancholy wreck of the *Tayleur*, the fate of which must be in the recollection of all our readers. The ship *Tayleur*, a new vessel, bound to Australia, sailed from Liverpool on Thursday, January 19th, 1844. She was 1,979 tons burthen, new measurement, and she had on board about 458 passengers—the crew and passengers, altogether, making a total of 528 persons. She left the Mersey about noon on the above-named day. The pilot left her between seven and eight o'clock in the evening, in a position between Point Lynas and the Skerries. On Friday she encountered very heavy weather; and about eight o'clock on the following morning (Saturday), it was for the first time ascertained that there was any material difference between the compasses.

There were three compasses on board. Dr. Scoresby makes special reference to two of these. One of the two was near the helmsman, and was the one by which he steered; and the other was near the mizen-mast. Both of these compasses had been what is called adjusted, by permanent magnets; so that if the principle of adjustment had been correct, they should not either of them have changed or differed from the other.

---

* The error of this estimation can never reach *five* seconds, so that the corresponding error in longitude cannot be more than about two miles; an error that is quite compatible with perfect safety, except in very extraordinary circumstances. (See page 1103).

Trusting to the compass near the helmsman, the captain had the idea firmly impressed upon his mind that he was sailing fairly down almost mid-channel; at all events, in a good position for navigating the Irish Channel. The other compass indicated a difference of about two points. The captain, however, judging from certain indications which he had noticed previously, assumed that the wheel compass was the correct one.

In the course of a few hours, about half-past eleven o'clock on the same morning, the wind having increased, and a heavy sea setting up the channel, the ship made rather a rapid progress, when they suddenly came in sight of land on the lee beam, in such a position that there was necessarily a great difficulty—in this case (according to the measures pursued) an insurmountable difficulty—in avoiding the land. An attempt was made to wear the ship round. This failed: and then an attempt was made to use the anchors to bring her up. Both the cables snapped on the occasion, and the ship was then left helpless, driving broadside upon the rocks of Lambay Island. The result was the fearful catastrophe—namely, the loss of about 290 lives: out of 100 females who were on the ship, only three escaped upon that melancholy occasion.

Investigations into the cause of the calamity were undertaken; and the Marine Board of Liverpool, after stating that Captain Noble had given very great attention to the ascertaining of the correctness of his compasses, and verifying their action on different occasions—report that, "notwithstanding these precautions, it appears to this Board that the *Tayleur* was brought into the dangerous position in which the wreck took place through the deviation of the compasses, the cause of which they (the Marine Board) had been unable to determine."

To these important matters Dr. Scoresby has given much thought and attention; and he finds, from numerous experiments, some of which are very simple, that mechanical violence has a very considerable influence upon the magnetic condition of iron. When an iron bar, entirely neutral as to its molecular magnetism, if held in an upright position, or inclined in the axial direction of the earth's magnetism, was subjected to percussion or other mechanical violence, not only did its magnetism become much more powerful than that of simple induction, but it strongly exhibited augmented polarity, when placed in the east and west equatorial position; and however it might be moved about and swung round, its polarity remained the same. Dr. Scoresby applies these facts to iron ships, and points out that, in consequence of the percussive action to which the material is exposed while the ships are in course of construction, it became as intensely magnetic as it is possible for malleable iron to be. This augmented magnetism, however, is not permanent or fixed, but, under different circumstances, as to the relative directions of the ship's magnetism and that of the earth, is easily changeable, and liable necessarily to be changed. The magnetism developed by mechanical violence can be readily neutralised or changed, under a proper change of conditions, by other processes of mechanical violence.

The general result of his experiments went to the establishing of the fact, that besides the two denominations of magnetism ordinarily received—that of simple terrestrial induction, and that of permanent independent magnetism—there is another denomination corresponding with neither; not being absolutely controllable, like the former, by terrestrial influences, nor capable, like the latter, of resisting all kinds of mechanical violence. To this third denomination he gives the name of Retentive Magnetism, and which he proves to be a fluctuating quality, though hitherto considered as permanent. On the contrary, the long-continued vibration of a ship under steam, and, much more so, the straining of the vessel in a heavy sea, under the circumstances when the terrestrial induction might be acting in a very different direction from the original axial polarities of the ship, would be sufficient to change the direction of the magnetism originally developed in the course of her construction. Hence, he observes, much would depend, in respect of the mechanical action of the sea, on the position in which the ship had been built. In the case of the *Tayleur*, when he first heard of the catastrophe and had read the evidence, he stated to some friends at Torquay, that he would venture to affirm that she had been built with her head *northward*; he found, on inquiry, that she had been built with her head nearly north-east. Here then, he adds, were the precise circumstances for expecting a change in the ship's magnetic distribution. Having been built with her head to the north-east, she had a certain magnetic distribution accordingly; and when she began to strain, with her head to the south-west, that distribution was necessarily changed, and the first effect of it had been to produce a great difference in the two compasses adjusted by fixed magnets. If the captain had been aware of the changes which might, and most probably would, take place when the ship began to strain in a different position from that in which she had been built; if he had known that the compasses, having so large an original deviation as 60°, might vary as much as two, three, or even four points, he would have known, of course, that he must place no reliance upon them.

It is most important, therefore, continues Dr. Scoresby, for safety in navigating these vessels, that captains should be made aware of the liability of the compasses to change, and so to mislead them; that they should know the circumstances under which, in accordance with natural laws regulating and applying the earth's inductive action, changes were most likely to occur; that they should be always watchful of opportunities for determining the true magnetic direction, with reference to their compasses, by observations of the sun and stars; and that by providing a place for a standard compass aloft, as far from the deviating influence of the body of the ship as possible, they might have guidance sufficient, with some small allowances, for steering a correct magnetic course. With such precautions, Dr. Scoresby did not doubt that the difficulties in respect of compass guidance, in the navigation of iron ships, might be mainly and practically overcome.

These remarks and suggestions, from an experienced navigator so well acquainted with his subject, deserve the serious attention of mariners; and there is no doubt that, even in wooden ships, such a locality for a standard compass, as he here recommends, would prove of service. In iron ships, as sufficiently shown above, any compass-adjusting apparatus, applied at the outset of a voyage, becomes of little or no avail when the vibration and strain of the vessel are thus known to change its magnetic condition; and any confidence placed in such adjustments is likely to beget a feeling of security, and to allay apprehension, even in situations of the most imminent peril.

For a full account of Dr. Scoresby's views, and of those of Mr. Towson, another very competent authority, the reader is referred to *The Proceedings of the Twenty-fourth Meeting of the British Association for the Advancement of Science*. (See, also, on this subject, p. 246, *ante*).

SECTION XII.

METEOROLOGY.

[THIS Section may be properly divided into three parts. That by Dr. Scoffern, affords a popular and comprehensive description of the science. Such portions of the original paper as referred to Light, Electricity, and Magnetism, have been omitted, for those subjects have already been discussed in detail, under their respective sections. The remarks on Heat and its laws have been left untouched, because, although they have been anticipated under that section, it was thought desirable to bring them again into prominence, in connection with Meteorological phenomena. The second part (Chapter IV.), by Mr. Lowe, is devoted entirely to Practical Meteorology, and affords valuable aid and directions to those who may be disposed to make accurate observations. The third part (Chapter V.), by the Editor, gives a *résumé* of the proceedings of Admiral Fitzroy and Mr. Glaisher, especially in reference to the balloon ascents of that eminent meteorologist; with other recent and important particulars.]

CHAPTER I.

INTRODUCTION.

DEFINITION AND LIMITATIONS.—The term Meteorology, derived from *μετεωρος*, elevated, was applied by Aristotle to signify phenomena occurring in elevated regions. It may be considered synonymous with the study of atmospheric phenomena; though all which concerns meteors proper is very nearly allied with astronomy.

In many respects, Aristotle's opinions on meteorologic subjects display the usual acumen of that deep thinker; his remarks on the subject of dew are particularly interesting. Deprived, however, of the barometer and thermometer—deprived of optical instruments—the nature of electricity yet undeveloped, and the composition and functions of the atmosphere unknown, ancient speculations on meteorologic subjects were necessarily unsatisfactory and vague.

The meteorological writings of Theophrastus, Aristotle's pupil, were more diffuse than those of that great philosopher, and were long recognised as constituting a text-book. They constituted the groundwork of the *Διοσημεια*, or prognostics of Aratus, and were embodied in a versified rendering by Cicero in his youthful days. Portions of these attempts at versification are still in existence, and do but little credit to the great Roman orator in a poetical capacity.

Meteorology, in its most common and restricted sense, may be considered synonymous with *knowledge of the weather*. It therefore involves a full acquaintance with the nature and composition of the atmosphere; with the laws of gaseous and vaporous elasticity; with the conditions determining the production of fogs, dew, snow, and hail; also with the laws of atmospheric, optical, and electrical phenomena. It is the province of meteorology, also, to study the phenomena of aërolites, and the relations which subsist between atmospheric conditions, and the development of organic species.

The above is a general outline of the scope and limits of meteorology. Its successful study will be seen to involve a pre-acquaintance with many sciences, more especially those of chemistry and electricity. There does not, indeed, exist any science having limits so undefined as meteorology. From a consideration of the theory of shooting stars, to a contemplation of the mutual alliance subsisting between certain forms of disease and atmospheric conditions, or the relation between certain animal and vegetable tribes and given atmospheric conditions, the divergency is wide. Nevertheless, all these branches of study are intimately allied with meteorology; and, perhaps, the most delightful part of botanical science is that which seeks to establish connections between the localisation of certain vegetable families, in districts characterised by some peculiarity of meteorologic condition. Horticulturists have been too ready to overlook the influence of remote atmospheric conditions on certain vegetable families. Too frequently it has been considered that a vegetable surrounded by an atmosphere having a temperature similar to that of its native region, and planted in a soil of similar chemical composition, must necessarily thrive. There are, nevertheless, meteoric conditions beyond these. Why is it that many species of the palm tribe refuse to grow very far away from their native regions, although transplanted to localities seemingly identical in all respects? Why is it that the cocoa-palm refuses to grow in regions very far distant from the sea? These questions involve meteorologic considerations of great interest: and not less interesting to a meteorologist, is the partiality evinced to a restricted region by the cinchona tribe. An atmosphere very much rarefied, and perpetually moist, is so essential to their existence, that they cannot live without it.

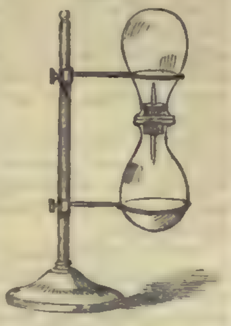
The natural approach to meteorology is the study of the atmosphere, which admits of being contemplated under many aspects. It may be contemplated either as the atmosphere proper or theoretical, composed of two gases—oxygen and nitrogen; or as the practical atmosphere or mixture of the gaseous theoretical atmosphere, with numerous vapours, extraneous gases, and fleeting undetermined miasmata. The atmosphere, too, admits of being regarded statically, *i.e.*, at rest; and dynamically, *i.e.*, in motion; the latter involving a study of the causes of winds. The atmosphere, lastly, may be considered in relation to the imponderable agents, to heat, light, electricity, and magnetism. We shall begin by investigating the nature of our atmosphere regarded chemically.

CHEMICAL CONSTITUTION OF THE ATMOSPHERE.—By the ancients, air was considered to be an elementary substance. Chemistry at length demonstrated it to consist of two gases, oxygen and nitrogen combined, or rather mixed in the proportions of about eighty parts, by measure, of nitrogen, and twenty of oxygen; or, in other words, one volume of oxygen to four of nitrogen.

Considerable difference of opinion once existed on the question, whether the atmosphere be a chemical or a mechanical compound. To adduce evidence bearing on this discussion, would be foreign to the subject of meteorology. The generally received opinion is in favour of the mechanical constitution of the atmosphere. The law of the diffusion of gases perfectly accounts for the intimate mixture with oxygen and nitrogen in the atmosphere, without having recourse to the assumption of chemical union. An outline of the law in question it will be proper to give.

Gaseous Diffusion.—If two glass vessels be taken, as represented in the accompanying diagram (Fig. 1), the upper one being filled with hydrogen gas, the lower one with oxygen gas, placed in communication with each other by a capillary tube passing through the cork stopper of both, and allowed to remain at rest for about half an hour, perfect mixture of the oxygen and hydrogen gases will have ensued. Inasmuch as no chemical union takes place between the two gases thus circumstanced, and as hydrogen gas, filling the upper vessel, weighs but $\frac{1}{16}$th of its bulk of the oxygen gas filling the lower vessel, some new cause of admixture has to be sought; it depends upon the mutual tendency of the two gases to become diffused through each other.

Fig. 1.



The above is an individual case exemplifying a general principle; any two gases might have been selected, and mutual diffusion would have ensued. Oxygen and hydrogen gases have been here chosen, because of the facility wherewith the circumstance of these having become diffused, may be determined. It is well known that neither oxygen nor hydrogen gas, taken separately, will explode on the application of flame, whereas a mixture of the two readily explodes; hence the propriety of selecting these two gases for illustration of the principle in question, will be obvious.

Faraday appears to have been the first to direct attention to the mutual diffusibility of gases. He noticed that bottles filled with gases, and corked or stoppered, or vessels filled with gases and inverted over mercury, in either case enclosed to all appearance accurately, nevertheless almost always permitted mutual admixture of the air without and the gas within. Döbereiner, Mitchell, and Graham, more especially the latter, have since investigated this class of phenomena more narrowly; and Graham has succeeded in determining the law which regulates this diffusion. He finds that the relative diffusiveness of any two gases is expressed by the reciprocals of the square root of their densities. Thus, the density of air being one, its diffusiveness is one also. The density of hydrogen being 0·693, its diffusiveness is $\frac{1}{\sqrt{0 \cdot 693}} = \frac{1}{0 \cdot 2633} = 3 \cdot 8$; the density of ammonia being 0·5898, its diffusiveness is $\frac{1}{\sqrt{0 \cdot 5898}} = \frac{1}{0 \cdot 7681} = 1 \cdot 30$; and generally representing the density of a gas by d, its diffusiveness is $= \frac{1}{\sqrt{d}}$ Applying this rule to practice, it appears that, supposing hydrogen and ammonia placed under circumstances promoting their mutual diffusion, 3·8 volumes of hydrogen will become mingled with 1·30 of ammonia.

It will be remarked that the atmosphere has hitherto been treated of, in a theoretical sense, as a mere mixture of nitrogen and oxygen gases. Practically, however, the atmosphere is far more complex. It invariably contains portions of carbonic acid (about one part in a thousand); also extraneous gases, besides aqueous and other vapours. A mixture of all these things may be termed, distinctively, the actual or *practical* atmosphere. They will hereafter come under our notice *seriatim*; but even a theoretical mixture of oxygen and nitrogen gases is subject to remarkable variations of property, its chemical composition remaining unchanged; portions of its oxygen are subject to be converted into *ozone*.

The change of common oxygen into ozone, furnishes an illustration of one of the most remarkable discoveries of modern science. It displays what is, perhaps, the most extraordinary example of the condition of *allotropism*, or the existence of one body under two different aspects; it promises to render evident some of these occult atmospheric causes which determine the progress of epidemics, and promote the existence of endemic diseases.

A summary of our knowledge relative to ozone may be briefly stated as follows:—Oxygen gas is susceptible of undergoing a change, the nature of which is altogether veiled in mystery. It is susceptible of becoming odorous, corrosive, and irritating when breathed; its chemical action may be exalted and modified, so that, whilst ordinary oxygen gas neither bleaches nor corrodes silver, nor decomposes iodide of potassium, the allotropic, or second form of oxygen gas, will accomplish all these results, and many more too numerous for mention here. The general conclusion to which it is desired to bring the reader is this: if causes can be proved to exist capable of changing atmospheric oxygen gas, in its ordinary state, into oxygen gas in its extraordinary state, how vast, how complicated must be the meteoric results determined thereby! That such natural causes do exist, will be readily inferred from a consideration of the artificial methods to which the chemist has recourse, for changing ordinary oxygen into ozone.

METHOD OF OZONISING OXYGEN GAS.—The most ready method of ozonising oxygen gas is as follows:—Take a few sticks of phosphorus; scrape them free from all superficial oxide, &c.; place them in a wide-mouthed bottle containing a little water, but not enough to cover the phosphorus. Let the whole remain at rest for about ten or fifteen minutes, and a considerable portion of the atmospheric oxygen will have been converted into ozone. The ozonised air thus generated will be at present mixed with vapours of phosphorus acid; washing will free the air from these, however, without removing the ozone. That the air thus treated has become considerably modified in some way, will, in the first place, be rendered evident by the smell. Atmospheric air, when pure and in its ordinary state, is devoid of smell; but the atmospheric air, the product of the experiment just detailed, will be found to have a very peculiar odour. It will be found, moreover, to be capable of removing the colour of sulphate of indigo, and other vegetable and animal colouring bodies. All this is due to the modification which ordinary oxygen gas assumed—due to its assumption of the allotropic state—to its conversion into ozone.

Another ready method of generating ozone is this:—Moisten the interior of a bell-glass receiver, or a large-mouthed bottle, with ether; then take a glass rod, heat it in the flame of a spirit-lamp, and plunge it into the bottle or bell-glass: under these circumstances ozone will be formed, provided the glass rod has not been heated to a very high temperature; for the circumstance has to be mentioned, that ozone is reconverted into ordinary oxygen gas by contact with any body heated above a certain, but not very well-determined point.

We have seen that the ordinary method of generating ozone, consists in bringing phosphorus into contact with atmospheric air (or oxygen) under certain conditions. Many other substances besides phosphorus are capable of generating ozone by contact. Oil of turpentine, and many other essential oils, will accomplish this; and the fact in question cannot be too forcibly remembered by the painter, who may discover, in the philosophy of ozone, the reason why certain pigments fade, or are bleached, thus destroying the general effect which he desired to produce. Meteorologically considered, however, the most important source of ozone remains to be described: we refer to the production of ozone by means of electricity. Every person who has been much accustomed to work with the electrical machine, must have noticed the generation of something powerfully odorous during the friction of the cylinder, or plate, against the rubber. This odour has, in point of fact, been called the *electric smell.* Now, if this electric smell be compared with the smell of the atmospheric air which has been treated with phosphorus, as just described, and the air washed, the two odours will be found to be identical, which is a presumptive evidence that electricity has in some way been concerned in the formation of ozone—an idea which extended experiment fully confirms.

It has already been stated that the most prominent quality of ozone is its highly developed oxidising power. By taking advantage of this property, we are supplied with an easy method of recognising it, by means of a test-paper, imbued with a mixture of iodide of potassium and starch. The chemical reader need not be informed that iodine colours starch blue, whereas iodide of potassium does not; therefore test-paper, containing iodide of potassium and starch, may occasionally be resorted to for indicating the presence of certain bodies, which have the faculty of decomposing iodide of potassium, and liberating free iodine. Ozone is one of these; which fact remembered, will render the following experiment intelligible:—If a piece of this paper be held between the prime conductor of an electrical machine and the knuckle, or a metallic ball, and electrical sparks transmitted through it, spots of blue discoloration will be seen on it, corresponding to each electrical spark.

The method of detecting the presence of atmospheric ozone is now readily indicated. If a strip of prepared paper turn blue, the existence of ozone is demonstrated. The experiment is very striking when performed near the sea. During the prevalence of a land wind, the test-paper will generally afford slight indications, or none at all; during the prevalence of a sea wind, however, ozone can generally be detected.

The reader will now be prepared to form some idea of the natural causes which may generate ozone. We need assume no other agency than that of electricity, to be assured that the production of ozone must be universal, and, looking on the world as an aggregate, continuous; and when we consider the potent nature of ozone, the irritation it produces when breathed, the facility with which it bleaches, corrodes, and destroys, we shall not be at a loss to understand that the consequences to living beings, of its excess or diminution, must be all-important. A most important function of ozone has yet to be indicated: it removes, almost more rapidly than chlorine itself, the bad odours resulting from the decomposition of animal or vegetable bodies. If a piece of putrid flesh be immersed for a few minutes in a bottle of ozonised air, the odour of decomposition is totally destroyed. With these facts before us, we may form some idea to ourselves of the important functions which ozone is designed to accomplish. Lessen the amount of atmospheric ozone, lower it below given limits, and increase the atmospheric temperature to the degree most congenial to organic decomposition, and the air will soon be charged with disease-bearing and putrid odours. It is in accordance with all that philosophy has been able to teach us, in relation to the laws of epidemic and endemic maladies, that the presence of such gaseous odours of organic decomposition as are here assumed, must be the fruitful source of disease; and it is not possible, after having studied the qualities of ozone, to refuse assent to the proposition, that the existence of this agent, in competent amount, must be followed by the destruction of the pestiferous odours of organic decomposition. If, however, ozone be naturally formed at any time in excessive amount, it is not difficult to foresee that other serious consequences must result to animal life. The inhalation of an irritating gas cannot but produce injurious effects on organs so delicate as the lungs; and, perhaps, many of the now anomalous and inexplicable effects of change of air, to patients suffering from chest diseases, may hereafter receive their solution in a more intimate acquaintance with the laws of ozone.

PHYSICAL PROPERTIES OF GASEOUS BODIES.—The word *gas* is of German origin, and was first employed by Van Helmont, to signify the vapour which escaped from liquids undergoing vinous fermentation. At later periods, the term was applied to designate every invisible substance disengaged from bodies by the application of fire. Macquer, a celebrated French chemist of the eighteenth century, extended the meaning of the term gas to signify every kind of air besides atmospheric air; and modern chemists have extended the meaning of the term still further, to indicate elastic fluids, whatever their colour may be, which are not readily condensible. At one time it was erroneously imagined that gases did not admit of condensation: in accordance with this belief, a gas was defined as being *a permanently elastic* fluid, thus distinguishing this class of bodies from mere vapours, which, so far from being permanently elastic, are very readily condensible. Modern discovery has proved this distinction to be untenable. All the known gases, except oxygen, nitrogen, hydrogen, nitric oxide, carbonic oxide, and coal gas, have been liquefied, and a great number of them solidified, by subjecting them to extreme cold and pressure.

Law of Marriotte—The Volumes of Gases are inversely to the Pressure applied.—This is a very celebrated law, and one that intimately concerns the meteorologist; it may be otherwise termed the law of compressibility of elastic fluids.

It will be recognised that the law in question, according to the exposition of it just given, is a general law, applying to a vast number of gaseous and vaporous bodies. For a long time its absolute truth remained unquestioned; but, more recently, M. Regnault and others have demonstrated it to be not of such universality.

Even atmospheric air and nitrogen do not rigorously conform to the law; and carbonic acid, and liquefiable gases generally, are so little amenable to the law, that, as applied to them, it cannot be regarded as approximately correct. Even the rate of compressibility of hydrogen is not strictly accordant with the law, although the deviation in this case is in the opposite direction to the deviation when atmospheric air is concerned; for it suffers less compression than, according to the law, should take place. Carbonic acid and nitrogen, compressed by a force of forty-five atmospheres, only fill seven-tenths of the space they ought to occupy according to the law.

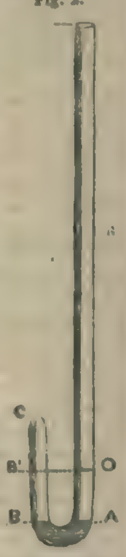
Now, inasmuch as the philosophy of estimating the height of mountains barometrically, is intimately associated with the law of Marriotte, it is well to indicate that this law is not quite correct; nevertheless, as regards atmospheric air, it is so nearly correct that we may accept it without demur.

The experiment by which the law of Marriotte was deduced is as follows:—Into a strong glass tube, of equal diameter throughout, bent on itself (as represented in Fig. 2), open at the long, and closed at the short extremity, a little mercury is poured, in such a manner that it shall be perfectly level in the two legs, as represented by the line A B. Under these circumstances, it will be evident that the air inclosed between B C and A D will be equally compressed. Let us assume the amount of compression to be represented by the weight x. Let us furthermore assume that the weight of a column of mercury between O and D to be $= x$, and let us call it m. If, then, on filling the long arm of the syphon with mercury, the column of air originally extending from B to C be diminished to the column extending from B′ to C, that is to say, to one-half, then we have $x + m = \frac{1}{2}$ B C, or

$$2x = \tfrac{1}{2}\,\mathrm{B\,C};$$

proving that the compression of air within the limits of the experiment is inversely to the pressure applied. In like manner, when the pressure is triple, the volume of gas is reduced to one-third; when quadruple, to one-fourth, &c. M. Arago has experimentally determined that the law rigorously applies to atmospheric air up to a pressure of twenty-seven atmospheres.*

Fig. 2.



The Atmosphere as a Ponderable Agent.—Owing to the equality of pressure which the atmosphere exercises on every side, we are not ordinarily conscious of its possessing weight. Nevertheless, its weight is no less definite, under proper limitations of demonstration, than the weight of any solid or liquid. The weight of the atmosphere may be contemplated under two conditions:

---

* The student will find a more extended mathematical investigation of this and the following subjects in the Section on *Pneumatics*, p. 709, *et seq.* —ED.

firstly, as the equivalent weight of an atmospheric column of known sectional area, but unknown height; secondly, as the equivalent weight of a known atmospheric volume under proper limitations, presently to be indicated. Both these investigations will now have to be considered.

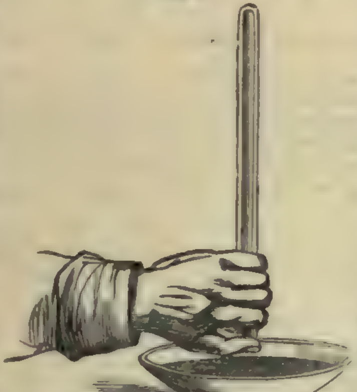


Fig. 3.

Determination of the Weight of an Atmospheric Column of known Sectional Area, but unknown Elevation. The Barometer.—*Experiment* 1.—If a piece of glass tube be taken equal in bore throughout, having a length of some thirty-three or thirty-four inches, closed at one extremity, and open at the other; if it be filled with mercury, then closed temporarily by the thumb, and inverted in a basin of mercury, as represented in the accompanying sketch (Fig. 3), we shall obtain a barometer of perhaps the most simple form this useful instrument can assume. We will proceed to study its philosophy. Firstly, let it be observed that though the tube *was* quite full of mercury, it does not remain quite full. No sooner is the restraining thumb removed, than a portion of the mercury sinks into the basin. If, instead of holding the inverted tube in the hand, as represented, some permanent support be devised for it; if the point corresponding with the present elevation or level of the mercury be marked on the tube; and if the tube be examined from day to day, the observer will soon find the level to fluctuate; sometimes it will rise, at other times fall. He will find, moreover, that the mercury will become depressed previous to stormy weather.

The instrument thus roughly extemporised is, in point of fact, a measurer of the weight of an atmospheric column of known sectional area (*i.e.*, the area of the interior diameter of the tube), but of unknown elevation. It is a barometer; and colaterally—inasmuch as depression of the mercurial column usually precedes stormy weather—the roughly-extemporised instrument is a weather-glass.

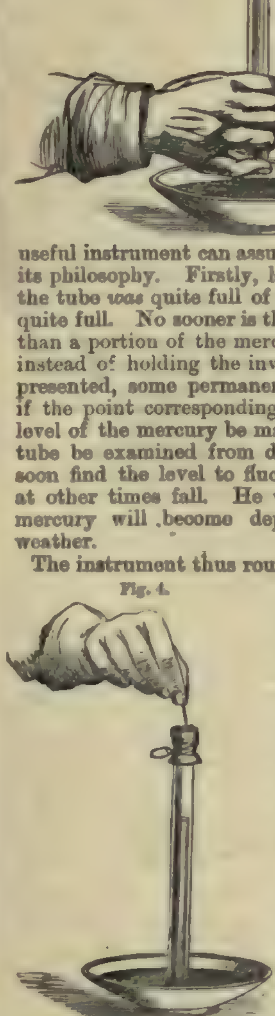

Fig. 4.

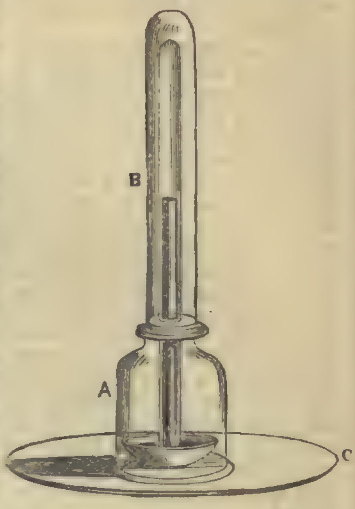
Demonstration.—It is desirable occasionally, when treating of natural phenomena, to violate the mathematical rule of accepting no fact until it has been demonstrated. Thus, in the present instance, we have taken the fact for granted, that the cause operating to maintain a mercurial column in the closed tube, is atmospheric pressure; and the cause to which variations of the height of that column is referable, is fluctuation of atmospheric pressure. The first proposition shall now be demonstrated, when the second will be accepted by inferential reasoning.

Experiment 2.—If, instead of a tube closed at one extremity, an open tube be taken, and one end be closed, by tying securely over it two or three strong pieces of moistened bladder—if the tube thus prepared be filled with mercury, as before, and inverted in a basin of mercury, we shall be in a position to demonstrate the proposition, that it is owing to atmospheric pressure—and that alone—that the mercurial column is supported. The operator has simply to prick the bladder, and let in air, when the whole column will suddenly descend to the level of the mercury in the basin (Fig. 4).

There is another form of demonstration, as follows; but it is not so simple as the last, inasmuch as it requires the aid of the air-pump:—

A is a glass air-pump receiver (Fig. 5), through the neck of which the tube B passes, inclosed in an exterior tube, which may be regarded as a prolongation of the receiver. C is the plate of an air-pump, on which the receiving jar is laid.

Fig. 5.



Let us assume that the barometer tube has been filled with mercury as before—plunged in the basin containing mercury underneath, the receiver A slipped over it, and finally extension made by the long glass sheath. Let us assume now that the air-pump is worked, and exhaustion gradually effected. Under these circumstances, the mercurial column will be seen to fall, and it will fall by jerks, each jerk corresponding with a stroke of the pump-handle. Hence, by the two preceding experiments, it is demonstrated, that to atmospheric pressure, and atmospheric pressure alone, is the variation of the mercurial column due. It is also proved, inferentially, that the fluctuations of height witnessed from day to day in a barometric column, are due to variations of atmospheric pressure. It appears, then, that by the barometer we actually weigh a column of atmospheric air, equal in height to the whole elevation of the atmosphere, whatever that may be, and equal in area to the internal sectional area of the barometer tube. The barometer, however, gives us no information in terms of cubic dimensions of the barometric mercury. Thus, supposing the barometric tube employed, to have a sectional area of one square inch, and supposing the mercurial column to be thirty inches high, then we should be correct in averring the pressure of an atmospheric column a square inch in sectional area, and extending the whole height of the atmosphere, to be equal to the weight of thirty cubic inches of mercury. Now the weight of thirty cubic inches of mercury will be about fifteen pounds; hence the atmosphere is said to exert a mean pressure of fifteen pounds on every square inch at the level of the sea.

INFLUENCE OF ELEVATION ON THE BAROMETRIC COLUMN.—It will be evident, on reflection, that the atmospheric pressure must decrease with every increment of elevation above the level of the sea. Founded on this principle, the barometer is frequently employed to determine the height of mountains; and, reversing the application, it might also be employed to determine the depth of mines and wells. At the elevation of about thirty-six miles, the pressure of the atmosphere cannot amount to more than 0·001 of an inch of the barometric column; and conversely, at a depth of about sixty-six miles, the density of the atmosphere would be about 100,000 times greater than at the surface of the earth, being six times more than the density of gold and platinum; so that, supposing either of these metals to be plunged into such an atmosphere, they would actually float.

If the atmospheric density were uniform, a barometric fall of one inch would correspond to 11,065 inches, or 922 feet of air. But it is not uniform, as we have already seen; therefore such deviation from the standard of uniformity, and indeed many other circumstances, must be taken cognizance of before we are enabled to employ the barometer as an indicator of atmospheric elevations.

The law of Marriotte teaches that the dilation of a volume of air is proportional to its density, so long as the temperature to which it is exposed is constant; whence it follows, that the density of the atmosphere diminishes from below upwards, in geometrical progression. Reasoning on this basis, it appears that, assuming any particular elevation above the point of observation, its numeral exponent may be regarded as the logarithm of the density of the lowest atmospheric layer, or, in other words, of the barometric column. A consideration of the mutual relation subsisting between numbers and their logarithms will render this evident, for logarithms are nothing more than numbers increasing by arithmetical progression, corresponding to other numbers, the increase of which is also in geometrical progression. Being possessed of a table of logarithms, expressing the densities of atmospheric layers, one might calculate the height of a mountain by two observations made at two stations; but the same result may be arrived at by using a common table of logarithms, and multiplying them by a constant factor. According to Deluc, the factor is 10,000.

Many other considerations have to be allowed for before the barometer can be accurately applied as a measure of mountain elevations: they are temperature, latitude, relation subsisting between the specific gravities of air, and mercury, and dilation of mercury for each degree of the thermometer = 0·0001 for each degree of Fahrenheit's scale. All these general considerations have been embraced in tables.

Although the circumstances necessary to be taken cognizance of when employing the barometer as an indicator of mountain elevation, are numerous and complicated, nevertheless, the results obtained are susceptible of a considerable degree of accuracy. Subjoined is a table of comparative results between trigonometric and barometric observations. The difference, it will be seen, is only trifling.

COMPARISON OF TRIGONOMETRIC AND BAROMETRIC MEASUREMENTS OF MOUNTAIN HEIGHTS.

Observers.	Place of Observation.	Latitude.	Longitude.	Trigonometric height in feet.	Barometric height in feet.

When an approximate result is alone required, and the height is inconsiderable, a fall of $\frac{1}{10}$th of an inch may be allowed for every ninety feet of elevation, or $\frac{1}{1000}$th of an inch for every foot. This rule suffices for the small differences of elevation at which barometers are hung, and enables the observer to institute a comparison between them. Correction for temperature must, however, not be omitted. The ratio of expansion for mercury, glass, and brass—the materials employed in the manufacture of barometers—will be pointed out hereafter; meantime we may as well indicate, that perhaps, after all, it is well in practice to ignore these complex elements, and to consider $\frac{3}{1000}$ths of an inch as the allowance for mercurial expansion for every degree above 32, and *vice versâ*. Applying the above corrections for temperature and pressure to practice, let it be required to know what height the mercury would stand at the level of the sea and at 32° Fah., if at an altitude of 150 feet, and temperature 55°, it indicated 29·565 inches?

Inches.

Actual height of mercurial column . . . 29·565

Deduct for 23° of temperature above 32

$\frac{3}{1000} \times \frac{23}{1} = \frac{69}{1000}$ . . . . . = ·069

Altitude of mercury . . . . . = 29·496

Add for elevation ·001 × 150 . . . = ·150

Altitude of level at sea, at temperature 32 Fah. = 29·646

The reader will remember that the previous remarks have reference to the barometer as affected by air at rest, this being the simplest atmospheric condition which theory can assume. Hereafter we shall discover that the barometer, when influenced by the atmosphere in motion —by winds, in other words—is subject to great variations.

Further Improvements of the Barometer.—The barometer in its simplest form, as already described, is a more perfect instrument than many in which that simplicity of form is departed from, in deference to portability; nevertheless, it is not quite correct. To be absolutely correct, it is indispensable that the mercurial level in the basin should bear a constant ratio to the mercury remaining in the tube, a condition which evidently cannot be obtained in the instrument just described. In proportion as mercury descends out of the inverted tube, the level of the mercury in the basin will be elevated, and to the extent of such elevation the indications of the instrument will be prejudiced. Various means are had recourse to for lessening, or absolutely removing, this evil. It may be lessened by increasing the width of the basin to such extent, that the ratio of elevation of the mercurial surface may be so greatly diminished that it will practically cease to impart errors. It may be absolutely removed by one of two devices. One consists in mounting the receiving basin on a screw, which, by elevation and depression, regulates the quicksilver to any desired level. Such is the contrivance of M. Fortin, whose construction of a barometer is here annexed (Fig. 6); but it is more usual to attach to the barometer, a long scale having a slide motion, so that the lower end, or commencement of the scale, may be made to coincide with the level of the mercury in the basin. Practically, however, the basin is usually dispensed with, the reservoir for mercury being a mere extension of the barometric tube, in some cases bulbed, and in others quite plain. Both these forms of construction are shown in figures 7 and 8.

Fig. 6.

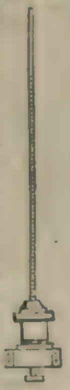

Fig. 7.

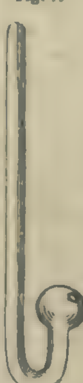

Fig. 8.

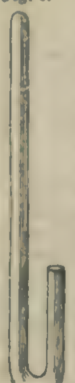
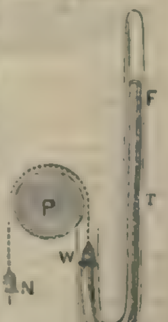


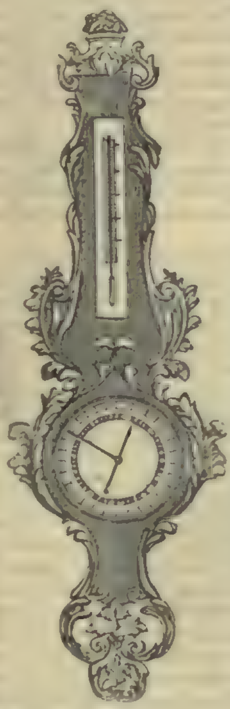
The Weather-glass.—The primary and only *direct* function of the barometer is, that its mercurial column indicates, by its rising and falling, the varying weight of the superincumbent atmosphere. Very frequently this direct function is taken no account of; variation in the state of the weather being all which the observer desires to make himself acquainted with. Subserviently to this intention, all direct rise and fall of the barometric column is lost sight of, and the indications of a dial-plate with movable hand are substituted. Such an instrument is termed the dial weather-glass, the construction of which is as follows:—T (Fig. 9) is a barometer tube; W is a small float attached to one end of a cord, the other extremity

Fig. 9.



of which is attached to a small weight, N. From this arrangement it will be seen that every rise and fall of the real barometric column, in the long arm of the tube, will correspond with a parallel fall and rise of the mercurial column in the short arm. It will be seen, moreover, how the small float, W, is raised and lowered; how the pulley, P, will be caused to revolve, and the index-hand to traverse the dial-plate of the instrument. The exterior of the wheel barometer is represented in Fig. 10.

Fig. 10.



We need scarcely state that the wheel barometer is considered, pneumatically, a very imperfect instrument. Not only is the varying ratio between the mercurial column and the level of the mercury in the reservoir here a necessity—the very index motion depending upon it—but the presence of the float, W, tends also to embarrass the free ascent and descent of the barometric column of mercury.

Manufacture of a Correct Barometer.—Not to render the principles concerned in the barometer complex, we have hitherto assumed that the act of charging a tube with mercury is simple and free from difficulties. Practically this is not so; many precautions have to be taken, otherwise the resulting barometer will be anything but correct. The tube selected must not be too small; many instruments are rendered incorrect owing to neglect of this precaution. The internal diameter of the barometer tube should never be less than a quarter of an inch; it may be even more with advantage. A small barometer tube prejudices the correctness of the instrument in two respects, for the variations of expansion and contraction of the mercury, due to variations of temperature, are more considerable; and the motion of the quicksilver, up and down, is impeded by friction against the glass.

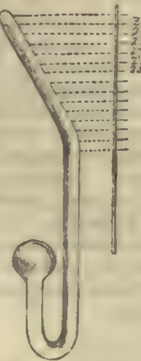
The Mercury must be Pure, and deprived of Atmospheric Air.—Mercury, as commonly existing, is generally impure. It contains uncertain quantities of tin, lead, and sometimes zinc. Of course these admixtures damage the mercury for barometric purposes. The observer desires to read off his atmospheric pressure in terms of inches of mercury, not in terms of inches of a mercurial compound. It is indispensable, therefore, that the impurities be discharged or extracted. Various processes are used to this end; but that usually followed by makers of barometers, consists in agitating the mercury to be purified, with dilute nitric acid, which gradually dissolves out the extraneous metal, and leaves the mercury pure.

Far greater difficulties are encountered in discharging atmospheric air from the mercury employed. This is accomplished by boiling the mercury after it has been poured into the tube. The operation requires great delicacy, and the instrument is frequently broken in the operation.

Method of Reading off Barometric Indications correctly.—It is not possible to read off, by referring to a common scale of inches and parts of inches, the various small elevations and depressions of a barometric column. Two methods are had recourse to for obviating this difficulty: one is the diagonal tube, a contrivance altogether peculiar to the barometer; the other is the Vernier or Nonius scale, employed for the general purposes of facilitating the reading of minute scale divisions.

The diagonal-tubed barometer is represented by the accompanying diagram (Fig. 11).

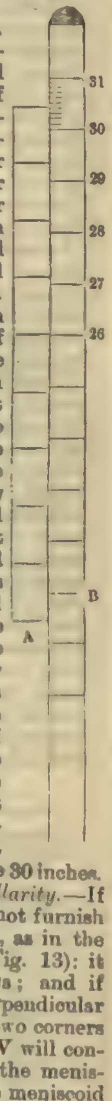
Fig. 11.



The Nonius or Vernier Scale.—This is an ingenious contrivance for measuring small linear divisions by means of larger divisions, and, consequently, more easily recognisable by the eye than larger divisions would be. Thus, for example, by means of a Vernier graduated in divisions of an inch and one-ninth, we can read off tenths of an inch, as will be seen by reference to Fig. 12.

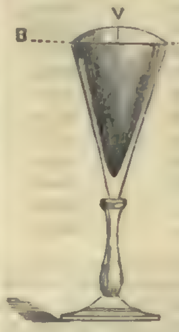
Let A be a scale sliding in proximity to B. Let each of the divisions on B be = one inch, and each of the divisions on A = one inch and one-ninth. From these considerations it follows that nine divisions on A are equal to ten divisions on B. Directing the eye to the upper limit of A, it will be seen that its edge corresponds to thirty inches, and *something more* on B. In this case the observer would have no difficulty in recognising the amount over and above thirty inches on B to be equal to four tenths of an inch. Our scale divisions are so large that a Vernier scale is not required for conveying that information. But, assume the tenth division between 30 and 31 to be obliterated, still we should be able to discover the overplus beyond 30 inches to be four-tenths by means of the Vernier scale A, inasmuch as the number of tenths will be equal to the number of whole parts on the Vernier scale A, above the first line of coincidence between it and the scale B. Now the line of coincidence in question is at 26, counting upwards; from which, to the extremity, we have four divisions, which indicate a fraction of four-tenths of an inch over and above 30 inches.

Fig. 12.



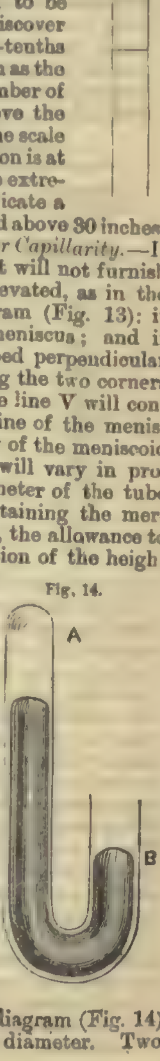
Correction of the Barometric Column for Capillarity.—If mercury be poured into a glass vessel, it will not furnish a perfectly level surface, but will be elevated, as in the accompanying diagram (Fig. 13): it will constitute a meniscus; and if the line V be dropped perpendicular to the line B, joining the two corners of the meniscus, the line V will constitute the versed sine of the meniscus. The convexity of the meniscoid surface of mercury will vary in proportion as the diameter of the tube or other vessel containing the mercury varies. Hence, the allowance to be made for diminution of the height of a mercurial column, owing to capillarity, is determined by two considerations—the diameter of the tube, and the length of the versed sine of the corresponding meniscus.

Fig. 13.



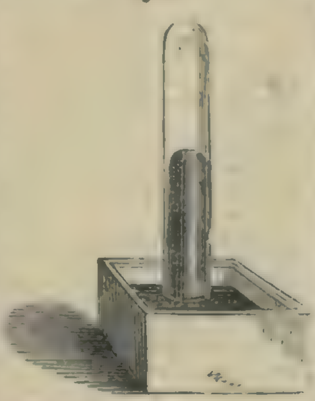
The necessity for such allowance does not apply, as will hereafter be seen, to barometers of every form; neither is it imperative, so long as the indications of one barometer are to be compared amongst themselves; but it is indispensable if we would compare the indications of barometers with each other.

Fig. 14.



First, let us consider the cases to which the correction for capillarity does not apply. It does not apply to any barometer, the reservoir of which constitutes part of the tube itself. The diagram (Fig. 14) represents a barometer of great tubular diameter. Two meniscoid surfaces of mercury are there apparent—one at A, another at B. Now it is evident that the columnar interference at A will be exactly equal to the columnar interference at B, provided the tubular diameter be equal throughout. Hence, whether the degree of elevation be counted from the summit of the lower to the summit of the upper meniscus, or from the base line joining the two corners of the lower meniscus to the base line joining the two corners of the upper one, the two resulting columnar estimations will be strictly equal and comparable. But it is different when the observer has to do with barometers constructed on the original, or Toricellian, plan of a separate reservoir; in this case the meniscoid elevation of the mercury in the reservoir is practically ignored, being so inconsiderable that it amounts practically to nothing, as will be seen by reference to the diagram (Fig. 15).

Fig. 15.



The following is a small table of depressions due to capillarity. Larger and more elaborate tables have been calculated; but the one given will suffice for, perhaps, every occasion. The meteorological student cannot have the fact too strongly impressed upon him, however, that the barometer is confessedly a very imperfect instrument; therefore correct results from barometric observations are to be looked for only as the mean resultant of a number of accumulated observations.

The Aneroid Barometer.—Of comparatively recent date is the invention of the *Aneroid* barometer. It consists of two discs of metal, accurately joined together, so as to enclose a space, from which the air is removed, and a vacuum produced. An increase or decrease of atmospheric pressure will cause the contraction or expansion of the sides of this vessel; and by means of tooth-wheels and rack-work, an index is thus moved on the face of the instrument, so as to indicate the pressure on a circular plate, divided into inches, &c., corresponding with the gauge of the mercurial barometer. The "aneroid" has been so greatly improved, that, according to Mr. Glaisher, a good one may be considered correct at a pressure so low as that equal to five inches of mercury. (See Chapter V.)

Thermal Expansion.—We will now examine the function of thermal expansion, which not only intimately concerns the barometer, but is the fundamental basis of the thermometer; and besides, it enters as an element into so many meteorologic calculations, that a thorough investigation of its laws cannot be omitted. We shall, therefore, embody the laws of thermal expansion in a few propositions for successive demonstration.

Heat may be regarded in the two senses: one signifying temperature, or that sort of heat which is recognisable to the sense of touch, and which affects the thermometer; and heat, which is devoid of these manifestations, which neither creates the sensation of warmth, nor is amenable to thermometric demonstration. The former we may express by the term *sensible heat*; and the second by the term *latent*, or *insensible* heat.

On the supposition that all the functions of heat, sensible as well as insensible, are referable to a real physical agent, the term *caloric* has commonly been applied as the representative of such agent; but though the term be in general use, it is perhaps objectionable—modern science leading us to infer that the functions of heat are due to a condition of matter, rather than to a separate agency. It is to evident heat, recognisable to the touch, that we shall now direct the reader's attention.

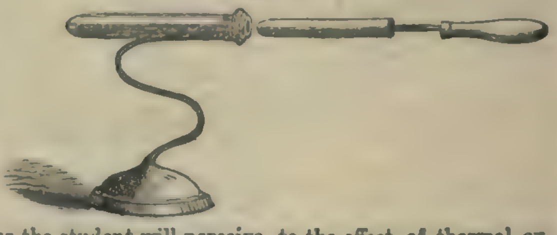
I. *Heat affects the Volume of all Bodies.*—The general effect of heat on bodies is to cause their expansion. So general is this rule, that we shall do well to consider it as universal; treating all deviations from it hereafter as so many exceptions.

II. *The Volume of all Solids is Increased by Increase of Heat.*—This proposition is demonstrated by so many instances commonly occurring, that specific experiments are hardly required. The wheelwright takes advantage of this property to bind tightly together the wood-work of his carriage-wheels. He heats the annular tire, by which he expands it; he then slips the tire over and around the wood-work, and, allowing the tire to cool, the wood-work is tightly braced together by an immense force.

Some years since, the walls of the *Conservatoire des Arts et Métiers*, at Paris, were found to be diverging from the perpendicular, and were restored to their original lines by the following beautiful expedient:—They were perforated transversely; copper bars were thrust through the perforations, each bar at either extremity being supplied with a nut and screw. Every alternate bar was heated by means of a spirit-lamp flame; being heated, the bars expanded, and the screw-nuts being now turned close up to the wall on either side, the bars were allowed to cool. By cooling they contracted—pulled the walls to some extent together, leaving the ends of the unheated bars protruding; their screw-nuts were now turned close up to the wall on either side, and the heating process repeated. Thus, little by little, the walls were restored to their original position.

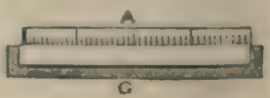
An exemplification of the expansion of iron by heat sometimes occurs to the laundress. Occasionally she is surprised to find that the heater of her Italian iron will not enter its corresponding sheath when red-hot, though it enters readily enough when cold. This is attributable, as the student will perceive, to the effect of thermal expansion on the iron (Fig. 16).

Fig. 16.



Thousands of familiar instances might be cited, all illustrative of the same property. We shall leave their consideration to the reader, concluding the remarks on this part of the subject by bringing before his notice a common lecture experiment, illustrative of solid thermal expansion. Let G (Fig. 17) be a gauge, into which the metallic bar, A, accurately fits, whilst cold; it will be found that when the bar A is heated—moderate heating will suffice, such as may be accomplished by means of

Fig. 17.



the flame of a spirit-lamp, or a basin of hot water—the heated bar will no longer fit into the gauge. In this way the student may demonstrate the fact that each different solid possesses its own definite rate of expansion for equal degrees of temperature.

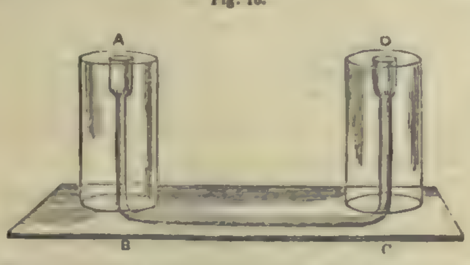
Investigations of the law regulating the thermal expansion of bodies, under every condition, are attended with extreme difficulty. They have been conducted by Regnault, Rudberg, and others, with great industry and much success; but, as in most cases where the investigation of natural phenomena through long ranges are concerned, the results are merely approximate. To give the reader a general notion of one of these difficulties, let it be assumed that A B C D stand for successive equal intervals of thermometric graduation. Let it be assumed that the rate of expansion of a substance from A to D be known as equal to a quantity expressed by Y. It by no means, however, follows—nor do philosophers believe—that, because the rate of expansion of the body between A and D is equal to Y, therefore the rate of expansion of the same body between A and B is equal to $\frac{Y}{3}$.

Further consideration of this matter may, however, be omitted in a Treatise on Meteorology. We merely want to be acquainted with approximate results of the law, in order to allow for practical discrepancies between the apparent and the actual indications of the instruments employed in the course of our researches.

To convey a general notion of this kind of knowledge to the meteorological observer, the student's attention may be directed to the fact, that, supposing a barometer-scale to be made of brass, and the tube to be filled, as usual, with mercury, then the amount of expansion of mercury by heat, and for which allowance has to be made, will be determined by the ratio $\frac{M}{B}$, if M stand for the co-efficient of expansion of mercury, and B for the co-efficient of expansion of brass. By the term, "co-efficient of expansion," is meant the number indicating the amount of expansion peculiar to any body for given ranges of temperature.

III. *The Volume of all Liquids is Increased by Addition of Heat.*—Investigations prosecuted for demonstrating this law, are attended with a difficulty which does not apply to the previous case. Liquids require vessels to hold them, and these vessels are themselves amenable to expansion. This difficulty has been very ingeniously avoided by MM. Petit and Dulong, who determined the expansion of liquids by a method founded upon the well-known hydrostatic principle, that the vertical heights of two fluids, communicating by a horizontal tube, are in inverse ratio to their densities. The apparatus shown in Fig. 18 was employed in their experiments. A, B, C, D is a tube bent twice at right angles, and enlarged at either extremity; the two vertical tubes are connected inferiorly, by a horizontal tube of exceedingly fine bore. By virtue of the hydrostatic law just mentioned, it follows, that if any liquid of homogeneous density be poured into the vertical leg of one side, it will rise to a corresponding elevation in the vertical leg of the other; and if the fluid in one vertical leg be now heated, and consequently expanded, its height will be in excess of the columnar height of the other, by a definite quantity. By an easy train of mathematical reasoning, the expansion due to heat can be deduced from a consideration of the different levels and the different temperatures of the two vertical tubes. Our diagram represents each vertical tube surrounded with a cylindrical vessel. These vessels are for the purpose of commanding variations of temperature; one tube filled with ice, whilst the other is filled with hot water.

Fig. 18.



By an experiment of this kind, the co-efficient of thermal expansion of mercury from 0 to 100 of the centigrade scale, is $\frac{100}{5550}$; whence, assuming its rate of expansion equal throughout, the expansion for every centigrade degree will be $\frac{1}{5550}$, or, for every degree of Fahrenheit, $\frac{1}{9990}$; in decimals = 0·000101; or, expressed in round numbers, one ten-thousandth part of its bulk.

IV. *The Volume of all Gases is Increased by Addition of Heat.*—Though the consideration of this law is not related, like the two preceding, to the *construction* of the barometer, it is intimately connected with the functions of that instrument, more especially as regards its application to the measuring of elevations; we shall do well, therefore, to consider it at once.

It has already been remarked, that the rate of expansion of all solid bodies for giving increments of temperature is various; and a similar remark applies to liquids. The rate of expansion of gases was first closely investigated by the immortal Dalton, who arrived at the conclusion, that all gases were equally affected by equal increments of heat, expanding to $\frac{1}{480}$th parts of their volumes at 32° Fah. for each of the 180°, between 32° Fah. and 212° Fah. As regards temperature, above 212° Fah. and below 32° Fah., it was imagined by Dalton that the same law of expansion held good. Various theoretical reasons exist of a nature to create a doubt as to the large generalisation of Dalton; and these doubts have been fully substantiated by M. Regnault. He finds that all gases do not dilate to the same extent between equal limits of temperature, neither is the dilatation of the same gas, between the same limits, independent of its primitive density. These are interesting facts: they prove that to assume one co-efficient of dilatation for all gases is obviously incorrect; nevertheless, his experiments go to prove that such a universal gaseous co-efficient of dilatation may be adopted for convenience, without appreciable error, within the theoretical limits of ordinary experiment. We must not, however, continue to adopt $\frac{1}{480}$th as our working gaseous co-efficient of dilatation for every degree of Fah. between 32° and 212°; nor $\frac{1}{483}$, as subsequently adopted by MM. Petit and Dulong, but $\frac{1}{491}$.

The Atmosphere Actually or Practically Considered.—We have hitherto regarded the atmosphere as a compound or mixture of nitrogen and oxygen gases only; but the reader need not be informed that such an atmosphere is altogether theoretical. Besides nitrogen and oxygen gases, there always exists a portion of carbonic acid, and aqueous vapour, either visible or invisible. These are invariable components of the atmosphere, indispensable to its functions, and adapting it to the purpose of this world's economy. The atmosphere contains also other materials, the results of local operations in nature, no less than the operations of man. As the subject of our present investigations, let us consider the atmosphere as a mixture of the theoretical atmosphere, *plus* aqueous moisture and carbonic acid.

Limits of the Atmosphere.—It follows, from a consideration of the laws of elasticity, that the atmosphere must vary in density for every difference of elevation. The atmospheric layer nearest to the earth must be pressed upon by the superincumbent atmosphere above it; whence the deduction follows, that when we speak of 100 cubic inches, or *any* definite measure of the atmosphere, weighing a certain number of grains, certain conditions and limitations are implied. Some of these have reference to the composition of the atmosphere chemically considered; others have reference to the atmosphere merely regarded as an elastic medium. To the latter consideration alone the reader's attention will be now directed.

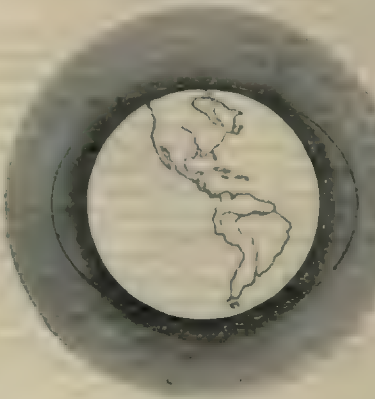
Seeing that the atmosphere, in accordance with the laws of elasticity, must necessarily expand, the higher we ascend above the normal level of the surface of our globe—or, in other words, the level of the sea—the first question which arises is this—To what extent do the atmospheric limits reach? does the expansion go on, *ad infinitum*, to the farthest realms of space, or are these limits definite? and if definite, what is the cause, or what are the causes, of limitation? Two theories have been adopted in reference to this question. According to one theory, the atmosphere is illimitable; according to the other, it is limited. Some of the arguments for and against we shall now proceed to give.*

If the atmosphere be really illimitable, let us see what should follow, to be in accordance with recognised laws, to which all ponderable matter, or matter subject to gravitating influences, is amenable. Gravitation being directly as the mass of gravitating bodies, it should follow that, were the atmosphere illimitable, each of the heavenly bodies should be surrounded with an atmosphere proportionate to its mass—an assumption which astronomy disproves. Thus, astronomy furnishes strong proof in favour of the finite extension of the atmosphere. A consideration of the laws of the atomic constitution of matter, lends further, and perhaps stronger, proofs. Chemistry is full of evidence in favour of the atomic constitution of matter; or, in other words, is full of proofs that all material substances are composed of molecules or particles; to which extent they can alone be divided, and not beyond. The mathematical reasoning, which has been employed against this atomic theory, as chemists term it, is specious at a first glance, but really untenable. To argue that the theoretical space, occupied by any material particle, may be supposed capable of division and subdivision, *ad infinitum*, is really not to the point. Space is one thing; the matter occupying such space is another. The mathematical objection touches the space alone, not the matter; therefore the chemical evidence in favour of the atomic constitution of matter is unanswered, and is apparently unanswerable. Let us now regard the consequences of this assumption as it relates to atmospheric air. The late Dr. Wollaston was the first person who directed attention to the limitation which should, theoretically, be imposed on atmospheric expansion, supposing the assumption of its atomic constitution to be correct. The atmosphere, like other ponderable material bodies, is subject to gravitating influences, thus imparting a tendency of descent towards the earth. On the other hand, the atmosphere being elastic, its particles are mutually separated from each other by the operation of this force. Now, assuming the atomic constitution of the atmosphere to hold good, there must be some finite distance from the earth's surface, at which the force of elasticity would be counterbalanced by the force of gravitation, which distance would correspond with the farthest limits of the atmosphere. The mean distance of this limit is assumed to be about forty-five miles, though it must differ from every point north and south; being greatest over the equator, and least at either pole, as indicated by the accompanying diagram (Fig. 19).

The reason of its being greatest at the equator is immediately referable to the diurnal rotation of our globe on its axis, thus generating a centrifugal force, which has determined the oblate spheroidal form of the earth. Material bodies will be affected by this centrifugal force, *cæteris paribus*, directly as their attenuation; whence it follows that the atmosphere, being a gas, must be affected to an extreme degree. It will be sufficiently evident, however, that the atmosphere is only affected by the earth's diurnal rotation intermediately, or by friction; the velocity of motion imparted to it by the earth being less considerable than the velocity of the earth itself. We shall hereafter find, when we come to treat of the trade-winds, that those permanent aërial currents are not altogether referable to atmospheric motion, but in some degree depend upon the diurnal motion of the earth.

Determination of the Weight of a given Volume of Atmospheric Air.—Nothing can be more easy than the theoretical means of solving this problem; and, though certain practical difficulties do interpose, we had better, for the sake of theoretical explanation, consider them absent.

Fig. 19.



The case under consideration is general, not specific. The determination of the weight of a given volume of atmospheric air, is accomplished similarly to the determination of the weight of a given volume of any other gas; nor does it differ in principle from the process had recourse to when solids or fluids are concerned.

If, to take the simplest practical case, without reference to cohesive state, it were desired to ascertain the weight of a given bulk of copper or brass—say one hundred cubic inches—the operator's first care would be to obtain a solid of copper or brass having these cubic dimensions; which having been obtained, no vessel for the purpose of weighing it in would be necessary. This is the simplest case of bulk-weighing which can occur; nevertheless, a condition has to be regarded which the superficial observer might forget, or, perhaps, not be aware of. The copper or brass alters its dimensions for every variation of temperature. If heated, it will expand; if cooled, it will contract; so that, practically, under no two degrees of temperature has the mass of brass or copper the same size. Practically, so long as solids are concerned, these variations of size, dependent upon variations of temperature, are not of much consequence in ordinary operations of weighing. It is necessary, however, to estimate them for other reasons, and to tabulate these variations. We shall have occasion to refer to this tabulation hereafter.

Let it now be assumed that the problem before us is to determine the weight of a given bulk of liquid—say water. In this case we must have recourse to some vessel of capacity, for the purpose of holding the water to be weighed; and further elements of complexity, in addition to that of temperature, are introduced. Firstly, the vessel employed has its own laws of expansion and contraction; secondly, the water, when poured into the vessel, will not have a perfectly flat surface; so that, except the mouth of the vessel be small, an error of considerable magnitude will be imparted; neither must it be too small, or the functions of capillary attraction will come into play, and then the water will present a higher level than properly belongs to it.

The chief source of inaccuracy, however, which the operator meets with in operating upon solids and liquids, is that dependent on the variations in bulk referable to thermal increments and decrements; any alteration due to variations in pressure being practically ignored. So far as atmospheric pressure is concerned—which is the only kind of pressure we need take cognizance of as affecting our subject—it exercises so little influence on the dimensions of solids and liquids, that we may put it altogether out of consideration. Far different, however, is it when gases are concerned. Their attenuation and elasticity are such, that variations of atmospheric pressure exercise the most powerful influence over them; so that the degree of atmospheric pressure operating at the time of the experiment, is, at least, of equal consequence with the degree of temperature.

---

* See Pneumatics, ante, p. 772.

We are now in a position to trace the theoretical steps necessary to be followed in obtaining the weight of a given volume of any gas.

Necessarily, as in the previous case, a vessel of capacity is required; but, inasmuch as a gas does not admit of being poured into the vessel like water, some practical expedient for accomplishing this must be devised. We had better omit all consideration of this for the present, and assume that the vessel (which will be a globe or flask having a neck with stopcock attached) is already filled with the gas to be weighed, at a definite temperature and definite pressure. This accomplished, the operator has only to weigh his flask full of gas, deduct the weight of the flask from the total weight of flask and gas, and the result is gained. Practically, however, many points have to be considered.

The Gas must be Pure.—Whether gas, liquid, or solid, any body, the weight of which we desire to know, must be pure; but this precaution applies in the highest degree to gases.

The Gas must be either Dry, or its Amount of Moisture must be Definite.—The property which gases have of taking up vapours, especially aqueous vapour, is well known; and it will readily be seen, that to the extent of the presence of such vapour, will the weight of a given bulk of gas, and vapour mixed, fluctuate. One of two processes has now to be followed: either the gas must be artificially dried by exposure to one of the hygroscopic bodies used by chemists for that purpose; or, it must be saturated with moisture to the fullest capacity at some given temperature.

The further steps of the calculation are based upon a consideration of the ratio between the specific gravity of steam or vapour, and the specific gravity of dry gas; and, lastly, the amount of vapour which a gas absorbs at a definite temperature. According to Gay Lussac, the ratio between the specific gravity of aqueous vapour and air, under similar conditions of temperature and pressure, is

$$\frac{0{\cdot}620}{1} = \frac{\text{vapour}}{= \text{atmospheric air}}.$$

The amount of aqueous vapour which a unit volume of gas can absorb at given temperatures, has been ascertained and tabulated.

Applying this knowledge to practice, let us assume that 100 cubic inches of moist air, at 60° Fah. and 30 inches barometer, weigh 31 grains, it is required to know how much 100 cubic inches of dry air would weigh.

We begin by turning to a table indicating the quantity of vapour present in a gas saturated with vapour at any given temperature. Dalton's table gives this quantity for 60° Fah. as 0·524. We next perform the following calculation:—

30 : 0·524 : : 100 : 1·747 = the volume of vapour in 100 cubic inches of moist air at 60° Fah.

And as 100 cubic inches of aqueous vapour weigh 19 grains, 1·747 cubic inches weigh 0·332 of a grain.

Weight of 100 cubic inches of moist air .	31
Deduct	0·332
	30·668

Therefore the weight of 100 − 1·747 = 98·253 cubic inches of dry air = 30·668 grains, and 98·253 : 30·668 : : 100 : 31·213 grains.

Whence it follows, according to the foregoing calculation, that the weight of 100 cubic inches of dry air, at 30 inches barometer and 60° Fah., is 31·213 grains.

Such, then, are the practical operations by which the weight of a known volume of gas is determined. We have chosen atmospheric air as the subject of illustration, but the processes are identical whatever the gas may be.

Although the result of the calculation just effected gives 31·213 grains as the weight of 100 cubic inches of atmospheric air at 30 inches barometer and 60 Fah., and although the number may be accepted for all purposes of meteorologic calculation, nevertheless it must not be viewed in an implicit sense. In point of fact, the exact weight of atmospheric air is not yet made out. Probably the determinations of MM. Dumas and Boussingault are most reliable. According to their experiments, 1 litre or 61·02791 cubic inches of air, at 0° centigrade and 0·76 metres barometer, weigh 20·065 grains; whence it follows that 100 cubic inches, under the same conditions, must weigh 31·093 grains at 60° Fah.

Barometric Pressure at the time of Experiment must be an Element of the Calculation.—A consideration of the laws of pressure, as influencing the volume of gases and vapours, will have made the student aware that due allowance requires to be made for variations referable to this cause. Now we are acquainted with the amount of expansion and contraction dependent on variations of pressure. This information is conveyed by a study of the law of Marriotte, which proves that a rule of proportion will furnish the information required. Thus, for example, suppose we have 100 measures of any gas at a pressure of 29 inches of the mercurial barometric column, and it is required to ascertain what volume the gas will fill at 30 inches of the same—this being the normal pressure to which all calculations as to the volume of gases are reduced—then we say

As 30 : 29 : : 100 : 96·66.

In other words, the 100 volumes of gas, under those conditions, would contract into 96·66.

Temperature must be an Element of the Calculation.—When it is considered to what extent gases and vapour suffer expansion and contraction by variations of temperature, the necessity of this calculation will be obvious. We have already explained the ratio of thermal expansion, to which gases and vapours are subjected by variations of temperature. *Practically*, we have seen at page 1127, that this ratio may be considered identical for all of this class of bodies, and to be equal to $\frac{1}{491}$th part of their bulk at 32° Fah. and 30 inches barometer for every degree of temperature between 32° Fah. and 212° Fah. Let us now apply this information to practice.

If the temperature of the gas be above 32° Fah., multiply its total volume by 491, and divide the product by 491 *plus* the number of degrees that the temperature of the gas exceeds 32° Fah. The numeral result of this operation gives us the correct volume the gas in question would occupy at 32° Fah.

For example, we have 100 cubic inches of gas at 50° Fah.; it is required to know what volume this gas would occupy if raised to 60° Fah.: thus

$$\frac{100 \times 491}{491 + 18} = 96{\cdot}46 = \text{the volume at } 32^\circ \text{ Fah.}$$

And

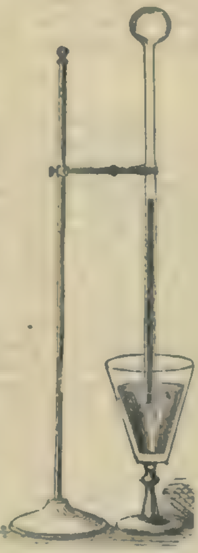
$$96{\cdot}46 + \frac{96{\cdot}46 \times 28}{491} = 101{\cdot}96 = \text{the volume at } 60.$$

Recapitulation and Deductions.—It appears, then, that the operation of weighing a gas demands in all cases that due allowance should be made for variations of heat and of pressure; and if the gas be charged with vapour, due allowance has to be made for moisture also.

THE THERMOMETER.—In the course of our preceding investigations relative to the atmosphere, we have seen that temperature is an important element. Not only are the chemical functions of the atmosphere intimately related with temperature, but, without allowing for the expansion produced by increments of heat, the meteorologic observer would be unable to comprehend some of the most ordinary physical conditions of the atmosphere. We have already seen that the general effect of heat, as regards alteration of dimensions, is expansion. If the amount of this expansion be determined for any particular range between fixed points, and the linear extension or space thus intercepted be divided into smaller spaces, each of these becomes a representative of heat or temperature. Supposing we assume the temperature at which water freezes to be our starting-point or first limit, and the temperature at which water boils to be our other limit; and supposing, furthermore, we assume the space between the two to be divided into any given number of parts—say, for example, 180—then we may describe any third body, the temperature of which is between the temperature of freezing and the temperature of boiling, to be one, two, or any number of parts above the former or below the latter. Thus, by applying these principles, we should have constituted the thermometer or heat-measurer. If the rate of expansion of any one body for given increments of temperature were regular and well determined, there would be no theoretical difficulties in the way of making a thermometer; practical difficulties there would be, but the hypothetical part of the task would be sufficiently easy. It so happens, however, that the number of expansive agents capable of employment for this purpose is limited.

The earliest thermometer was that of Sanctorini. Its construction is represented in the following diagram. A glass stem, open at one extremity, is terminated at the other by a bulb (Fig. 20). Into the bulb and a portion of the tube is poured a coloured fluid, which being done, the stem is inverted into the lower vessel. By virtue of the ordinary laws of hydrostatics, the level of the fluid in the stem will remain constant for every constant temperature; but inasmuch as every increment of heat will cause the air contained in the bulb to expand, so will it necessarily cause the coloured fluid—which latter merely serves as an index—to descend in such a manner, that were the ratios of successive equal linear measures of descent equal, the instrument would be a no less delicate measurer of variations of temperature than it is a delicate indicator of the same. For certain reasons, now to be described, it is not a delicate heat-measurer. Its successive linear columnar measurements are not comparable among themselves; whence it follows, that the instrument is not a thermometer or heat-measurer, but a thermoscope or heat-indicator.

Fig. 20.

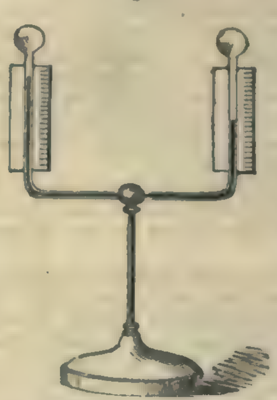


Concerning the reasons wherefore the instrument just described is not a perfect instrument, they readily admit of being made evident. They are immediately referable to the fact, that the coloured fluid, which, according to the necessities of the experiments should be dynamically passive, is really active. Its activity, moreover, is a variable quantity. If the coloured fluid were merely an index, having no dynamical power of its own, then the total increments of expansion and contraction of the air, contained in the bulb and part of the stem, would be proportionate to the increments of heat and cold within so small a deficit of the truth (see page 1127), that the error need not enter into calculation; but examination of the structure of the instrument will show that this cannot be so. *Actually*, the total expansion of the air in the bulb is the resultant of two forces—the force of aërial elasticity due to heat, and the force of pressure or downward tendency of the columnar liquid. Inasmuch, therefore, as the columnar height of the liquid in question varies for every temperature; and, moreover, as the rising and falling of the liquid in the reservoir, or lower receiving-vessel, also confuses the result, the heat-determining instrument of Sanctorini is not a correct measurer of temperature.

The Differential Thermometer.—Although various forms of air-thermometers are occasionally used in conducting certain specific experiments, their use is rare. Almost the only form of air-thermometer in frequent use is the differential thermometer, an instrument the function of which is to determine the difference between the temperature of any two adjacent bodies, or of the adjacent parts of any one body, without informing the observer concerning the actual temperature of either.

The differential thermometer is represented by the accompanying diagram (Fig. 21). It consists of a glass tube having a bulbular expansion at each extremity, and joined by a stem bent on itself twice at right angles, so that the two bulbs look upwards. During the process of manufacturing this instrument, whilst one of the bulbs is yet unclosed, liquid is poured into the instrument just enough in quantity to reach a little way up the vertical part of the stems; each of these vertical parts are supplied with a scale-division of equal lengths or degrees. Looking at this instrument, the observer will readily see that, supposing the tension or expansive force of the atmosphere in each bulb to be equal, the index fluid in the stem will stand at precisely the same elevation in both vertical stems; but supposing the air in one bulb to become heated to a higher degree than the air in the other; supposing, in other words, its expansion to be greater, the corresponding columnar height will be diminished, and necessarily, the opposite columnar height will be raised. Hence the difference between the two columnar heights will indicate that of the temperature of the two bulbs, expressed in equal parts of columnar measurement.

Fig. 21.



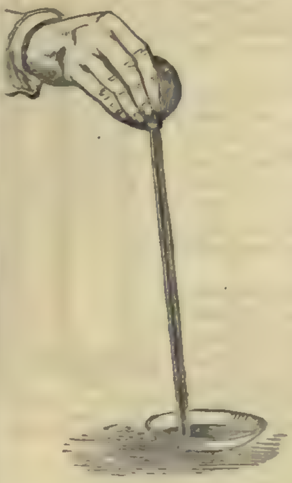
Thermometer Scales, and Ordinary Thermometers.—The liquids ordinarily employed in the manufacture of thermometers are mercury and alcohol. The former is preferred to all others, when its use is practicable, on account of the comparatively equal expansion to which it is subject for equal grades of temperature. In the manufacture of thermometers, however, intended to be employed for the measurement of temperatures below the freezing point of mercury, that fluid is necessarily inapplicable. Spirit, or alcohol, has never been frozen by the most intense cold yet produced, therefore it is substituted for mercury on such occasions. We shall now proceed to detail the successive steps in the manufacture and graduation of thermometers.

Under the head of *Barometer*, the inconvenience was pointed out of using a glass tube of small diameter, because of the interference resulting from the expansion and contraction of mercury by heat. Now that which is a cause of embarrassment in the barometer, is the function on which the action of the thermometer depends. It follows, therefore, that in proportion as the bore of a thermometer tube is smaller, so is the resulting instruments more delicate, because greater linear increments of expansion will be generated for given amounts of temperature. However, it happens in practice, that if the diameter of the tube, and the diameter of the mercurial column contained in the tube, be smaller than certain limits, it is difficult to be seen. It is hardly necessary to indicate, moreover, that the length of linear expansion may be increased to any given limit, by increasing the dimensions of the corresponding bulb, or mercurial reservoir. Practice alone can determine the proper relation which should subsist between the bore of a thermometer tube, and its corresponding bulb.

The following directions, for the manufacture of a thermometer, are not intended to enable the meteorological student to usurp the functions of the mathematical instrument-maker; on the contrary, they are intended to make known to him the defects which he should look for in a thermometer, and which, if discovered, should cause the thermometer to be rejected.

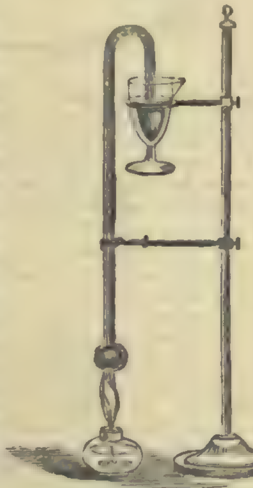
The Tube must be Equal in Bore throughout.—If the bore or diameter of a thermometer tube be not equal throughout, it is evident that the amount of linear expansion cannot be equal, and that the instrument will be absolutely worthless. A very easy means of gauging this equality is the following:—Having selected a piece of thermometer tube open at both ends, tie on to one extremity a rigid bottle of india-rubber, and dip the other end in mercury, thus (Fig. 22). Pressing the bottle, a portion of the atmospheric air will be expelled; then, allowing the bottle to expand, some mercury will enter, forming a mercurial column, the length of which admits of being measured. Let it be measured by means of a pair of compasses; and let the mercury be driven to various parts of the tube, and the measurements repeated. If the tube be of equal bore throughout, the mercurial column will necessarily be of equal length throughout; and if the tube stand this test, it may be considered good. Instead of the india-rubber bottle the breath might be employed, but it would be attended with the disadvantage of moistening the tube. However, it is possible to use the breath without prejudice, if the operator take the precaution of blowing through some material absorptive of moisture. The next step in the manufacture of a thermometer consists in fusing one end of the tube, and blowing it into a bulb; this, again, should be effected by means of the caoutchouc bottle, lest moisture be deposited. Mercury has now to be introduced, which is accomplished as follows:—

Fig. 22.



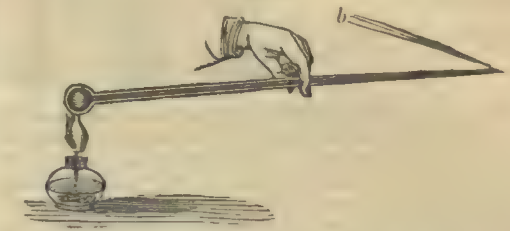
The thermometer tube having been bent as represented (Fig. 23), its open extremity is immersed in a vessel of mercury. Heat being now applied to the bulb, the air therein contained is expanded; and the heat being removed, a partial vacuum results, to fill which, mercury rushes in. By repeating the operation, the mercury already contained in the bulb is vaporised, and the vapour, expanding, drives out all the remaining atmospheric air; so that on the removal of heat, the whole—tube, bulb, stem and all—becomes filled with mercury. The bent part of the tube is now broken off, and the final quantity of mercury duly apportioned to the tube. The amount of this apportionment can be only determined by practice; but, in general terms, it may be described as being such a quantity, that, at the boiling point of mercury, it shall nearly extend to the extremity of the tube.[*]

Fig. 23.



The next process is one of extreme delicacy. It has for its object the sealing or melting the open extremity of the thermometer tube, without admitting the slightest portion of atmospheric air, the presence of which would materially interfere with the delicacy of the instrument. The operation is conducted as follows:—The open end of the tube having been melted in the blow-pipe flame, is drawn out to a fine termination, thereby diminishing still further the internal bore of the tube, and rendering the final closing of its orifice more easy. The mercury in the bulb is heated once more; and at the very instant when it is seen to fill the tube and to be in the act of overflowing the capillary extremity, the tube is closed by the fine jet of blow-pipe flame *b* (Fig. 24). It only now remains to graduate the thermometer.

Fig. 24.



Graduation.—The instrument just described is, in its present condition, a thermoscope, or indicator of heat; but it is by no means a heat-measurer—to convert it into which, it requires to be graduated into a determinate number of equal parts. These parts are usually called degrees; but it must be remembered that the so-called degrees have no ratio whatever to any particular unit. They are not like the degrees on the circumference of a circle, each one of which is related to the trigonometrical ratio, or the ratio of the circumference to the diameter. Thermometric degrees are altogether arbitrary, except insomuch as certain usages in this respect obtain. This much is, however, invariable and universal—the divisional parts or degrees must be established between certain limits, fixed by nature. The limits usually adopted in the manufacture of thermometers are the boiling and the freezing of water, which phenomena always, under similar conditions, take place at similar respective temperatures. Founded on the bases of these limits, three principal scales of graduation have been devised. They are the centigrade scale, or scale of Celsius; the scale of Reaumur, and the scale of Fahrenheit. The latter is mostly used in this country; the former is chiefly adopted on the continent.

Let us commence our illustrations with the centigrade scale, as being most easy. The term centigrade seems to be significant of a hundred divisions. In point of fact, the centigrade scale has for its 0, or zero, the temperature at which water freezes, and, for its 100, the temperature at which water boils; the intermediate space being divided into 100 equal parts. And if it be desired to carry the graduations above or below the gauge limits, this is accomplished by measuring off equal parts by means of a pair of compasses.

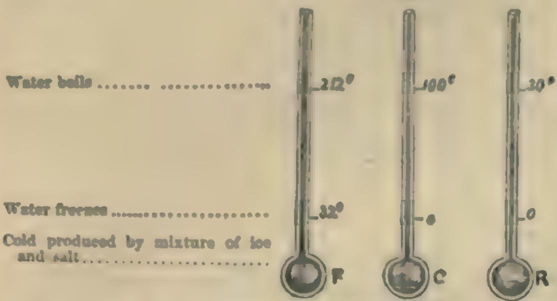
Reaumur's scale has also its zero point, at the elevation of mercurial column corresponding with the freezing point of water; but at the other extremity of its scale the boiling point of water is considered to indicate 80; hence the intermediate space is divided into 80 equal parts. The following diagram (Fig. 25) will render evident the peculiarities of the ordinarily employed thermometric scales.

Conversion of One System of Graduation to Another.—This conversion of thermometric scales is frequently necessary. The rules for effecting the conversion are evident on reflection; nevertheless it is well to reduce them to general formulæ. If all these scales counted their zero from the same point, the method of converting one scheme of graduation into another would be still easier than we find it. Actually, some little confusion at first arises from the circumstance that Fahrenheit's zero is placed not at, but below the freezing point of water.

---

[*] Care is required, in this process, that the cold metal shall not suddenly impinge on the hot bulb, as that would certainly break it.—ED.

Fig. 25.



Conversion of Fahrenheit to Centigrade Degrees.—The proposition is evident that one Fahrenheit degree is equal to five-ninths of a centigrade degree, inasmuch as the number of Fahrenheit degrees, between the freezing and the boiling point, is to the number of centigrade degrees for the same space as unity to five-ninths, as is seen to be established by the following proportion :—

$$\overset{F.}{(212 - 32)} = 180 : \overset{C.}{100} :: \overset{F.}{1} : \overset{C.}{\tfrac{100}{180}} = \tfrac{5}{9},$$

whence it appears that we may convert Fahrenheit degrees into their centigrade equivalents, by first subtracting 32°, which leaves 180 ; then multiplying this number by five, and dividing by nine, as in the following proportion :—

$$212 - 32 = 180 \text{ and } \frac{180 \times 5}{9} = \frac{900}{9} = 100.$$

Conversion of Centigrade to Fahrenheit Degrees.—Inasmuch as each centigrade degree is longer than a degree of Fahrenheit in the ratio of $\frac{9}{5}$ to 1, therefore the former may be reduced to the latter by multiplying by 9, dividing by 5, and adding 32. The truth of this operation may be readily demonstrated by working on the number 100, which should give, if the rule just enumerated be correct, 212 :—

$$\frac{100 \times 9}{5} = 180, \text{ and } 180 + 32 = 212.$$

The examples just given, illustrate the process of calculation when positive degrees, or degrees above zero, thus (+), are concerned. Exactly the same rule has to be followed when negative degrees (—) are in question, although the rule, when stated in common terms, appears to be different, inasmuch as following the diction of arithmetic, the operator must be told to subtract 32. An example will render this more evident. Suppose we require to represent 5° below zero, or — 5° of C, by its equivalent F. Now the number 32, with 9 subtracted, gives 23 for remainder. Viewing all the steps of the calculation involved algebraically, it will be found that the rule of adding 32 has been implicitly followed; a negative 5 however (— 5) yields in the following operation a negative 9 (— 9), which, being added to + 32, is equivalent to subtracting a positive 9 (+ 9). For example—

$$\frac{-5 \times 9}{5} = \frac{-45}{5} = -9, \text{ and } -9 + 32 = 23.$$

The various steps for the reduction of one system of thermometric degrees to another, are comprehended in the appended formulæ :—

Fahrenheit to Centigrade, $\frac{F. - 32 \times 5}{9} = C.$

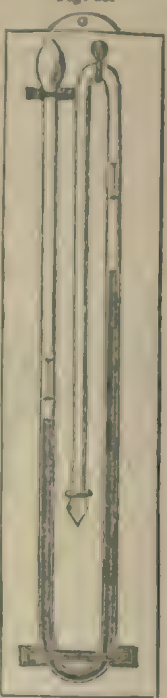
Centigrade to Fahrenheit, $\frac{C. \times 9}{5} + 32 = F.$

Fahrenheit to Reaumur, $\frac{F. - 32 \times 4}{9} = R.$

Reaumur to Fahrenheit, $\frac{R. \times 9}{4} + 32 = F.$

The Register Thermometer.—The greatest difficulty attendant upon the use of the thermometer for meteorologic observations, is referable to the necessity of frequent examination. To obviate in some measure the necessity for this, the instrument called the *Register Thermometer* has been devised—an instrument which depends for its action on the traversing of two steel bars in the bore of the tube, each pressed forward by the expansion of a liquid column. An instrument of this kind is represented in Fig. 26. The register thermometer is accurate enough in its indications for some rough purposes, but it is by no means adapted to supersede the use of thermometers of ordinary construction.

Fig. 26.



The Thermometer of Breguet.—A very delicate thermometer has been invented by M. Breguet. It differs from all which we have hitherto described, in the fact of its dispensing altogether with mercury, or other expansive liquid, and utilising the expansion or uncoiling of a compound metallic bar.

The illustration of the different rates of expansion by heat of two different metals (for instance, iron and brass) is often made by the following contrivance :—*a* (Fig. 27) is a compound bar of this kind, perfectly straight when cold ; but if this same bar be heated, it becomes curved, as represented by Fig. 28.

Fig. 27.

Breguet's thermometer is merely an amplification of the preceding experiment ; instead of a straight compound bar, a compound bar twisted into the spiral form is employed. One end of the spiral is fixed ; the other end is free, and is attached to an index. The mode of action of the instrument will be obvious. Variations of temperature producing variations of curve, will cause the spiral to unfold, or contract, according as the variations are towards the direction of increased heat or increased cold. The metals employed in making the spiral of Breguet's thermometers, are platina, gold, and silver. Experiment has demonstrated that the needle of this intrument travels over equal arcs for equal increments of temperature ; hence Breguet's thermometer is not only comparable with itself, but with all other instruments on the same construction. Unfortunately, this delicate instrument has no great range of application, its indications being limited between the freezing and the boiling points of water (Fig. 29).

Fig. 28.

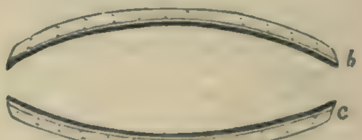


Fig. 29.

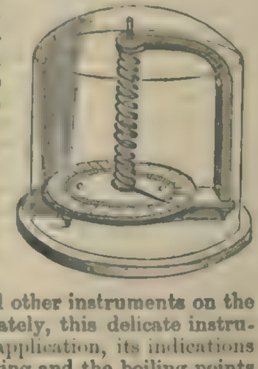

The Thermoscope of Nobili.—By far the most delicate indicator of minute increments and decrements of temperature, is an instrument founded on principles totally different to any already described. The electrical thermoscope of Nobili admits of being thus described :—The action of the instrument is based upon the fundamental fact of electro-magnetism ; viz., that a magnetic needle, freely suspended and placed in the vicinity of an electric current, finally arranges itself at right angles to that current. Hence the deflection of a magnetic needle becomes indicative of the existence of such current. Founded on the consideration of this fact, we have the instrument termed the galvanometer, which, in its simplest form, is represented by Fig. 30 ; and a still more delicate construction of which is represented in the following engraving (Fig. 31).

Fig. 30.

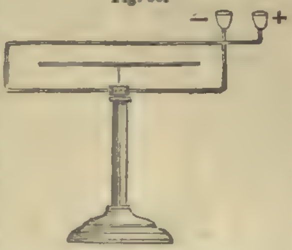

Fig. 31.

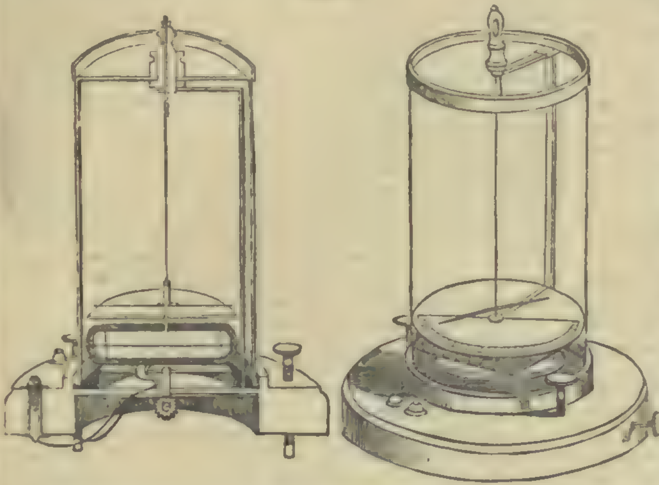
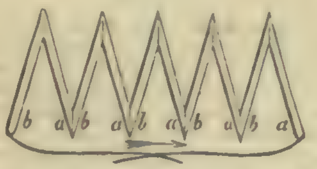


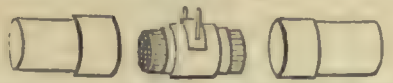
It remains now to remark that heat is a fruitful source of electricity, especially when heat is applied to one end of a mechanical arrangement of alternate bars of two metals, such as bismuth and antimony, as represented in the accompanying diagram (Fig. 32).

Fig. 32.



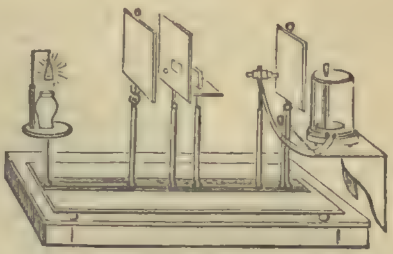
In order to render the combination of metallic bars more compact, they are usually arranged in a bundle, as represented below (Fig. 33).

Fig. 33.



Very few words will now render comprehensible to the reader the structure and functions of the thermoscope of Nobili. A bundle of bismuth and antimony reduplications, as just described, being placed in communication with a galvanometer, the magnetic needle of the latter is ready to be deflected on the first occurrence of an electric current, and such electric current is a direct consequence of the application of heat to one extremity of the system of compound metallic bars. The following diagram (Fig. 34) represents the thermoscope of Nobili, as employed to indicate small increments of radiant heat evolved from the little lamp on the left, and transmitted through the central diaphragm.*

Fig. 34.



Considerations respecting the Use of Thermometers.—Much that is incorrect passes current respecting the functions of the thermometer—the accuracy to which it is susceptible, and the spontaneous deteriorations to which the instrument is subject. A few words, therefore, on these matters may be advisable.

Let us assume the thermometer under consideration to be a mercurial thermometer, and that the mercury used was absolutely pure ; that the tube was proved to be of equal bore throughout ; that the process of sealing was accomplished without permitting the ingress of the slightest amount of atmospheric air ; let us, finally, assume that the tube has been accurately graduated—such an instrument may be regarded as free from all errors of construction.

Nevertheless, it is found that a thermometer thus unexceptionable at first, is liable to deteriorate by time, the gauge points—*i.e.*, 32° and 212°—corresponding with higher portions of the tube than they should do, and, necessarily, all other degrees similarly change. Most probably this result is referable to a gradual contraction of the sides of the tube and of the bulb, the contraction being determined by continuous atmospheric pressure. Looking at this contraction, the propriety is suggested of retaining thermometer tubes filled some time previous to graduation.

The kind of Heat indicated by Thermometers.—The term *heat* is commonly held to be synonymous with *temperature* ; but philosophy accepts it in a more extended sense, as comprehending not merely one effect (temperature), but the cause of many effects. The philosophy of latent and specific heat is almost too purely physical for extended examination here ; hence a slight reference to these conditions will suffice.† The thermometer is not adapted to take cognizance of heat in this latent or specific form. It is only indicative of evident heat or temperature ; nor are its indications in this narrow field so complete, nor the information it conveys so extensive, as is frequently supposed. The thermometer does not even profess to indicate the *quantity* of heat, but only its *degree* ; terms which are totally distinct, as will soon be perceived. Let us take the following as an illustration of the difference :—A pint of boiling water is as hot as a quart of boiling water, the temperature of both being 212° Fah. ; hence the thermometer, if appealed to, will indicate this identity of temperature. But, necessarily, a quart of boiling water must contain twice as much calorific force as a pint of the same : the deduction is too obvious for comment.

Again, strictly speaking, the thermometer cannot be said to present us with the *correct* temperature of anything, inasmuch as the degree of columnar expansion is not the degree corresponding with that of the thing, with which the thermometer is brought into contact, but the mean of the thing touched, and the bulb which touches it. This objection attains its minimum when the atmosphere itself is the medium, the temperature of which we desire to investigate; but it becomes of practical importance in all other cases; and its consideration teaches the thermometric observer the necessity for employing instruments, the bulbs of which are as small as compatible with well-marked amounts of columnar expansion. This remark especially applies to cases in which the bulk of liquid or solid operated upon is small. As concerns the graduation of thermometers, the most correct instruments are those of which the graduations are effected on the tube of the glass itself. If the graduation be made on a scale of brass, the resulting indications will be very incorrect, except the relative expansibility of brass and glass be taken into consideration, and duly allowed for; this, however, is so troublesome, that it will be too frequently evaded, and errors will creep in. Far better than brass is box-wood; and slate and ivory are better still.

---

* For more detailed descriptions of these instruments, the reader may consult the Sections on *Electricity* and *Magnetism* generally, in which these principles of action are investigated.—Ed.

† These subjects have been fully discussed in the Section on *Heat.*

Correspondence between Thermometers.—Scarcely any two thermometers exactly correspond, even though the same materials be employed in their construction, so numerous are the points which require attention. Between thermometers constructed with different materials—air thermometers and mercurial thermometers, for instance, or either of these, and spirit thermometers—the discrepancies are still more considerable.

The experiments of M. Regnault relative to the discrepancies subsisting between mercurial and air thermometers, are amongst the latest on this important subject. He found, that between 32° and 212° Fahrenheit, there is an almost absolute coincidence between the degrees of the air and the mercurial thermometer. From 212° to 482° Fahrenheit, the mercurial and air thermometers remain pretty equal; but after the latter point the mercurial gains on the air thermometers.

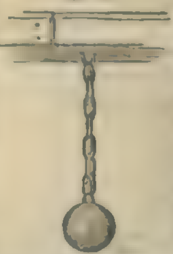
Hitherto we have treated of the atmosphere, statically, that is, in a condition of repose; but perfect atmospheric quiescence is unknown in nature—it is always agitated, more or less; hence we are led to the consideration of atmospheric currents or *winds*.

So variable are winds in these northern latitudes, that their incertitude has passed into a proverb; primary atmospheric currents, nevertheless, are constant in their direction, and are referable to variations of temperature simultaneously existing in different parts of the world.

Heat, in its non-latent condition, or, in other words, that condition of heat which is recognisable by the thermometer, has a tendency to equalise itself. Hence, if two bodies *a* and *b*, of which *a* is hotter than *b*, be situated in proximity to each other, there is an immediate tendency to equalisation of temperature as between the two; but the thermal conditions which regulate the production of winds, will be most readily appreciated by reflecting on what takes place when a heated solid is suspended in the atmosphere by a small chain or wire; we shall find, on investigation, that a heated solid thus circumstanced gradually becomes cool by the operation of three distributive influences—*conduction*, *radiation*, and *convection*. It will be unnecessary for us to do more than give a very general illustration of these terms, as the subjects are fully investigated in the first section of this volume.

Conduction.—If the chain by which the heated cannon-ball is represented to be suspended in the annexed diagram (Fig. 35), be examined from time to time by the thermometer, or even by the fingers, it will be found to increase in heat, evidently because it removes a portion of temperature from the heated cannon-ball by conducting it away. This function of heat is so well understood, and so commonly exemplified, that no further consideration of it will be necessary here.

Fig 35.



Radiation.—If a thermometer be held even at the distance of some feet from the heated cannon-ball, the mercurial column will be sensibly affected, thus demonstrating the transmission of heat. But how transmitted? By contact with the atmosphere? Clearly not, inasmuch as the result just indicated, still occurs if the cannon-ball be placed in the vacuum of an air-pump. By experiment, it has been determined that the temperature, in the case under consideration, has been given off in the condition of rays, precisely as light is evolved, and hence the propriety of the term *radiant heat*.

Convection.—Independently of the two processes of heat-distribution already described, there is yet a third. Referring to the suspended hot cannon-ball, we shall find that, if suspended in a room from the ceiling, the air near the ceiling becomes hotter than the air below: hence a portion of the temperature of the hot cannon-ball must have become accumulated there, by reason of some cause besides those of conduction and radiation, both of which distribute the temperature equally in all directions, through a homogeneous medium—such as the atmosphere for example—in our assumed experiment. The process of heat-distribution known as convection, is the necessary result of the expansion of liquids and fluids by heat; for when expanded they are specifically lighter; and when specifically lighter, they must necessarily ascend. It is by virtue of the process of heat-distribution, termed convection, that the child's soap-blown bubbles ascend instead of at once falling to the surface of the earth.

Temperature and pressure being equal, breath evolved from the lungs is heavier than atmospheric air, because it holds more carbonic acid. Nevertheless, inasmuch as it is evolved from the lungs hotter than the surrounding atmosphere, soap-bubbles blown with it ascend. Presently, however, they descend, because the heat acquired from the lungs being evolved, and equalisation of temperature with that of the surrounding atmosphere having ensued, the great specific gravity of the gas wherewith the bubble is blown, causes the latter to sink to the surface of the earth.

It is to the process of heat—convection—that we owe the salutary draughts in our chimneys, and also unsalutary draughts in our apartments. No sooner is fuel lighted in a fire-place, than the superincumbent air becomes higher and specifically lighter; it therefore ascends, and cold air rushes in to fill its place. Thus we have, in point of fact, a local wind; and the causes which determine that wind are exactly comparable to the causes of winds which take place in the grand economy of nature, as will soon be rendered manifest.

CHAPTER II.

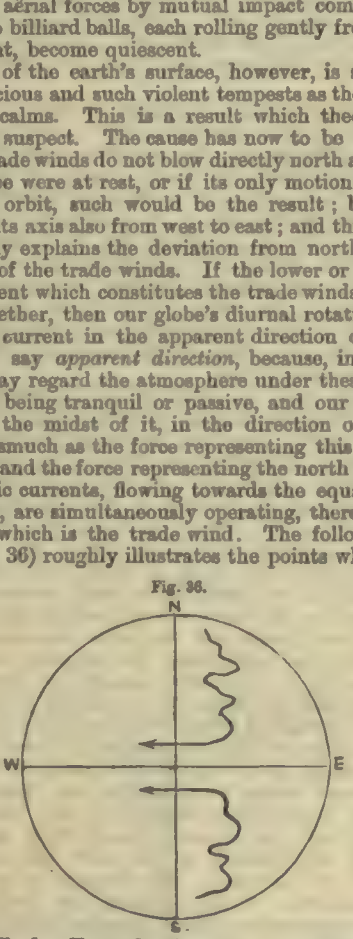
ATMOSPHERIC PHENOMENA.

THE TRADE WINDS.—Applying the facts already developed, let us now regard the surface of our globe in the aggregate, with reference to the localities of maximum and minimum temperature, and the consequence of such difference of temperature in originating an aërial current. It is evident that the hottest portions of our globe's surface are comprehended within the tropics, and the coldest portions are the arctic regions—north and south.

These circumstances being premised, we are now in a condition to anticipate the direction of the aërial currents or winds which must necessarily ensue. Firstly, an ordinary current of heated air should rise aloft in the tropical regions, then diverge and pass north and south to either arctic circle, thus constituting what may be termed the upper trade current. This current, as it proceeds north and south, gradually becomes cold, in which condition it is rendered specifically heavier, falls to the surface of the earth, and floats along towards the equator, thus generating two principal currents—one north, the other south. Whilst yet in the frigid and the temperate zones, these primary currents encounter so many interferences, that their primary or fundamental direction is masked or veiled: but still proceeding north and south, the persistent directive tendency of the trade winds is at length developed. But the currents no longer flow directly north and south. By the operation of a cause which will presently be rendered evident, the directive tendency of either current has acquired a certain impulse towards the west; or, in other words, both currents come more or less from the east. But at length they blow almost from due east, and finally cease altogether; so that the equator, and a certain space north and south of the equator, are comprehended within what is termed the region of calms. The north trade wind meeting the south trade wind, they are mutually destructive of each other. Two conflicting aërial forces by mutual impact come to rest, just as two billiard balls, each rolling gently from an opposite point, become quiescent.

No part of the earth's surface, however, is subject to such capricious and such violent tempests as the so-called region of calms. This is a result which theory would lead us to suspect. The cause has now to be explained why the trade winds do not blow directly north and south. If our globe were at rest, or if its only motion were motion in its orbit, such would be the result; but it revolves on its axis also from west to east; and this circumstance fully explains the deviation from northness and southness of the trade winds. If the lower or returning aërial current which constitutes the trade winds ceased to exist altogether, then our globe's diurnal rotation would generate a current in the apparent direction of east to west. We say *apparent direction*, because, in point of fact, we may regard the atmosphere under these circumstances as being tranquil or passive, and our globe revolving in the midst of it, in the direction of west to east. Inasmuch as the force representing this apparent east wind, and the force representing the north and south atmospheric currents, flowing towards the equator from either pole, are simultaneously operating, there occurs a resultant, which is the trade wind. The following diagram (Fig. 36) roughly illustrates the points which have been described. Towards the extreme north and extreme south, the great aerial currents, ultimately destined to become the trade winds, are represented fluctuating and variable; gradually, however, they acquire a northern and a southern directive tendency respectively; lastly, they come from the point of almost due east, and then cease altogether.

Fig. 36.



A consideration of the influences which determine trade winds, leads to a facile explanation of many aërial currents of less extent. The heating influence referable to the geographical position of the tropics is not the only influence of this kind A peculiar condition of the earth's surface, taken conjointly with a favourable condition of the sun's rays, may bring about similar results. In this manner the Mediterranean etesian winds, or aërial currents from the north, may be accounted for. Looking at the geographical condition of localities south of the Mediterranean, we find the Sahara, or Great Desert, a region whose surface is strewed with masses of pebbles and sand, and almost totally devoid of vegetation. Such a surface must necessarily become elevated by the solar rays to a high temperature, an atmospheric column must ascend, travel to the north, then fall, and at length return from the north to the Sahara, from whence it came.

LAND AND SEA BREEZES.—Many countries near the sea are subjected to winds of diurnal periodicity, known as land and sea-breezes. About eight or nine A.M., an aërial current begins to flow from the sea towards the land, and persists until about three P.M., when a current in the reverse direction, or from the land towards the sea, takes its place, and continues throughout the night until sunrise next morning, when it ceases, and a calm ensues until the completion of a period of twenty-four hours from the occurrence of the preceding land-breeze. These currents, in reverse directions, can be easily accounted for when we consider the heating agency of the sun. Necessarily, land becomes hotter than water under an equal power of calorific rays; whence it follows, that the surface of the ground, becoming heated after sunrise, determines the ascent of an atmospheric current vertically; thence, proceeding oceanward, the same current returns from the sea to the land. No sooner does the sun set, than this current is reversed.

In the preceding explanations of the cause of winds as being owing to inequalities of temperature, it will be observed that reference has alone been made to the calorific effects of the sun's rays. This is, in point of fact, the only source of heat which has to be noticed in meteoric considerations; for, although the earth's own temperature gradually increases as we pierce downwards below the surface, so imperfect are the conducting powers of the materials of which the crust of our planet is composed, that all consideration of them may be safely omitted in accounting for the present phenomenon.

PROCESS OF REVERSE ATMOSPHERIC CURRENTS.—Although the existence of atmospheric currents, proceeding in a direction reverse to those we meet with on the earth's surface, is forced upon the mind by inferential reasoning, and the fact must be accepted, even though no further evidence of it could be adduced, nevertheless direct proofs are not wanting. The direction of upper layers of clouds afford their testimony to the truth of the opinion. Where the trade winds prevail, the higher strata of clouds may be seen taking a direction opposite to that of the wind itself; and travellers, during their ascent of high mountains, have frequently proved the existence of a superior wind pursuing a course opposite to the wind below. This has been especially obvious on the Peak of Teneriffe, a mountain situated in the belt of the trade winds. On the summit of this peak, it has been always found that a south-west wind prevails; whereas the trade wind, at the base of the same mountain, blows from the north-east.

A similar remark has been made by travellers who have ascended Mona Kea, in Owyhee, the height of which is 18,000 feet. But, perhaps, the most striking illustration is the following:—The island of Barbadoes lies eastward of St. Vincent, and between the two the trade wind continually blows, and so forcibly, that it is only with difficulty, and by making a long circuit, that a ship can sail between the latter and the former. Nevertheless, on one occasion, during an eruption at St. Vincent, dense clouds formed over Barbadoes, and large quantities of ashes fell on the island. A similar result was observed after an eruption of the volcano of Cosoguina, on the shores of the Pacific, in Guatemala, in January, 1835, some of the volcanic ashes falling in Jamaica, more than 800 miles in a direct line distant, and directly opposed to the prevailing lower current. At the same time, another portion of ashes was carried westward, or in an opposite direction, falling on Her Majesty's ship *Conway*, in the Pacific, more than 1,200 miles distant.

The trade winds are, for the most part, only recognisable at sea; the solid material of land developing local aërial currents of their own. The extent of prevalence of the trade wind is various. In the Atlantic it prevails from 8° to 28° or 30°, but in the Pacific only to 25° N.L. In the southern hemisphere, the extent of the trade wind has been less accurately determined. When first the phenomena of trade winds were noticed by Columbus and his associates, they caused the greatest consternation. Accustomed to the fluctuating and irregular breezes of Europe, they regarded the continuance of a wind from the east as emblematic of their perpetual banishment from their native shores. The early Spanish navigators, however, very soon learned to appreciate the value of trade winds, by the aid of which treasure-laden galleons could, setting out from Acapulco, manage to arrive at Manilla almost without changing a sail.

As respects the upper current proceeding from the equator to either pole, it varies, as might be anticipated, in different localities. Travellers, who have ascended the Peak of Teneriffe, inform us that this upper current is found in that locality, at an elevation of 9,000 feet; but Humboldt, during his explorations on the Andes, discovered the eastern trade wind to be blowing at an elevation of 8,000 feet above the level of the sea. As the upper or equatorial current loses its heat, its specific gravity becomes greater, and it sinks lower and lower, no longer manifesting any well-marked directive tendency.

On the ocean, and between 30° and 40°, there is a prevalence of westerly winds, especially in the southern hemisphere. In the Atlantic this tendency is manifest; whence it follows, that the voyage from Europe to America occupies more time than a voyage in the reverse direction. It is difficult to say what may be regarded as the prevailing wind in these isles—probably, however, a south-western wind, as stated in the following table :—

Table representing the Relative Prevalence of Winds in different Countries for a Period of 1,000 *days.*

Countries.	N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.
England . .	82	111	99	81	111	225	171	120
France . .	126	140	84	76	117	192	155	110
Germany . .	84	98	119	87	97	185	198	131
Denmark .	65	99	100	129	92	198	161	156
Sweden . .	102	104	80	110	128	210	159	106
Russia . .	99	191	81	130	98	143	166	192
North America	96	116	49	108	123	197	101	201

The direction of winds is found, taking the average of many years, to vary according to the season. In Europe, south winds are more prevalent than any others during winter; east winds belong more especially to the spring; west and north winds to the summer; and towards October the wind usually veers round to the south. Usually, the wind is more strong in February and March than at any other time; and at all seasons the wind is usually strongest at noon.

STORMS.—Whenever the air, from any cause, is thrown into violent commotion, the result will be a storm. The philosophy of storms, notwithstanding the attention which has been devoted to the subject, is by no means well understood. In point of fact, the causes of storms are numerous and complex. If we reflect on the agency of temperature on the air, one prevalent cause of storms will at least become manifest. If one portion of the atmosphere be suddenly heated, violent commotion must arise—there must follow a storm. The laws of latent heat demonstrate, that whenever water is suddenly condensed, the surrounding air must be raised in temperature; and thus we have one of the most frequent local causes of storms. According to modern observations, storms are, for the most part, circular whirlwinds progressing in a north-eastern direction from the south to the north of the tropic of Cancer. In proportion as a locality is devoid of mountains and near the sea, so is it more liable to be subject to storms. Perhaps the most violent of all European storms are those which occur in the south of France during the prevalence of the north-east wind, termed *mistral;* but the most violent storms occur in and near the tropics, and are termed *tornadoes, trovadoes, hurricanes, typhoons,* &c. Hurricanes are essentially tropical; the West Indies suffer from them more than any other region. Hurricanes are of yearly occurrence in the West Indies; but the islands of Trinidad and Tobago, being protected by mountain elevations, usually escape them altogether. The wind, during a hurricane, frequently makes an entire circuit, blowing from every point of the compass; and it is by no means an unusual occurrence for the wind to cease awhile altogether, and then commence blowing again. Perhaps the most violent hurricane on record is the one which occurred in 1780. It destroyed the fleet of Lord Rodney, and a vast number of merchant ships. It killed no less than 9,000 individuals in Martinique; 6,000 in St. Lucia; and did immense damage at other places.

The eastern, western, and southern coasts of Africa are also subject to storms of almost equal violence with the West Indian hurricanes: these storms, however, in the localities under consideration, are called tornadoes. At Sierra Leone and the adjacent parts, two or three tornadoes usually usher in the dry season; they are sometimes accompanied with rain, and sometimes without: when of the latter kind, they are called white tornadoes.

The term *cyclone* is now applied to those storms, which are produced by a rotatory motion of the air. In the Northern Hemisphere, the rotation is contrary to the motion of the hands of a watch; whilst, in the Southern Hemisphere, it proceeds in the same direction as they move. The knowledge of the nature and motions of cyclones is now so complete, that, in many cases, the navigator, by watching the barometer and the direction of the wind, may so guide his vessel's course as to escape the violence of the storm. It is found, that near the centre, and the circumference of a cyclone, a calm usually exists, the force of the tempest being produced between those positions.

Typhoons may be described as hurricanes of the Chinese and Japanese seas; like hurricanes, they have a rotatory motion, but they are more localised in their action, having no distinct rectilineal progression.

Hot Winds.—Although heat may be regarded as primarily the cause of all winds, it does not follow that all winds must be hot; indeed, we know that the result is the direct opposite—that many winds are very cold. The temperature of a wind is for the most part totally independent of the temperature which caused it, and is determined by the nature of the surface over which it blows. The principal hot winds are those denominated the simoom, the harmattan, the chamsin, the sirocco, and the solano. The term simoom, or *samiel,* means poisonous, and is derived from a belief of the Arabs, that the devastating effects of this wind are attributable to some poisonous emanation which it bears. There is no foundation, however, for this notion. The terms chamsin and harmattan, are little else than Egyptian and negro appellations respectively for the simoom. The Egyptian term *chamsin* means fifty, and has reference to the duration of the wind fifty days—from April 27th to June 18th. The simoom is the terror of desert caravans. At its approach the horizon grows dark; the sun's rays scarcely penetrate with lurid gleam the atmosphere charged with particles of burning sand. The wind blows with fitful violence, scattering death and desolation in its track, withering the trees and shrubs which it encounters, suffocating animals, and burying them under waves of sand. The camels no sooner perceive the advent of the simoom, than rushing to the nearest tree or bush, or seeking the spur of some projecting rock, they place their heads in the direction opposite to which the wind blows, and endeavour to screen themselves from its violence. The traveller throws himself on the ground on the lee-side of the camel, and screens his head from the fiery blast within the folds of his robe. Too frequently, all these precautions are unavailing, both man and beast falling a prey to the terrible simoom. In the western part of Asia, more especially in Arabia, the simoom only blows in the summer months, and with maximum violence in July. It occurs only in the day-time, and for the most part only lasts a few hours. In Lower Egypt, the direction of the simoom is from the south-west; in Mecca, it comes from the east; in Surat, from the north; in Bassoria, from the north-west; in Bagdad, from the west; and in Syria, from the south-east; in every case, proceeding from the neighbouring desert, where the air has suffered rarefaction. The simoom, far from being poisonous, is in some localities beneficial to health, by drying up aqueous exhalations, which, if not removed, would give rise to fevers and other diseases. This is particularly the case on the western coast of Africa. It is, nevertheless, always injurious to vegetation.

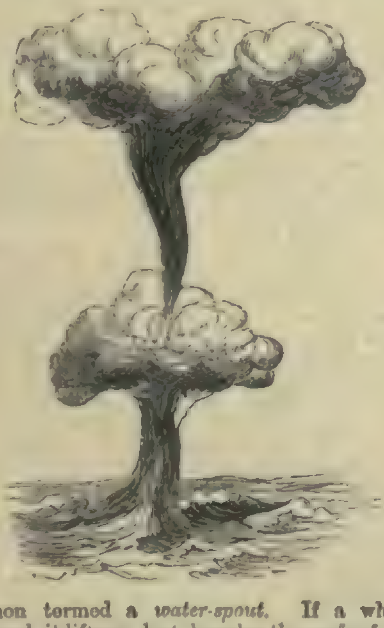
The Italian sirocco and the solano of Spain may be regarded as European continuations of the harmattan or simoom of Western Africa. The sirocco, although usually restricted to Malta, Sicily, and Southern Italy, sometimes extends into Germany and Switzerland: in the latter locality it is denominated the *föhn*. The föhn, although prejudicial to trees, develops, to a surprising degree, the vegetation of young plants, and can hardly be regarded as a calamity. It is most prevalent in Switzerland, near the Lake of the Four Cantons. Its period of duration does not usually exceed a few hours, though sometimes this period is exceeded; and it rarely occurs in winter.

The southern part of Australia is subject to a hot north wind, presenting such a marked resemblance to the sirocco, that geographers are led to the natural inference, that the unknown interior of the Australian continent is a desert of sand and rock, like the Sahara and the wilds of Arabia Petræa.

Cold Winds.—These winds are less noticeable and fewer in number than those already mentioned. Their low temperature is usually referable to the circumstance of their passing over mountain ranges covered with snow. The most considerable winds of this kind exist in Mongolia, Beloochistan, and the Russian steppes. To this class also belongs the *mistral*, a north-east wind prevalent in southern France, and which is exceedingly prejudicial to vegetable life.

Whirlwinds.—When two violent winds meet, the result is a whirlwind, so called from its rotatory character. If a whirlwind occur at sea, or over water, it elevates a large column of water aloft, sometimes to the height of many hundred feet, thus giving rise to the meteoric phenomenon termed a *water-spout*. If a whirlwind occur on land, it lifts up dust, boughs, the roofs of houses, and other solid matters, producing a column of well-defined shape. These whirlwind columns, whether they consist of water or solids, present the same general formation and contour. They consist of a hollow cone, sometimes straight, but more frequently curved or horn-shaped, its upper portion proceeding from a cloud; its lower part consisting of an aggregation of water or of sand and dust, according to the locality. The upper and lower portions of these columns are so much denser than the remainder, that they are generally opaque, whereas the middle portion is generally transparent. The tint of these colours is various—sometimes grey, sometimes brown or nearly black, and occasionally fiery red.

Fig. 37.

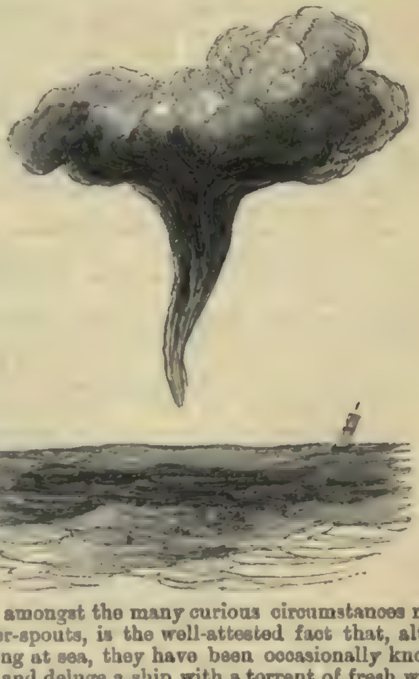


Independent of the circular or axial motion of these whirlwind columns, they pursue an onward course, sometimes straight, at other times curved. The velocity of this course differs within wide limits. Sometimes a man on foot can readily keep pace with it, whilst at other times they proceed at the rate of nine or ten miles an hour; sometimes more.

Whirlwind columns, whether they eventually become water-spouts or not, always originate on land, or in the vicinity of land where the winds and temperature are mutable. They are usually attended with thunder, lightning, and other electrical phenomena; and they constitute the centre of an aërial commotion, all around the focus of which, a profound calm prevails. Bodies which they have taken up are not readily deposited, but carried along in their onward course. Sometimes they are quite in the clouds, at other times on the surface of the earth or water; and their formation may be prevented. Even when already formed, they may frequently be destroyed by some violent aërial commotion, such as that produced by the discharge of a piece of ordnance—a fact well known to seafaring men. The size and height of these whirlwind currents are various; occasionally they present a diameter of no more than two feet; while the diameter of some has been estimated at two hundred, or even more. Again, the height of some is no more than thirty feet; whereas others have been known, the height of which was no less than three thousand feet.

WATER-SPOUTS.—Of these columnar whirls, the water-spout is less damaging than the dry-whirl, probably because the weight of fluid which it carries diminishes the violence of its rotatory motion. Not the least extraordinary amongst the many curious circumstances relative to water-spouts, is the well-attested fact that, although occurring at sea, they have been occasionally known to break, and deluge a ship with a torrent of fresh water.

Fig. 38.



Influence of Wind on the Barometer.—Although the barometer has hitherto been considered in reference only to the pressure of a tranquil column of air, its variations are influenced by many other circumstances, which we must not omit to consider. Amongst the most important of these are winds. Having regard to the ultimate cause of winds, it will be evident that the existence of a wind bespeaks the condition of different temperature in two different places. Hence, every wind necessarily varies to some degree the temperature which would have subsisted at any given place under a perfectly tranquil atmosphere. Now, as the atmosphere expands by heat and contracts by cold, varying, to a corresponding degree, its density or specific gravity, so it follows that the height of the barometric column will be influenced by winds. In Europe, it will be generally found that a fall of the barometer corresponds with a rise in the thermometer; this rule also prevails for the tropics: nevertheless it is subject to many variations. The barometer may rise and fall without any corresponding change in the thermometer, or both may rise and fall together.

The application of the barometer as a weather glass is altogether collateral and secondary; nevertheless its indications in this respect are, for the most part, worthy of confidence: generally, the barometric column sinks the day before rain occurs, and rises during its prevalence. The barometric column is much agitated during the existence of a storm, owing to the conflict which then ensues between atmospheric currents tending towards opposite directions.

Other Variations in the Barometer.—Besides the elevation of barometric mercury due to direct atmospheric pressure and to aërial currents, there exist other fluctuating causes, both diurnal and annual. The former is scarcely noticeable in temperate, but very conspicuous in the torrid zone. Every day the barometric column twice attains a maximum, and as often a minimum. The two periods of maximum elevation occur between 8½ and 10½ A.M. (say an average of 9h. 37m.); and between 9 and 11 P.M. (say an average of 10h. 11m.) The two periods of minimum elevation are between 3 and 5 A.M. (average 3¾); and between 3 and 5 P.M. (average 4h. 5m.) During winter and the rainy tropical season, the diurnal elevations of the barometer are least, and they assume their maximum in April. The variations are much less on elevated mountains than in the plains below.

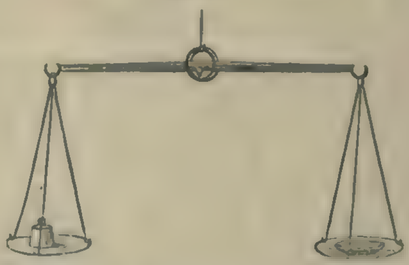
Mean Barometric Condition of a Place.—It was formerly assumed that everywhere, at the level of the sea, the barometric condition for the same time was identical. This opinion is fallacious, latitude having a well-determined influence in this respect. It is least of all at the equator, whence it increases north and south, attaining its maximum about 30° or 43° of latitude: it then decreases to between 60° and 70°. Within the polar circle it would appear to reascend; but further experiments for this locality are a *desideratum*.

Longitude also appears to exert some influence over the elevation of the barometric current. It is greater in the Atlantic than in the Pacific, by a small but readily perceptible quantity.

Causes of Periodical Barometric Variations.—Various opinions have been advanced to account for these periodical barometric variations. To say that they are attributable to difference of temperature, is to advance a cause too remote from the result. Many philosophers have attributed these variations to the existence of veritable atmospheric tides; but the most plausible explanation of diurnal barometric variations would seem to be that of Dove, who assumes them to depend upon the varying amount of aqueous vapour. Aqueous vapour and atmospheric air are possessed of different specific gravities; and the barometric height of a column of mercury for any time, will be the sum of pressure of dry atmospheric air and associated moisture; as the relative amount of the two varies, so will vary the height of the barometric column.

ATMOSPHERIC MOISTURE AND ITS DERIVATIVES.—When treating, at page 1129, of the means to be employed for weighing a gas, the facility wherewith gaseous bodies absorb moisture, was adverted to. Some idea then may be gained of the amount of moisture present in the atmosphere, seeing that the latter is ever in contact with large expanses of water. The atmosphere, in point of fact, is never dry, or in any way near dryness. Even when the air seems parching hot, drying the skin and withering vegetables, it is easy to demonstrate, by the aid of chemical agents, the existence of aqueous moisture; without the presence of which, neither the functions of animal or of vegetable life could be maintained. Even when the air approaches the condition of dryness, within very remote limits, breathing is difficult, and symptoms of feverish restlessness speedily set in. The natural craving of the lungs for moisture is demonstrated by the presence of a close stove in a small room. The sensations, which are very unpleasant, can always be alleviated by placing a small dish of water on the stove, so that evaporation may go on continuously. It is of the utmost importance, then, to be enabled, not only to demonstrate the existence of atmospheric moisture, but to determine its quantity. A few experiments for effecting this demonstration we shall now detail.

Fig. 39.



Experiment 1.—The accompanying diagram (Fig. 39) represents a balance, or pair of scales, into one pair of which there has been placed a small dish of oil of vitriol, and into the other a counterpoise. If the apparatus be exposed to the air, even when the earth is hottest and dryest, nevertheless, the equilibrium of the pair of scales will soon be destroyed. Some ponderable increase will have been acquired by the pan containing the oil of vitriol; and analogy demonstrates the increase in question to be due to the absorption of water. Founded on this property, oil of vitriol is frequently employed by the chemist for desiccating substances which could not be heated without damage. Accordingly, if a pan of oil of vitriol and a moistened sheet of paper be enclosed together, under an inverted glass, the paper will in course of time become dry. Far more rapid and powerful is the operation of the oil of vitriol when, instead of being placed together with the substance to be dried, and in a mere bell-glass, the two are placed under the receiver of an air-pump, and the air exhausted. Under these circumstances, an atmosphere of aqueous vapour soon fills the air-pump receiver, and the absorptive operation of the oil of vitriol being continuous, the water is speedily evaporated.

Experiment 2.—Instead of oil of vitriol, carbonate of soda, or chloride of calcium, and, in an inferior degree, impure common salt (chloride of sodium) may be used; for these bodies are all hygrometric—that is to say, they have the property of absorbing water from the air. Of the three bodies mentioned, chloride of calcium is the most hygrometric, and is of constant application by the chemist. Founded on the hygrometric quality of common salt, and other saline materials contained in sea-water, is the property which certain sea-weeds have of becoming moist in damp weather, and of indicating, by their dry crispness, an opposite atmospheric condition.

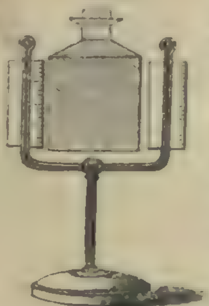
Although aqueous vapour is always present in the atmosphere, it is not always visible. Frequently it is quite transparent, and only demonstrable by the process of extracting it by such means as we have described; but at other times it aggregates, becoming vesicular, and forming clouds, fog, dew, rain, snow, hail, or sleet.

DEW.—Although the philosophy of dew is now perfectly well understood, no atmospheric phenomenon, before the happy researches of Dr. Wells, was more imperfectly explained and involved in greater mystery. The formation of dew is immediately referable to the function of radiation, concerning which it will be proper to make a short explanation, in addition to that which has been already stated.

The general indication only has been made that a heated body—for example, a cannon-ball—if suspended in space, darts off heat cognisable under the condition of rays. It remains now to be stated that the function of radiation is determined as to its extent by the surface of bodies: rough metallic surfaces radiate more than those which are smooth; glass surfaces radiate more than metallic surfaces; plants radiate more than the earth; grass and leaves more than bushes and trees; loose gravelly land more than hard soil.

To demonstrate the effect of surface on radiation, many instructive experiments may be performed by means of the differential thermometer and a cubical canister of tin plate. If such a canister be taken, and one side of it scratched, another polished smooth, another painted white, and the fourth black—a mixture of lamp-black and size being used by preference for the latter purpose: if the canister be now filled with hot water, and held between the two bulbs of a differential thermometer, as represented in the accompanying diagram (Fig. 40), each side of the canister will represent and indicate a different amount of radiating influence, as shown by the complementary disturbance of the two mercurial columns. It will be found that the polished side has the minimum, and the blackened side the maximum, radiating effect. It will soon be perceived that these deductions concerning the property of radiation are intimately connected with the philosophy of dew.*

Fig. 40.



Until the experiments of Dr. Wells, which will be soon adverted to, the most erroneous notions prevailed concerning the theory of dew. According to some it fell from the sky; according to others it rose from the ground; both which theories are altogether untenable.

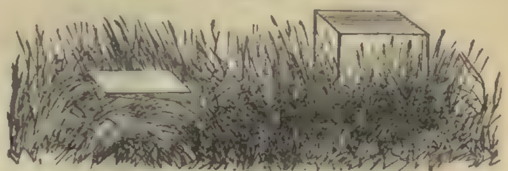
It is a sufficient answer to the proposition that dew falls from the sky, to say that dew never occurs when nights are cloudy; and it is a sufficient answer to the statement that it rises from the ground, to remark, that a slight screen thrown on the ground, or elevated above the ground, is incompatible with the formation of dew.

The theory of dew is easily explained by a consideration of the laws of radiant heat. The starting-point of the investigation is the atmosphere. Now the atmosphere always contains moisture, as we have already explained; and the amount of this moisture will, *cæteris paribus*, be correlative with the degree of atmospheric heat at the time. If, then, the atmosphere being raised to its fullest point of saturation for any given degree of temperature, that temperature should by any chance fall, the result will necessarily be a deposition of moisture. Let us now apply these principles to the conditions of a heat-radiating surface of the earth and a clouded sky. In this case no dew occurs, nor, according to theory, should any occur, inasmuch as the clouds perform the functions of a second radiating surface. The earth radiates heat owing to the clouds; but the clouds, in their turn, radiate heat back again to the earth; whence it follows that the earth practically does not lose heat, and its temperature not falling below the temperature of the circumambient atmosphere, no atmospheric moisture can be deposited; in other words, no dew can occur.

For these facts we are indebted to the late Dr. Wells. They are demonstrated by thousands of natural conditions, and bear the test of any properly-devised experiment.

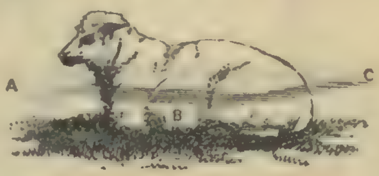
The following diagram (Fig. 41) is intended to show the manner in which a screen will prevent the occurrence of dew. Two plates of glass are represented as supported over an expanse of grass. Underneath the glass plate not the slightest dew will be found, though the grass around will be dewed heavily.

Fig. 41.



A very pretty illustration of the conditions which regulate the formation of dew, will frequently be supplied by a sheep lying down on the grass, on a clear, tranquil, cloudless night, when, to use a popular but incorrect expression, dew is falling; it will be found that the upper part or aspect of the wool of a sheep, is completely drenched with dew, although the under part or aspect of the animal is dry, as represented in the accompanying diagram (Fig. 42).

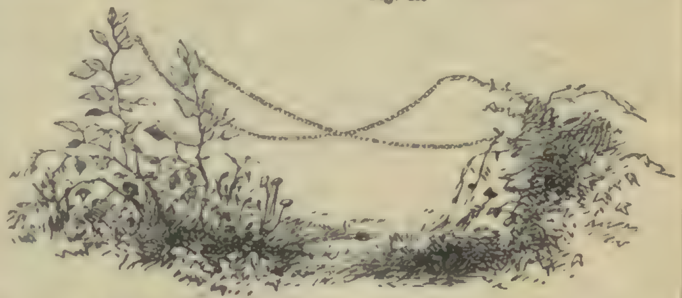
Fig. 42.



The explanation of this phenomenon will be so obvious that no further remark concerning it is necessary.

Consideration of the laws of radiant heat will render manifest the reason wherefore some surfaces are more bedewed than others. The amount of dew will depend, *cæteris paribus*, on two circumstances—firstly, on the kind of surface; and secondly, on its angle of inclination. Reference has already been made to the comparative facility wherewith certain bodies found in nature, favour the deposition of dew upon them; and the most casual observer cannot fail to be struck with the difference. In all cases, the bodies which radiate heat are the most favourable to the deposition of dew upon them. Few, if any, objects, naturally occurring, are so solicitous of dew as spiders' webs; and no object presents the phenomena of dew under a guise so beautiful. Not unfrequently, a thin filament of cobweb, so small that it would be invisible to the naked eye, presents itself to the vision on a dewy morning as if it were strung with little pearls (Figs. 43, 44).

Fig. 43.



That angular inclination of a body should influence, and be intimately connected with, the function of dew formation, directly follows from a consideration of the laws of radiant matter; and it may be readily illustrated by a diagram. Let us suppose that a screen of glass be supported over the radiating surface of the earth—in one case horizontally, in the other case at an angular inclination—as represented by the accompanying diagrams (Figs. 45, 46).

---

* The student may refer to the article "Radiation," in the Section on *Heat*, in this volume.—Ed.

Fig. 44.

Fig. 45.

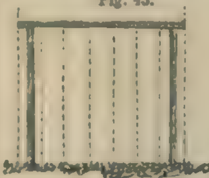


Fig. 46.

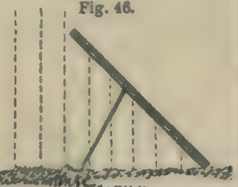


It will be evident that the horizontal glass in Fig. 45 will radiate more heat than the diagonal glass in Fig. 46.

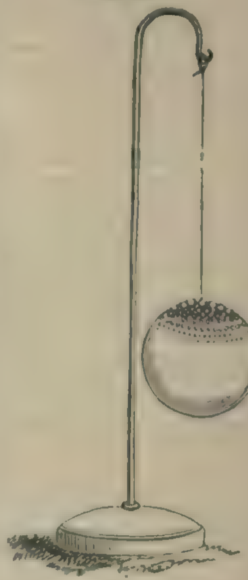
Determination of the Amount of Dew.—Although the laws which regulate the formation of dew are perfectly well known, and a rough method of determining the amount of dew deposition not difficult, yet no correct means of estimating its actual amount has yet been devised. Instruments for determining the amount of dew are called drosometers. A drosometer is a balance, suspended to one arm of which is a plate, to the other a pan containing weights, exactly proportionate to the weight of the plate, so that both may be in equilibrio. Supposing dew to be deposited on the plate, the latter will evidently increase in weight by the amount of such deposition, and a deviation of the beam from the horizontal will ensue. The principle of the instrument is unimpeachable, but in practice it is imperfect. Instead of the plate as described, recourse may be had to a lock of wool or eider-down, or one of a large choice of hygrometric materials. Bodies of this kind were employed by Wells. Wilson and Flangergue had recourse to a plate; but it seems that the materials employed by Dr. Wells should have the preference.

A very instructive experiment relating to a dew formation, and one which may be regarded as presenting a summary of the whole matter, is as follows:—

If, on a clear, cloudless night, when dew is being deposited, a glass ball (Fig. 47) be suspended in the open air, some height from the ground, dew-drops will form on the ball; not, however, equally on all portions of its surface. Its upper aspect will be bedewed, then its sides; but only rarely, and in extreme cases, the inferior aspect of the glass globe becomes covered with dew-drops; and when they do occur, they are very small; indeed, a complete gradation of size is manifest, the dew-drops decreasing in size as the upper aspect of the globe is departed from.

Generalisations.—The following generalisations relating to the phenomena of dew may now be appended; they will, for the most part, be seen to be directly deducible from a consideration of the laws of radiant heat:—Clouds and brisk winds are both inimical to the formation of dew; the former, because of their own radiating power; the latter, because of the removal of cool air, its place being supplied by air already warmed. If the night be cloudy, and the wind still, very little dew results. If clouds and wind occur together, dew is totally absent. Screen-like objects, interposed between the sky and the radiating surface, produce an effect identical with clouds; hence bodies freely exposed to the atmosphere, *cæteris paribus*, are most freely bedewed. Morning and evening are not the times, as commonly supposed, when dew is formed most copiously. It is deposited at all hours of the night, but most copiously rather after midnight. It sometimes occurs even before night, late in the afternoon. Dew is not deposited with equal readiness in all parts of the world, but attains its maximum in warm lands near the margin of the sea, rivers, or lakes; as, for example, near the Red Sea, the Persian Gulf, the coast of Coromandel, at Alexandria, and in Chili. It is quite absent in very arid regions, in the interior of continents; such, for example, as central Brazil, the Sahara, and Nubia; neither does it frequently occur at sea, because of the bad radiating quality of a surface of water.

Fig. 47.



The imperfect radiation of a surface of water is well illustrated by the following striking experiment:—Glass is a good radiating surface; whence a piece of glass freely exposed in an atmosphere when dew is forming, soon becomes covered with dew. If, however, the glass have its surface wetted previously to exposure, instead of becoming more wet it becomes dry, simply because radiation is impeded, and evaporation takes place unchecked. *Cæteris paribus*, the amount of dew produced, will be proportionate to the amount of aqueous vapour present in the atmosphere; and this readily explains the fact, that a copious production of dew is frequently the precursor of rain.

Honey-Dew.—Occasionally a sweet, damp, sticky moisture attaches itself to leaves during the night, and does not disappear throughout the day. The term honey-dew has commonly been applied to it, though, in point of fact, it is not dew at all, being merely an excretion from certain insects termed *aphides*.

Hoar-Frost.—Hoar-frost differs only from dew in the circumstance of temperature. One is deposited, and remains uncongealed; the other, becoming consolidated by the agency of freezing cold, is converted into ice. Every meteorological observer knows that the existence of hoar-frost is held to be indicative of coming rain, and in most instances the opinion is verified. The phenomena of hoar-frost are even more beautiful than the corresponding ones of unfrozen dew. Upon leaves and vegetable stems, the deposition of hoar-frost is particularly beautiful. If hoar-frost be examined microscopically, or sometimes even attentively by the naked eye, a crystalline structure will be evident. The crystals belong to the same crystallographic system (the rhombohedric) as those of snow, but their general appearance is somewhat different.

FOGS.—Fogs may be regarded as clouds, which form close to the earth's surface; hence we might discuss their peculiarities under the general head of Clouds. They are characterised by some peculiarities, chiefly dependent, however, upon the vesicular aqueous vapour of which they are composed, embracing and retaining volatile particles evolved naturally, or from the operations of man. In this way it is well known that London fog is anything but pure aqueous matter. One of its very important constituents is the condensible part of smoke. As regards the production of fog, it is usually referable to one of two circumstances: either non-visible aqueous vapour may be converted into the visible or vesicular form, by decrease of atmospheric temperature immediately, or by the cooling agency of the earth's surface, depressing the temperature of the layer of air next to it, below the dew point. In this country, and in Europe generally, fogs are of most frequent occurrence in spring and autumn. There are regions, however, in which fogs prevail throughout the year. The coasts of California are almost constantly veiled in fog; and the same remark applies, in a minor degree, to the western coast of the American continent, even so far south as Peru. Newfoundland, Nova Scotia, and Hudson's Bay, are all subject to frequent and dense fogs, attributable, in these localities, to the condensation of vapour, which arises from the hot gulf-stream, by contact with neighbouring and colder air. Fogs do not occur so frequently on level plains as in mountainous regions. In Arabia and the arid table-land of Persia they are almost altogether wanting. London and Amsterdam have acquired a somewhat evil character for fogs; but this meteoric condition applies to many other European localities with an almost equal amount of propriety. At Antwerp, fogs are very prevalent; and the navigation of the lower and middle Rhine is sometimes impeded for weeks together by the occurrence of this pest of the sailor. Neither can Paris boast of much immunity from fogs; they are somewhat less dense and less frequent than our own London fogs, it is true, but are, nevertheless, far from contemptible. Amongst the regions which are likely in future to be celebrated for the prevalence of fogs, the Black Sea may be enumerated. Until recent events, that locality was comparatively unknown to us; but during the time of the Crimean war, which necessitated a constant navigation of the Black Sea, the embarrassment of fogs became but too apparent.

Dry Fogs.—Under this name has been described a dull opaque appearance which the atmosphere of certain regions occasionally assumes, deadening the fiery beams of the sun, and dulling that luminary so that he may be looked at without pain by the naked eye, and embarrassing respiration.

The dry fog is most common in certain parts of North America, during the period known as the *Indian Summer.* It also occurs in Germany, and more rarely in England. There can be no doubt that many atmospheric opacities, different in character as well as in cause, have been summarily classed under the denomination of *dry fog.* When the phenomenon occurs locally, it can generally be traced to such causes as the burning of extensive districts of turf or of forests. When its prevalence is more general, the most rational explanation would seem to be that which attributes it to volcanic eruptions. Some meteorologists have invoked electricity as the cause of this phenomenon; but it is not easy to see in what way the assumed cause could produce the effect in question. Electricity has long been to meteorologists what the class *radiata* was to Cuvier; namely, the receptacle for things unknown or unexplained.*

Clouds.—Clouds are perhaps the most beautiful of all aërial phenomena. All the charms of changeful variety of colour, of form, and of motion are theirs; nor is their utility inferior to their beauty. Without clouds there would be neither rain, nor snow, nor hail; the consequences of this deprivation may be anticipated, or they may be readily learned, by turning to the geography of countries where rain, and snow, and hail are unknown. All regions thus circumstanced, provided irrigation be impossible, and the altogether exceptional condition of copious dews be absent, are, despite the most favourable conditions of climate and of soil, barren wastes.

Notwithstanding the thousandfold varieties of clouds—their Protean shapes, their manifold colours, and other distinctions—when the observer comes to regard them with a scrutinising eye, he will not fail to recognise broad distinctions between them, admitting of being made the basis of a philosophic classification. Thus, some clouds are devoid of outline, their edges merging away into circumambient air; some are black and massive, almost conveying the idea of a hard substance; some are white and fleecy; others extended like a pennon. All these are forms of cloud which present manifest distinctions amongst themselves. Mr. Howard was the first who effected a regular classification of clouds. This classification is now generally adopted. We shall, therefore, present the reader with an outline of his system. According to this meteorologist, there are three elementary and four secondary forms of cloud.

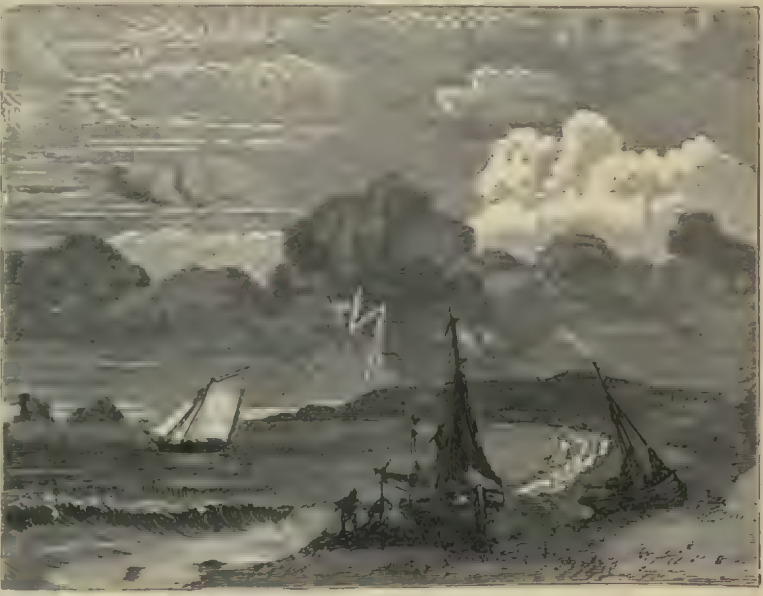
Primary Forms.—The first primary form is the *cirrus*, consisting of feathery expansions, and which is only seen in clear weather.

The second primary form of cloud is the *cumulus*, composed of large hemispheroidal masses, superiorly, and apparently resting below on a horizontal base. This form of cloud chiefly occurs in summer.

The third primary form of cloud is *stratus*, composed of horizontal layers, the smaller layers being underneath. It is this form of cloud, more than any other, which presents itself under a variety of beautiful colours. It chiefly appears at sunset.

Secondary Forms.—The secondary forms of clouds are —(1) *Cirro cumulus.* It is a mixture, as its name indicates, of cirrus with cumulus, and is made of an aggregation of small white clouds, which have been compared to a flock of sheep. (2) *Cirro stratus.* A compound cloud, which is formed of the two primary clouds embodied in its name. (3) *Cumulostratus.* This compound cloud chiefly appears towards night, in dry windy weather, and is of a leaden colour. (4) *Nimbus*, or *rain cloud.* This cloud is seen in greatest perfection during a thunder-storm. All the varieties of clouds described are represented in the above diagram (Fig. 48).

Fig. 48.



It will be readily anticipated that clouds are frequently so mingled and confounded, that they are not always susceptible of the precise classification just announced; nevertheless, a prevalence of one type of cloud over another will be generally seen to prevail.

---

* Some have broached the curious theory that such fogs are caused by the immersion of the earth in the tail of a comet.—Ed.

Relation between Clouds and the Weather.—People who are in the habit of narrowly studying the phenomena of clouds, are enabled to draw conclusions of much accuracy respecting the coming weather. Thus cirro cumuli are for the most part indicative of serene, fair weather; the prevalence of wind subsequently to the appearance of much-extended and highly-coloured stratus clouds is a matter of popular experience. The appearance of nimbus clouds proclaims the advent of rain; and the cirro stratus, which sometimes colours the sky as with a veil, all well-defined form being absent, is almost a sure forerunner of bad weather.

Composition of Clouds.—That clouds are composed of water in some condition does not require to be demonstrated; but some explanation must be given of the circumstances enabling water, a material so much heavier than atmospheric air, to remain suspended frequently in very elevated regions, where the atmosphere, thin though it be on the earth's surface, is still more attenuated. This is a matter which, it must be confessed, is still veiled in considerable obscurity; but, perhaps, the most rational explanation of cloud formation is the following:—Firstly, aqueous vapour is diffused, or rather absorbed, invisibly throughout the air. The laws of the absorption or diffusion are perfectly well known. The amount differs, as we have already seen, for different temperatures, being proportionate to the temperature. Assuming, then, that the upper regions of the atmosphere at any time are saturated with atmospheric moisture in its invisible condition, let us now contemplate the effect of cooling that atmosphere by any cause. It is not difficult to furnish reasons for these cooling agencies; they are numerous and varied—such as sudden variations of electric condition, sudden variations in the direction of winds. If, then, from any cause, the atmosphere is cooled below its capacity for holding vapour in the invisible form, aqueous deposition occurs. If this deposition take place on the earth's surface, the result is dew; if aloft in the air, we have a cloud.

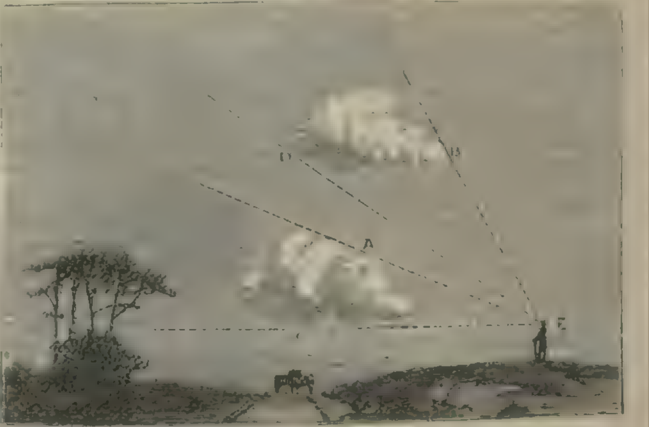
Thus far the steps of each succeeding change are evident; but the remaining points of cloud-formation are more obscure, the circumstances of chief difficulty being to find an explanation of the aërial permanence of clouds, seeing that the material of which they are composed is so much heavier than air. Probably the most consistent explanation is this:—Atmospheric moisture, when it changes from the invisible to the visible form, assumes the physical condition of spheroids or vesicles—minute bubbles of water, in point of fact, each bubble filled with air. If these vesicles be exposed to the sun's rays, it is evident, from consideration of known laws, that they must become specifically lighter than the surrounding medium; and thus affected, they would float, for the same reason that a soap-bubble floats whilst it is yet warm, notwithstanding that the air, which it contains, is heavier than the surrounding atmosphere. We seem, therefore, in a position enabling us to account for the upper part of cloud strata. Directing our attention now to the lower part of these strata, it seems rational to assume that the vesicles of which they are composed should descend. Probably they do so; continuing their descent until they come in contact with an atmosphere sufficiently warm to dissolve their aqueous coating, and convert their water once more into the vaporous or invisible form. Thus it may be, and most probably is, that a cloud, which looks permanent to the eye, is really exposed to the continued operation of resolution and reformation: or, rather, that the two opposing causes, which are here spoken of as producing active changes, balance themselves, and give rise to a condition of equipoise.

Although it has hitherto been taken for granted that clouds are formed of unfrozen water, we know that such is not invariably the case. If the temperature of a nimbus cloud sink to freezing point, or 32° F., its contents freeze, and snow is the result. Many philosophers, indeed, but more especially Kaemtz, are of opinion that the cirrus—the cloud which soars in the highest regions, frequently at an elevation not less than 30,000 feet above the earth's surface—consists of particles of snow or ice. Assuming this to be the case, it is not easy to advance the reason of such molecules remaining aloft in a medium so attenuated as is atmospheric air in a position so elevated.

Position of Clouds.—It is somewhat remarkable that every known form of cloud assumes more or less the horizontal position. Vertical clouds are very rare, and, if we choose to except water-spouts, not recognising them as clouds, perhaps we may say unknown. The horizontality of clouds, warrants their being spoken of as composed of strata; generally, indeed, these strata are very well defined. MM. Paytier and Hoffard have carefully examined the thickness of these cloud-strata on the Pyrenees, and have found their average variation to be between the limits of 3,400 and 1,000 feet. Mr. Glaisher, during his balloon ascents in 1862-'63, passed through clouds of about 8,000 feet thickness. In the fifth chapter of this section, the reader will find the observations of that meteorologist fully detailed.

Height of Clouds.—Several meteorologists, amongst whom Riccioli, Wrede, Kaemtz, and Arago must be particularly mentioned, have set themselves to the task of discovering the height of clouds. The methods by which these investigations were made have been various. Riccioli determined their height by placing two observers a certain and known distance apart; Wrede by making use of their shadows, and then reducing the computation of height to the solution of a problem in trigonometry. Riccioli stated the maximum height of clouds to be 25 000 feet; and Lambert gave their minimum height at 13,000: whilst their maximum height, according to the same, is from 15,000 to 20,000 feet. Gay Lussac, when he acquired in his balloon an elevation of 21,600 feet, perceived small clouds floating much above him. Kaemtz believed that the usual range of cumulus runs from 3.000 to 10,000 feet; of cirrus, from 10,000 to 24,000 feet; of nimbus, or thunder-cloud, between 1,500 and 5,000 feet. That very accurate physicist, Pouillet, as the result of certain experiments performed in 1840, states that he has proved the existence of clouds at an elevation from about 22,300 to 38,000 feet: and Mr. Glaisher, in 1862-'63 observed them at those heights.

Fig. 49.

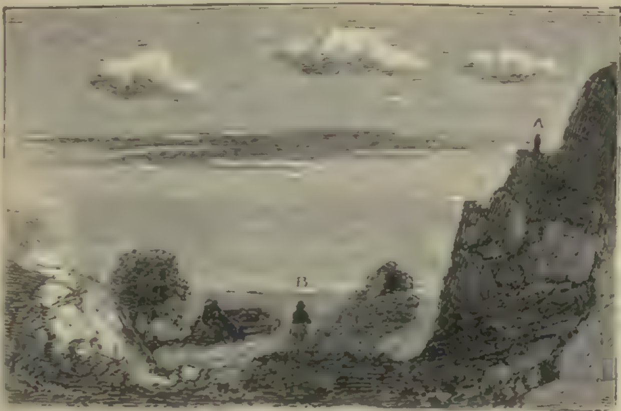


As regards the elevation of clouds, we may arrive at the conclusion, that cirrus does not descend below 2,000 or 3 000 feet; whilst nimbus occasionally descends so low that it approaches the earth within a few hundred feet of surface. The maximum mean elevation of clouds seems to be in low latitudes, evidently on account of the greater capacity of the atmosphere to absorb and dissolve aqueous vapour. It should here be remarked that the elevation of a cloud cannot be determined by reference to its apparent place in the sky; and, except the distance be known, neither can its actual size. These remarks are illustrated by the above diagram (Fig. 49), where the same cloud will be seen, at different times, under very different angles by the same observer, as reference to the angles A E C and B E D will testify, whence the height would differ for two different statures.

And again, as in Fig. 50, it is demonstrated that the observer at A will see clouds which are quite invisible to another observer at B.

RAIN.—When, from any cause, cloud-vesicles aggregate into drops, and these drops fall, the result is rain. Some years ago, Mr. Green, the aeronaut, stated that rain only fell when the cloud producing it was covered by another floating directly over it. This seems to be confirmed by Mr. Glaisher, during his balloon ascents of 1862–'63. Still, the phenomenon of rain without clouds is well attested.

Fig. 50.



The amount of rain which falls is measured by a pluviameter, or rain-gauge. The principles on which this instrument is founded are of the simplest kind. If, for example, a cup or basin, of known cubic capacity and known orifice, be exposed so that it may receive the fallen drops of rain, the cup or basin would be a rough rain-gauge. Were it not that the collected water thus exposed would be continually evaporating, thus apparently diminishing the total fall of rain, no better rain-gauge need be desired; but in practice it is necessary to provide against such evaporation; and it is usually accomplished by forming an instrument of such construction, that one part may be destined to collect the fallen rain, and another part to diminish, within the smallest limits, the amount of evaporation. In expressing the amount of rain which falls at any particular spot, it is necessary to express the height also at which the observation is made. The annual fall of rain increases as land acquires elevation; nevertheless, at one and the same place, the amount of rain decreases with elevation, for the reason that each drop of rain throughout its descent goes on collecting moisture, and becomes larger. Dalton appears to have been the first to notice this fact. He proved, on comparing two sets of observations—one set made at the base, the other at the summit, of a high tower—that the amount of rain at the top to that at the bottom was as two to three. Similar observations made at the Paris Observatory have led to similar results. This variation between the amount of rain at different elevations in one locality, is the more considerable as the point of aërial saturation is more nearly attained; for which reason, it is less in summer than in winter. The heaviest rains usually occur in the tropics, and during the hot season. There the fall of rain is enormous, sometimes amounting to an inch per hour; nay, Humboldt has related, that in South America, no less than five inches of rain fell in one hour. In these islands, we can hardly say that any one season merits the designation of the rainy season; but in tropical regions, except the belt of calms, and in the sub-tropical regions, the separation between the dry and rainy seasons is well marked. In the continental portions of the torrid zone, the rainy season sets in when the summer heat attains its maximum, and continues during four or five months, the atmosphere being clear and bright throughout the remaining portion of the year. Near the equator there are two wet seasons, sometimes separated from each other by a totally rainless period; but at other times demarcated only by periods of maximum and minimum fall of rain. Dutch Guiana furnishes the well-known illustration of a country having two well-marked rainy seasons; one, and that the chief, commences in April, and lasts till June; the other, or minor rainy season, commencing in the middle of December, lasts till the middle of February. The drops of tropical rain attain a magnitude never seen in the tamer showers of these northern regions; their weight is so considerable, and the force with which they descend so great, that their splash or stroke leaves a smarting sensation on the skin. The region situated between the influence of the two trade winds, and commonly known as the region of calms, is devoid of periodic rains, although the fall of rain there is frequent and heavy.

Rainless Portions of the Earth.—There are some localities in which rain never occurs: for example, Egypt, the Desert of Sahara, the table-lands of Persia and Mongolia, the rocky flat of Arabia Petræa, &c. Rain is generally the most abundant near mountain ranges; but there are exceptions, one of the most remarkable of which is presented by the part of Spain south of the Sierra Nevada.

Condition of Europe with regard to Rain.—Europe, considered in relation to the prevalence of rain, admits of being divided into three districts—the South European, the Middle European, and the Swedish. In Portugal, and the larger portion of southern and central Spain, there is an almost total absence of rain during summer; but north of the Pyrenees, rain occurs at variable times throughout the whole year. All the portions of Europe, north of the Alps and Pyrenees, are subject to the Middle European and the Swedish pluvial conditions. The characteristic of the Middle European climate, as regards rain, is, that the latter chiefly occurs during westerly winds; whereas the Swedish climate is characterised by the prevalence of rain during both easterly winds and westerly winds, which bring rain to the whole of Central Europe, and deluge our isles with wet, leaving the bulk of their moisture by the mountainous Scandinavian range, which separates Norway from Sweden. St. Petersburg and Moscow cannot be said to belong either to the Central or Northern European climate; these places lie on the confines of both; hence neither westerly nor easterly winds are there prevalent. In England, the maximum number of rainy days throughout the year occurs in Cornwall and Devonshire; passing thence east into Central Europe, the total number of rainy days per annum continually declines. If we assume the annual amount of rain which falls at St. Petersburg to be nearly three, the corresponding annual amount for the West of England will be 2·1;[*] in Central England, 1·4; in Central Germany, 1·2. This statement assumes an average of some special localities to have been taken into consideration: special places present many deviations. In describing any place as subject to rain, or *rainy*, distinction must be made between the actual quantity of rain per annum which falls, and the total average number of rainy days. Understanding by the latter term every day on which rain, much or little, falls, the number of rainy days increases in Europe from south to north. The mean average for Southern Europe may be taken as 120, in Central Europe as 146, and in Northern Europe as 180. The following statement indicates the total number of rainy days per annum for a few places specifically named:—

Buda	112	Ratisbon	115
Warsaw	138	Rotterdam	137
Germany, average of	150	Paris	160
Carlsruhe	174	Poictiers	99
Tagernsee	170	St. Petersburg . .	168
Munich	149	Moscow	205
Stuttgardt	127		

Annual Distribution of Rain.—The time of year at which rain is most prevalent, is subject to much variation for different countries. Throughout Central Europe rains are most prevalent in summer; but in Southern Europe the preponderance is on the side of winter rains. Norway is subject to copious winter rains; whilst in Sweden they are almost entirely wanting. Sweden, in point of fact, although placed so near the sea, has a climate altogether like that prevalent in continental regions The reason why Norway is subject to winter rains, and Sweden is deprived of the same, hinges upon the explanation already made, that western winds (which predominate in Scandinavia during winter) lose their moisture in passing over the Scandinavian range. Although summer rains are in many places rare, yet when they occur they are generally more copious than rains at any other period.

---

[*] The position of our Western Coasts, in reference to the Gulf Stream, which washes them, must be borne in mind.—ED.

Rain which falls in summer at different places, taking the rain which falls on a winter's day at the corresponding place as unity—is in,

England	1·07
Western France	1·03
Central France	1·57
Germany	1·76
St. Petersburg	2·17

From which statement it appears that the prevalence of summer rain increases towards the east.

Peculiarities of Rain-Water.—Fresh-falling rain-water, collected far from towns or other sources of local contamination, is very nearly pure; nevertheless, modern chemical observation has succeeded in discovering the presence of many substances, in small quantities. Nitric acid and nitrate of ammonia are by no means unusual constituents; and iodine has been frequently recognised. As regards the sources of these and other extraneous bodies, much still remains to be discovered. Nitric acid is most probably formed in the atmosphere by the agency of electricity; and the ammonia may be referable to exhalations from decomposing matters on the earth's surface. Many of the extraneous bodies, especially salts, are unquestionably due to the action of winds upon finely-divided ocean-spray.

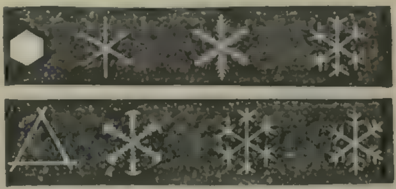
Showers of Fishes, Stones, &c.—Instances are on record of whole shoals of fishes, and numerous collections of other animals—also stones, &c.—being cast on the earth by showers. At one time these phenomena were regarded mysteriously, and referred to occult causes. At present they are deprived of their mystery, and referred to the previous elevation of the fishes, &c., by aërial currents, whirlwinds, and water-spouts.

SNOW.—If the temperature of a cloud should fall at any time to 32° F., or lower, instead of rain the result is snow. Much that is beautiful and beneficent is seen in this divided form of frozen water. In our own temperate clime we do not comprehend, except by reflection, the true value of snow in the economy of nature. Its fall amongst us is uncertain and exceptional; we know not when it is to come, or how long it is to remain. We therefore make no provision for it—regard it as a condition to be tolerated—regret that it interferes with our locomotion—that it impedes our railway trains, and wets our feet, and wish it away. Nevertheless, even in these isles, the farmer, from experience, is not insensible to the value of snow. He says it keeps his winter crops *warm*; and the thoughtless passer-by, wrapped in his own self-conceit, laughs at him for making a statement so apparently grotesque. The philosopher, however, who is aware of the low heat-conducting power of snow, and who can appreciate the evil consequences of frost on vegetation, endorses the farmer's statement.

If we would desire to recognise the full benefits of snow, we must direct our attention to northern climes—to Sweden, Russia, and Canada. There, the advent of snow is looked forward to as a blessing; and when it comes, the period of its duration admits of being predicted with tolerable accuracy. No sooner is the ground covered with sufficient snow, than wheeled carriages, which but yesterday were sticking up to the axletree in mud and wet, are put aside, and sledges supplied in their stead. Market-places, which, before the snow had fallen, were naked and unworthy, now teem with good things brought from hundreds of miles away. Snow has, all at once, laid down a far-stretching track, over which the sledges glide almost with the ease and velocity of a railway train.

Form of Snow-Flakes.—In certain conditions of temperature snow falls as a pulverulent body; in other conditions as a flaky amorphous mass; but if very dry snow be microscopically examined before it has been broken up, indications of crystalline structure will be recognisable. Sometimes these crystalline snow-flakes attain such large dimensions, that they are quite evident to the naked eye. The crystalline forms thus developed are numerous, but they are all referable to one crystalline system, the *rhombohedric* or *rhombohedral*; the characteristic of which is, that crystals belonging to it have three axes crossing each other at the angle of sixty degrees, and one axis at right angles to these. Scoresby, who has minutely examined these snow-flakes describes five principal forms of snow-crystals:—1st, crystals having the form of thin plates, which are the most abundant; 2nd, surfaces or spherical nuclei, with ramifying branches in different planes; 3rd, fine points, or six-sided prisms; 4th, six-sided pyramids. The latter form is the least frequent of all. The above diagram (Fig. 51) represents the principal crystalline varieties of snow-flakes.

Fig. 51.



The Snow-Line.—Inasmuch as the upper regions of the atmosphere are intensely cold, there is an elevation for every latitude at which atmospheric moisture is changed into snow. This elevation corresponds with what is termed the *snow-line*. At the equator, the snow-line is elevated from 12,000 to 15,000 feet above the sea-level. As we proceed towards the north, the elevation of the snow-line will evidently be lower. Snow does not fall on level ground in Europe, farther south than Central Italy; but in Asia and America the region extends nearer to the equator. Through Florence, passes the isothermal line of 59° F., and it may be regarded as the southern limit of the region, in which snow falls on level places. Snow does not usually fall at the time of maximum cold; some meteorologists say it never does—but this is an error. After snow has fallen, the weather generally increases in severity. We are usually in the habit of assuming that the total quantity of snow which falls, increases as we reach either pole—an assumption, however, which is only correct within certain limits. Thus, taking the northern hemisphere, for instance, the fall of snow increases from the isothermal of 59° F., to the isothermal of 41° F., which latter cuts the town of Drontheim, in Norway. Passing still further north, the quantity of snow goes on diminishing, evidently because, in the polar regions, the temperature of the air is too cold to retain much moisture, and atmospheric moisture must necessarily be the antecedent to either rain or snow.

The atmospheric condition during the fall of snow, may vary from the limits of almost complete tranquillity, to the other extreme of most violent perturbations. In Germany, and other countries having a corresponding latitude, the fall of snow is usually tranquil, except during the months of February and March. In high latitudes, snow usually occurs during violent tempest-gusts, almost equal, sometimes, to the West Indian hurricane, or the Chinese typhoon. In Norway, these storms are very frequent, also in Kamtschatka; in which latter region they are called *purga*. They are veritable thunder-storms, as is completely proved by the intense electrical condition of the atmosphere. On mountainous elevations, snow-storms are commonly prevalent, irrespective of latitude.

Coloured Snow.—Red and green snow have been frequently described by travellers. The cause of these phenomena is now referred to the presence of minute algæ—the *protococcus nivalis* in the so-called red snow, and the *protococcus viridis* in the green variety.

Hail.—Frequently, cloud vesicles become aggregated and frozen into lumps of various sizes and shapes, sometimes opaque, sometimes transparent, and occasionally, though not very often, containing neuclei of solid foreign matters. Meteorologically, aggregations of this kind constitute hail. In most parts of the world where rain occurs, hail is known; but certain localities are particularly subject to hail-storms. Generally hail falls by day; indeed an opinion prevails that hail-storms are unknown by night. This supposition is, however, erroneous. The form of hail-stones is various, though for the most part they assume a spherical, spheroidal, paraboloidal, or pyriform contour; and still more frequently they are rounded, flattened, or angular. According to Delcross, the most common form of hail is that of a three-sided spherical segment, resulting from the comminution of larger spheres.

The diameter of hail-stones at a mean latitude is, according to Muncke, not usually greater than one and a-half, or one and three-fourths of an inch, although, on some occasions, blocks of ice of enormous dimensions have fallen. For example, in 1719, there fell at Kremo, hail-stones weighing not less than six pounds; and at Namur, in 1717, others weighing not less than eight pounds. Again, it is stated that, in 1680, masses of ice fell in the Orkneys, twelve inches thick; and in 1795, hail-stones fell in New Holland, from six to eight inches long, and two fingers thick. It is recorded, but on doubtful testimony, that there fell in Hungary, on May 28th, 1802, a piece of ice three feet square by two feet thick, and the weight of which was 1,100 pounds. But even this is much exceeded by a statement that, in the latter part of the reign of Tippoo Saib, a lump of ice fell at Seringapatam as large as an elephant. The *size* of the elephant, however, is not mentioned.

With regard to foreign substances existing in hail-stones, they are described as various. In 1755, there fell, in Iceland, hail-stones containing sand and volcanic ashes; others which fell in Ireland, in 1821, contained a metallic nucleus, which proved, on analysis, to be iron pyrites (sulphide of iron); a similar phenomenon occurred in Siberia in the year 1824. The presence of small pieces of straw in hail has been frequently demonstrated.

The largest hail-stones fall in summer, during thunder-storms. Storms of this kind are most frequent in June and July; they are more rare in May, August, and September, and still more so in April and October. They usually occur at the close of long periods of calm, sultry weather. Hail-clouds are much lower in the sky than rain clouds; and are generally recognisable by a peculiar ragged or jagged contour, and by their lower portions being marked with white streaks, the other portions of the cloud being inky black. Previous to the occurrence of hail, the barometer sinks very low; and, what is unusual before rain, the thermometric column suffers a corresponding depression. The thermometer, during a hail-storm, has even been known to sink through 77° F. A peculiar rustling sound in the air is also indicative of speedy hail, accompanied by a darkness resembling that dependent on an eclipse of the sun. Hail-storms are very seldom of long duration, usually lasting a few moments only—seldom longer than a quarter of an hour. The rapidity with which hail-storms travel is very great: one which occurred in Central France, in 1788, travelled at the rate of forty miles an hour. The force of hail-stones is sometimes dangerously great, not only breaking windows and shattering tiles, but killing men and animals, cutting off branches of trees and herbage, and, in short, desolating all save the largest vegetable growths. The hail-storm in France of 1788, already adverted to, extended its devastations over 1,039 parishes, destroying property to the amount of 25,000,000 of francs. Although hail-storms often extend very far in a linear direction, their breadth is usually inconsiderable—often but a few hundred, or at most a few thousand feet; while the linear extension has been known to exceed four hundred miles.

It has been already mentioned, that wherever rain-clouds rest, hail may occur; nevertheless, latitude and local conditions determine the frequency of the phenomenon. Rain seldom occurs on the level land of tropical countries; and it is rare in the extreme north. The hail-belt, pre-eminently so considered, is comprehended between 30° and 60°, and to elevations less than 6,000 feet. Even within this belt, and below the limit of elevation just assigned, there are certain localities where the occurrence of hail is a very rare phenomenon. Certain of the Swiss valleys may be cited as a well-known illustration of this remark; more especially in the Valais and its allied dales. It has also been well determined that hail more rarely occurs at the base of mountains than in localities a short distance removed. Perhaps no country, upon the whole, is more subject than France to the ravages of hail-storms, and in no country are the effects more serious. It has been ascertained that the average annual number of hail-storms in France is about fifteen. They are especially prejudicial to the vine and the olive, sometimes laying whole districts under desolation. Having regard to the highly excited electrical condition of the atmosphere, as the rule, during the occurrence of hail-storms, great hopes were once entertained that they might be prevented, or their ravaging power diminished, by means of suspended conductors. The idea of using such conductors appears to have been first suggested by Guenaut de Montbeillard, in 1776; and hail-conductors have been extensively tried, but hitherto without any amount of practical benefit to justify their longer continuance. In 1820, a peculiar kind of hail-preventer was suggested by La Postolle, and subsequently by Thollard. The instruments consisted of straw ropes, in which a metallic wire was interwoven, and suspended by means of pointed rods similar to lightning-conductors; but, like instruments having a similar object, and which preceded them, they were found to be unavailing.

Methods of Determining the Amount of Atmospheric Moisture.—Having described the numerous forms under which aqueous moisture may exist in the atmosphere, it now remains to indicate and describe certain instruments which have been devised by different experimenters for determining its amount. These instruments, founded on different principles, as will be seen, are termed hygrometers.

It is a matter of common experience that many bodies are affected as regards their dimensions, more particularly their linear dimensions, by mutations of atmospheric moisture. Wood is a very common example of this property; more particularly a stick of wood cut transversely to the grain. Founded on this property of wood, the late Mr. Edgeworth constructed a very ingenious toy, which, though not a hygrometer, inasmuch as it does not measure the amount of atmosphere prevalent in the air, is at any rate a *hygroscope.* It is related, that the somewhat eccentric philosopher, just named, once laid a wager that a certain toy—a wooden horse—constructed by himself, should, after the lapse of some time, walk across his room. The horse was accordingly made, and placed at one end of a chamber; the door of the chamber was then locked, and the key deposited in safe keeping. In process of time the horse did indeed arrive at the other end of the room; and the manner in which this was accomplished will now be made evident.

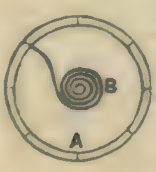
Underneath each hoof was a claw, long enough to stick into the flooring, and there take hold. The horse itself was made out of a piece of wood cut transversely to the grain; the consequence was, that when the weather was dry the linear dimensions of his back contracted, and when the weather was wet his back again elongated. Now, bearing in mind the construction of the feet of this toy-horse, it is evident that these alternate contractions and expansions must necessarily result in a forward motion.

Again, the condition of human hair illustrates the effect of varying amounts of moisture in the atmosphere. Every lady knows that she cannot retain her hair in curl during wet weather, so well as when the weather is dry, because of the moisture present, which causes the hair spirals to relax and unfold. In point of fact, each hair contracts and elongates alternately, by every mutation of dryness and moisture; so that if only the exact ratio of contraction and expansion could be determined and applied, the meteorologist might construct a hygrometer, having for its basis of actuation, a human hair. The hair-hygrometer of Saussure takes advantage of this principle.

To construct this hygrometer, a soft human hair is boiled for a short time in a solution of sulphate of soda; afterwards for a few minutes in pure water; it is then well washed to free it from all adhering salt, and dried in a shady place. Next, one extremity of the hair is fastened to the extremity of a little tongue, and the other end is wound round a small pulley having two grooves. The second groove is for the purpose of retaining a filament of silk, from which a weight is suspended for the purpose of retaining the hair in a constant state of tension. To the pulley is fastened an index, traversing a graduated arc, whenever the pulley turns in any direction by the contraction or elongation of the hair. The graduation of the instrument is thus effected:—It is placed in a receiver holding chloride of calcium or concentrated oil of vitriol; the air is exhausted from the receiver, and the place where the index then stands is marked. This mark corresponds with the point of greatest dryness, or 0 of the scale. We have next to determine the point of greatest saturation, which is thus effected:—The instrument is next placed in a receiver containing a dish of water; so that as the hair elongates the index turns, and finally coming to rest, the point at which it stands is marked. This mark corresponds to the maximum of moisture, which of course may be indicated by any number arbitrarily selected; this number being usually 100. Finally, it remains to divide the interval between the two extremes into 100 equal parts, and the instrument is complete. Notwithstanding all the care which may be devoted to the construction of this instrument, it is, after all, scarcely deserving the name of a hygrometer—it is little better than a hygroscope.

Occasionally, certain helical vegetable fibres have been used as hygrometers, in a way which the accompanying diagram will render manifest.

Fig. 52.



Let A (Fig. 52) represent a circular card or other flat disc, and B a vegetable filament helically coiled—it is evident that the helix will unravel in a damp, and tighten its coil in a dry, atmosphere. An instrument of this kind has been sometimes employed for the purpose of determining whether a bed be moist or dry. The instrument is a very good hygroscope; but, inasmuch as the coiling and uncoiling of the helix is most comparable with equal arcs, the instrument can hardly be termed a hygrometer.

We are under obligations to the ingenuity of the Dutch for another hygrometer, or rather *hygroscope*—for, like the instrument just described, it is not a true indicator of the *quantity* of moisture present in the atmosphere. The instrument is of this kind:—A piece of catgut is suspended from one extremity, and to the other, or lower extremity, is fixed, transversely, a little horizontal bar. On one extremity of the bar, a lady, in gay summer attire, is represented; on the other a man, dressed appropriately for a rainy day: finally, the catgut and its toy-appendages are surrounded with a case, having two openings, and in such a fashion that only one of the toy-images can be visible at a time. Now, it is evident that the fibres of the suspended catgut will partially untwist under the influence of moisture, and re-twist as the atmosphere becomes dry; whence it follows that the lady will appear under the latter circumstances, and the man under the former. This instrument, though something more than ingenious—for it is a good *hygroscope*—does not merit the dignified term of *hygrometer*.

The Dew-point Hygrometer of Daniell.—If a wine-bottle be taken from its bin, it will frequently be found covered with moisture; and in proportion as the air is saturated with moisture, so will the depression of temperature be at which this moisture begins to be deposited on the bottle. In this manner, if we had the means of regulating the temperature of the bottle at our will, depressing it at pleasure, we might ascertain the exact temperature at which moisture would begin to be deposited; and thus, noticing the variations of temperature at different times, we might establish and tabulate a correspondence between each particular temperature at which moisture was deposited, and the corresponding amount of moisture contained in the atmosphere. Now, the degree of temperature at which moisture begins to be deposited in this way, is called the *dew-point*; and hence the propriety of the appellation, *dew-point hygrometer*, which has been given to the instrument presently to be described. It consists of a doubly-bent, exhausted glass tube, each end terminating in a bulb. One bulb is covered with a coating of thin gold or platinum foil, the other with a fine linen rag. The former bulb is partially filled with ether, and holds a small thermometer, the graduated portion of which passes up the tube. If ether be dropped on the second bulb, evaporation rapidly ensues, and the bulb is cooled, thereby condensing the vapour of ether which it contains, and permitting a new evolution from the ether in the bulb. This evolution of ether cools the bulb, and causes dew to be deposited on its surface. The inclosed scale indicates the dew-point. The following reasoning explains how the determination of the dew-point can indicate the amount of aqueous vapour in the atmosphere. In proportion as the temperature of the air is elevated, will it be capable of holding more moisture. Hence, by cooling the air, its power of holding moisture is diminished; a portion of moisture, therefore, becomes condensed in the form of dew-vesicles. The greater the moisture contained in air, the more readily will condensation ensue for a given reduction of temperature.

The dew-point hygrometer of Daniell, though a great advance upon the rude instruments just described, is attended with some imperfections. Its construction has been improved upon by Dobereiner and by Regnault; but the instrument, in its most perfect form, still leaves much to be desired. Not only does its employment necessitate the use of a large amount of ether; but, what is of more consequence, when the weather is extremely dry, the deposition only takes place with great difficulty. A far more effective instrument, though based on different conditions, is that now to be described.

The Psychrometer.—The psychrometer consists of two thermometers mounted on the same frame, the bulb of one thermometer being naked, whilst the bulb of the other is enveloped in muslin or other similar absorbent texture, from which there extends a wick-like absorbent stem, terminating in a cistern of water. From a consideration of the structure of this compound instrument, it will be evident that the mercurial column of the naked or uncoated bulb will stand higher than the mercurial column of the second or wetted bulb. The reason of this is obvious. The process of evaporation lowers the temperature: and it follows that, under one condition, and *only one*, can the readings of the pair of thermometers which constitute the psychrometer correspond—namely, when the atmosphere is saturated with moisture, to such an extent that it is unable to take up more. By an extension of this reasoning it will be now evident that the mercurial readings of the pair of thermometers will continually vary, according to the amount of dryness or moisture of the surrounding atmosphere. The variation, in point of fact, is in an inverse ratio to the amount of moisture; so that by means of formulæ we can easily connect the indications of the psychrometer with the dew-point.

Diurnal Variation of Atmospheric Moisture.—The amount of moisture present in air varies at different times of the day. There appear to be two maxima and two minima. The first maximum occurs about 9 A.M., the second at 9 P.M.; the first minimum shortly before sunset, the second about 4 A.M. Popularly, the air is said to be most damp at sunrise; and in the sense of dew or palpable moisture, the popular expression is correct; but, provided the air be hot enough, we have already seen that it can absorb large quantities of moisture, retain it invisibly, and impart no sensation of moisture; indeed, pure steam is no more wet than a pure gas.

Monthly Variation of Atmospheric Moisture.—The fact needs no comment, that all months throughout the year are not equally moist. It appears that at London, Paris, Geneva, and Great St. Bernard, the absolute amount of vapour in these places attains its maximum in January, and its minimum at the end of July or the beginning of August; but the relative moisture is greatest at London, Paris, and Geneva, in December, and least in May.

Like the true aërial atmosphere, atmospheric aqueous vapour continually varies as to its amount of tension or elasticity. According to Dove, the amount of tension is less during north and south winds than during eastern and western winds, an observation which has also been confirmed by Kaemtz. Necessarily, too, the direction whence the wind blows must influence the quantity present of aërial vapour. North and north-east winds are, at least in these latitudes, less moist than winds blowing from the opposite direction. Mr. Glaisher found, during his balloon ascents in 1862, that the aqueous vapour rapidly decreased as increased elevation was attained. (See page 1174).

Inasmuch as the aqueous vapour dissolved invisibly in air, assumes the condition of vapour whenever the air is cooled below the dew-point, the influence which mountain ranges exercise in robbing winds of their moisture and producing rain, will be readily evident. By an extension of the same reasoning, it is evident that winds which have reached into continents far distant from the ocean, and lost considerable bulks of water, must be necessarily dry.

CHAPTER III.

ATMOSPHERIC PHENOMENA—(*Continued*).

PHENOMENA OF ATMOSPHERIC REFRACTION. — The amount of atmospheric refraction is due to inequality of the density of the air. But inequality of density, and therefore inequality of refractive power, may be the result of varying amounts of expansion, referable to the operation of varying degrees of heat; and thus arise what may be termed the abnormal effects of atmospheric refraction.

Every one must have noticed the peculiar, tremulous condition of the air in summer-time over an ignited brick-kiln, or near a red-hot bar of metal, or even on the surface of the ground, provided the weather be sufficiently hot. This tremulous appearance is referable primarily to the expansion of the air near a hot surface, and immediately to the diminished refrangibility attendant on such expansion. These local sources of heat set up local currents, each being composed of air of a different density from that of neighbouring currents, whence each has a different refractive power. That which an ignited brick-kiln, or a glowing metal-bar, can accomplish on the small scale, is accomplished on a larger scale by many natural causes, giving rise to phenomena both striking and delusive. Pictures of ships and towns inverted, the vain semblance of lakes of water in the midst of burning sands where no water really exists, aërial cities, spectral forms of men and animals—all these, and many more—are the phenomena of atmospheric refraction and reflection.

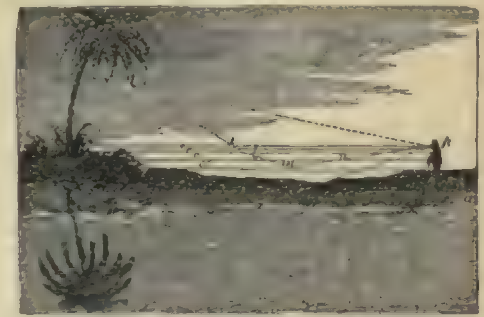
One of the most common effects of irregular atmospheric refraction is the twinkling of the stars. This appearance is strictly conformable with all the teachings of theory in reference to the laws of refraction, and is due to the fluctuations of variously-heated currents of air. When these small aërial currents, having different temperatures, are numerous, bad weather is likely to supervene; hence, an explanation of the increased twinkling of stars before bad weather sets in—a phenomenon which has been very commonly noticed.

Extreme examples of atmospheric phenomena are, for the most part, only seen in hot climates; but there they are frequent. The mirage is an atmospheric phenomenon, in part attributable to refraction, and in part to reflection; it occurs in Egypt, and gives rise to the impression in a stranger's mind, of a lake or tranquil expanse of water, though the region is only a waste of sand. The explanation of the phenomenon is this:—The villages throughout Lower Egypt are usually built on elevated mounds; hence the houses are to some extent raised above the general level of the earth, which level becoming intensely hot, imparts heat to the atmosphere placed in contact with it, and alters the refractive power of that portion of atmosphere. An optical illusion now ensues—the lower or heated atmospheric layer assumes a tremulous appearance, like the surface of a lake, on which the images of the buildings of the village are seen reflected, whilst the direct view of the village is still evident in its true position. The Egyptian mirage is so deceptive, that a stranger seeing it for the first time, can hardly be convinced that the semblance of water is only an optical delusion. The term *mirage* is peculiar to India; yet the phenomenon to which it refers is common in many other hot regions, especially in Central India and the Sahara.

The visual inversion of objects, a phenomenon not at all uncommon in hot places, is partly due to refraction and partly to reflection—for, in point of fact, the function of reflection may be demonstrated to be only an extreme case of refraction.

The *locale* is supposed to be a hot, sandy region, and a date-palm is the object seen inverted; the explanation of which phenomenon is as follows:—The eyes of the observer being at p (Fig. 53), will first see a direct image of the palm-tree by rays which come straight in the direction of the line $h\,p$; simultaneously he will see an inverted image of the palm-tree. Let us examine how this happens. Referring to the illustration, several parallel lines will be seen, $c\,c'\,c''\,c'''$. These are intended to denominate atmospheric layers of different amounts of density. Tracing the ray of light $h\,i$, let us now examine what becomes of it. First, it impinges on the upper atmospheric layer, which is hotter, and consequently more expanded, than the next layer above; the ray $h\,i$ is, therefore, refracted *from* the perpendicular. Passing on to the next layer, it is refracted still more *from* the perpendicular; and this refractive gradation is repeated on the ray $h\,i$ until it arrives at m, at which point, the ten-

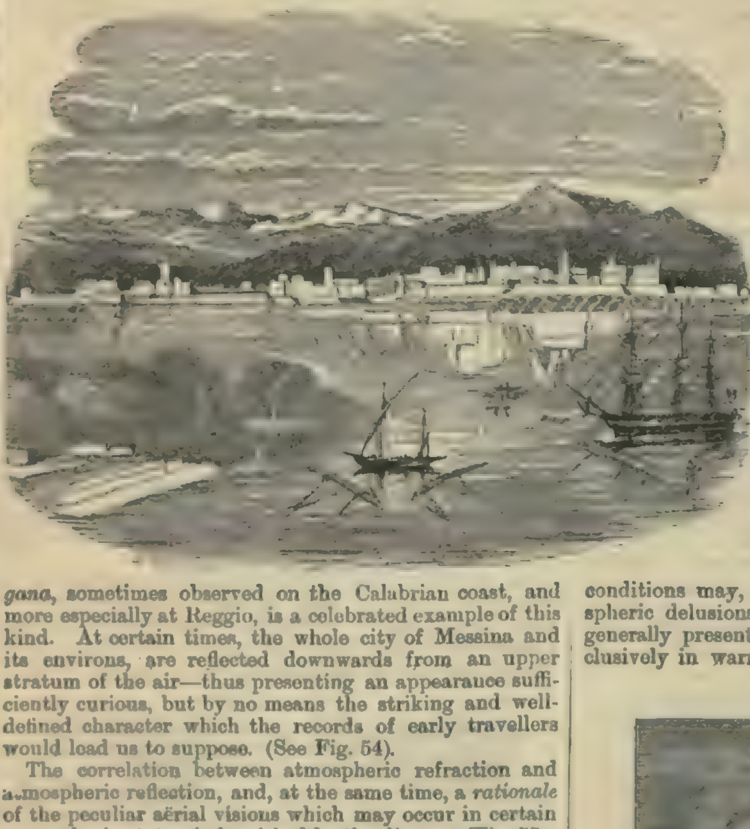
Fig. 53.



dency to fly from the perpendicular still remaining, this tendency is manifested, not under the condition of refraction, but reflection; consequently, the ray *h m* is directed towards the eye of the observer, and, along with the other rays upon which a similar operation has been effected, gives rise to the appearance of an inverted object. In order that the phenomenon should occur, however, there must be the following conditions besides those already mentioned:—Not only must the solar heat be considerable, but the air must be calm, so that the lower atmospheric layers may retain a density less considerable than the density of those above them.

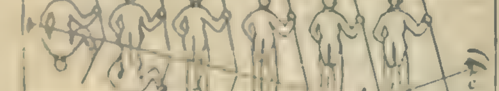
As, under the peculiar circumstances just mentioned, refraction may pass into reflection, and the reflection may be excited upwards from below, so may the operation be reversed; in which case the inverted images of terrestrial objects will be seen in the air. The celebrated *fata morgana*, sometimes observed on the Calabrian coast, and more especially at Reggio, is a celebrated example of this kind. At certain times, the whole city of Messina and its environs, are reflected downwards from an upper stratum of the air—thus presenting an appearance sufficiently curious, but by no means the striking and well-defined character which the records of early travellers would lead us to suppose. (See Fig. 54).

Fig. 54.



The correlation between atmospheric refraction and atmospheric reflection, and, at the same time, a *rationale* of the peculiar aërial visions which may occur in certain atmospheric states, is furnished by the diagram (Fig. 55), suggested by M. Biot. The line *b t c* is supposed to be a ray of light proceeding from *b*, passing thence downwards to the point *t*, whence it is reflected to the observer's eye at *c*. Now the optical conditions of this arrangement are such, that any rays proceeding from *b* below the ray *b t c* represented, would be invisible to the observer at *c*, whilst two images will be seen of all objects above this line. Supposing the object in question to be a man—suppose, further, the man to be walking *from* the observer, he would be presented to the latter under the successive forms seen in Fig. 55.

Fig. 55.

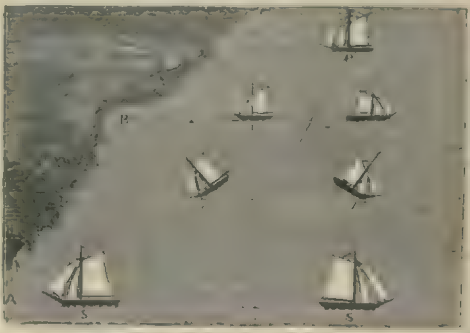


In these atmospheric optical delusions, involving the appearance of two images, one of them inverted, both natural and inverted images have occupied a horizontal plane. Occasionally, however, the reduplication of image has been projected on vertical planes, of which phenomenon the following is an example. On June 17th, 1820, whilst MM. Soret and Turine were in the second storey of a house on the lake of Geneva, they looked towards a ship two miles off, and making for the harbour. Immediately the vessel in question arrived at *q* (Fig. 56), she appeared reduplicated on a vertical plane; when she came to *r* the reduplication still continued, but the second image was further removed than before, and both were distorted; lastly, when the vessel arrived at the point *s*, the reduplicated image had receded to a distance still farther away, and both images, though distorted, presented an appearance of distortion very different from before; they were apparently drawn out, elongated both as to the hull and rigging, as represented in the diagram (Fig. 56). The following is the explanation of the phenomenon, as suggested by the two observers above-mentioned; and there seems no reason to doubt its correctness.

The letters, A B C, represent an outline of the eastern bank of the lake of Geneva; the air over that bank had, at the time of observation, been long under the shadow thrown upon it by the mountains of Savoy, whilst, contemporaneously, the western bank had been strongly heated by the sun; hence, from the conjoint operation of these two causes, there were two vertical layers of atmosphere of different temperature, and consequently of different densities; hence, they were of two different refractive and reflective powers.

All that is necessary to determine aërial reflections, is a sufficient difference between the temperatures of any two adjacent atmospheric layers. In the instance already mentioned, this difference had been occasioned by portions of the ground being hotter than the strata of air with which they were in contiguity. The reverse of these conditions may, however, obtain, and fantastic atmospheric delusions may be the result. This latter case generally presents itself at sea, and by no means exclusively in warm localities. Thus, for instance, it is prevalent enough in the Northern Ocean. Sometimes the atmospheric delusion has merely the effect of prolonging the appearance of an object really below the horizon; sometimes not only is the appearance prolonged, but the body is seen double. Whatever the appearance, the atmospheric delusions now under consideration are usually seen near the horizon—a position where the optical powers of the atmosphere attain their greatest intensity (Fig. 57).

Fig. 56.



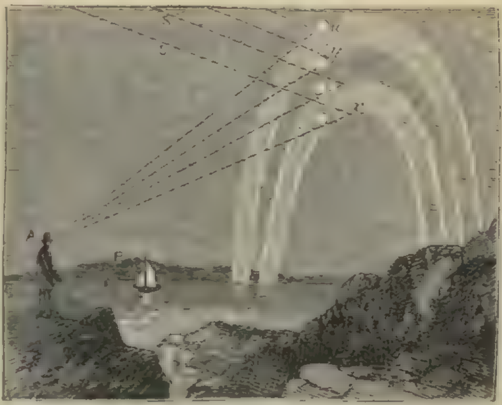
The Rainbow.—The most beautiful of all luminous meteorologic phenomena is the rainbow, which results from the decomposition of light by refraction through drops of rain, and subsequent reflection. Rainbows are of two classes, solar and lunar; the latter, however, are rare; and even when they do occur, the bow is seldom coloured.

Fig. 57.

The chief conditions under which a solar rainbow may occur, are the following:—The sun must not have less than 42° of angular elevation; the back of the spectator must be towards the sun, and rain must be falling from a highly illuminated cloud. The rainbow is usually double, and the theory of its formation may be thus explained. Let it be assumed that a straight line passes from the eye of the observer through the sun; then this line will constitute the axis of a cone, the base of which will be the rainbow, and its vertex the eye of the observer. If the bow be at the horizon, and the place of observation be a level plain, then the rainbow will appear as a perfect circle constituting the base of the cone. This complete circular appearance is, however, rare, the rainbow being far more generally, as its name implies, a mere arc of coloured light. The explanation is now evident of the fact that the rainbow cannot appear when the sun has attained an elevation greater than 45°. The rainbow, though still depicted, is depicted below the horizon, and is, therefore, invisible. It follows, then, that the size of the visible rainbow is inversely as the elevation of the sun above the horizon.

The following diagram (Fig. 58) illustrates the formation of the rainbow. The straight line A P is supposed to be drawn between the sun and the eye of the observer, passing through the latter. Through this line a vertical plane is supposed to be drawn. If the line A x be drawn through A so that the angle P A x shall amount to 42°, the rain-drops will reflect coloured drops to the eye. Assuming the line A x to rotate, a cone will evidently be generated, part of which, lying below the horizon, will be invisible. It is the surface of the cône thus generated which is the reflecting surface, and to which, therefore, the rainbow is due. Inasmuch as every colour has a refractive quality peculiar to itself, each drop only represents one tint to the eye. An arc having the breadth of about 2° is sufficient to include all the prismatic colours; 2° therefore is about the breadth of the rainbow.

Fig. 58.



The colours of the rainbow are partly due to refraction and partly to reflection, as has been observed. The first effect of light on the drops of rain is refraction, by the operation of which, white light arrives at the posterior side of each drop, and is decomposed or dissected into the primitive colours of which it is composed. At the posterior aspect of each drop of rain the dissected colours are reflected unto the eye, and a coloured image is presented.

Such is an explanation of the theory of the primary rainbow—besides which, the surrounding rainbow requires to be noticed. The secondary rainbow is outside the primary, and is larger than it, but also much fainter. Its angular position is defined by the limits 50° 59′ and 54° 9′, measured with reference to the axis A x. The secondary rainbow has all the colours of the primary, but less completely defined, and in a reverse order. Its existence may be explained by the statement that it is the result of light twice decomposed, whereas the true rainbow is the result of light only once decomposed. The secondary rainbow, then, is produced by drops of water very far off.

Inasmuch as any angular elevation of the sun above 45° is incompatible with the existence of a rainbow, it is evident that this beautiful meteor can never occur in the south. It may occur, however, either in the east, west, or north.

As concerns lunar rainbows, they are, as we have before remarked, exceedingly rare, and are very seldom coloured. Nevertheless, in northern latitudes, where the moon shines with a brilliancy unknown to us, coloured lunar rainbows are occasionally seen.

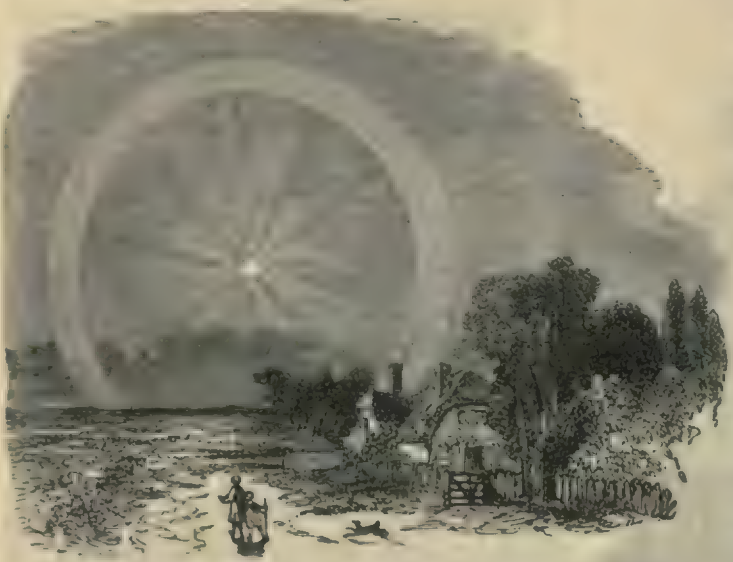
HALOS AND PARHELIA.—These meteoric phenomena are far more rare with us than in more northern latitudes, where they are continuously visible for long periods of time, and give rise to phenomena of extraordinary beauty. The term *halo* is applied to a luminous circle occasionally seen around luminous bodies, more particularly the sun and moon, and is partly due to the refraction of light by vaporous water, sometimes in the form of true clouds, sometimes not; and partly to the properties of light termed *diffraction* and *interference*. As respects diffraction, the circumstance has been already announced, that when light passes through a minute orifice—such, for example, as a small aperture punctured in a card—the edges of such light bend: this is termed diffraction. The term, *interference of light*, is used to explain the phenomena of colour, or alterations of luminous condition generally, which result from the assumed jarring impact of luminous waves meeting in different phases of their vibration.[*]

Solar halos frequently exist, though unnoticed; the sun's light being so powerful that the eye of the observer cannot withstand its impressions. By the aid of a sheet of glass rendered dull by smoke, these halos are frequently rendered visible (Fig. 59).

---

[*] See the Section on *Light*; articles "Interference of Light," and "Diffraction"—ED.

Fig. 59.



Although halos, and also the phenomena next to be described, are referable to the action of atmospheric moisture on luminous rays, yet it is evident that the condition of that moisture will vary according to temperature; in other words, the aërial moisture which would be mere cloud-vesicles at temperatures above the freezing point, would, if depressed below 32° F., be converted into snow, or spiculæ of ice. The alteration which these are capable of effecting on luminous rays being far greater than mere uncongealed vesicular water can effect, the resulting optical phenomena are far more brilliant and remarkable. Hence, in northern latitudes, the phenomena of halos and parhelia—as arcs of light appearing near the sun, and sometimes intersecting each other, are called—are brilliant and impressive beyond anything which corresponding phenomena occurring in this region would lead us to conceive. These luminous arcs, sometimes intersecting each other, are as often occasioned by the moon as by the sun. As the phenomena in question, when referable to the latter cause, are demonstrated *parhelia*, so, when dependent on the former cause, they are termed *paraselenæ*.

Frequently parhelia and paraselenæ consist, not only of the intersecting arcs just mentioned, but of circular luminous meteors, to which the term *mock suns* are especially applicable. Associated with parhelia, and sometimes included under the same name, is a luminous band, passing horizontally through the sun, and not unfrequently making a circuit of the whole heavens. Where this luminous band and the inner parhelion cross, a mock sun usually appears, as represented in the following diagram (Fig 60).

Aurora Borealis.—It has already been indicated, in the section on Electricity, that various circumstances materially operate to produce the condition termed electrical. By far the best-studied of atmospherical electrical phenomena are thunder-storms; but it is an error to suppose that the atmosphere contains, at the time of a thunder-storm, its maximum of electricity; the experiments of Faraday have sufficiently made out this point.

Reserving the consideration of thunder-storms for the present, we shall introduce here the subject of electrical phenomena by a description of the aurora borealis—a phenomenon sometimes said to be magnetic, inasmuch as the magnetic needle is strongly affected during its prevalence, but which, nevertheless, seems more naturally to belong to electricity.

The term *aurora borealis*, or northern light, is applied when the phenomenon presently to be described occurs in the north; and the term *aurora australis* is applied when it occurs in the south. But the former has been seen as far south as 45° of southern latitude, and the latter has, more than once, been visible in Britain. Nevertheless, the beautiful phenomena of northern and southern lights are most prevalent towards the north and south poles respectively.

Northern and southern lights, when in their greatest perfection, consist of a well-defined arc of white light, and luminous streams of coloured light flowing therefrom. The arc is not permanent, as in the rainbow, but bends and twists in all directions like a ribbon agitated by the wind. The intensity of the aurora varies within extensive limits: when faint, the light is only recognisable at night by careful examination; but when highly developed, the aurora borealis, or australis, can be seen during broad sunshine.

These phenomena may occur at any season, but they are most prevalent in the months of March, September, and October, or about the period of the equinoxes. The aurora borealis and australis are sometimes said to be magnetic storms; a more reasonable foundation is required for the remark than is supplied by the turbulent agitations of the magnetic needle with which they are attended; but we have already seen that the functions of magnetism and electricity are so nearly connected, that it is impossible in some cases to distinguish between the two.

Fig. 60.

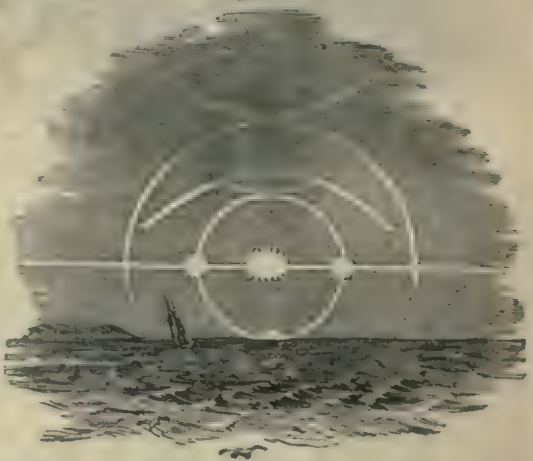


Fig. 61.

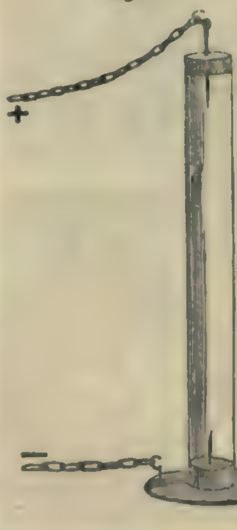


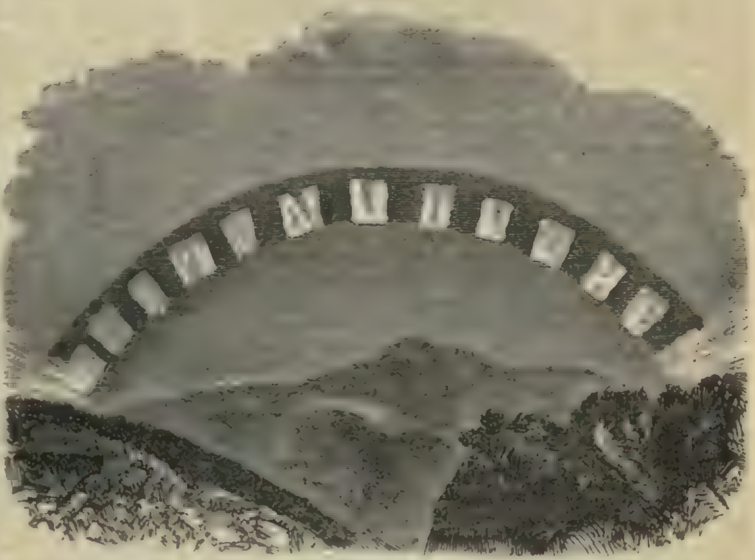
There is a very common electrical experiment which furnishes an artificial phenomenon very nearly resembling the northern and southern light, in all respects except in the shape of the illuminated body, which is a luminous arc.

The experiment consists in exhausting, by means of an air-pump, all the air out of a glass tube furnished with a metallic point at each end, looking internally, and placed in the electric current, as represented in Fig. 61. When a stream of electricity, of adequate intensity, is passed through the apparatus from + to —, the whole interior of the tube becomes illuminated with flashes of light, very similar in appearance to the flashes of the aurora.

The phenomenon of the aurora borealis was noticed by Aristotle and Pliny, although neither philosopher could have seen it to advantage. Gassendi first originated the term aurora borealis, to indicate the phenomena of this kind observed by him on September 12th, 1621. These phenomena appear to be subject to some laws of secular variation not yet understood. That they have appeared in certain years, and certain groups of years more than others, is certain. According to De Mairan, twenty-six occurred between A.D. 583 and 1354; thirty-four between 1446 and 1560; sixty-nine between 1561 and 1592; seventy between 1593 and 1633; thirty-four between 1634 and 1684; two hundred and nineteen between 1685 and 1721; nine hundred and sixty-one between 1722 and 1745; and twenty-eight between 1746 and 1751.

After 1790, auroras became unfrequent, but since 1825 they have been on the increase. A very remarkable aurora borealis occurred in the autumn of 1847: it was conspicuous not only in England, but even so far south as Italy and Spain (See Fig. 62).

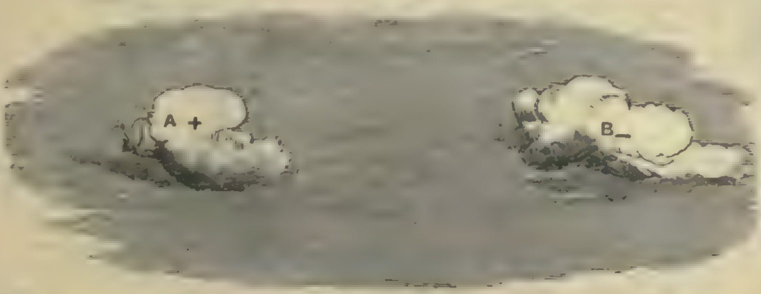
Fig. 62.



Height of the Aurora.—As a proof of the doubt which exists concerning the height of the aurora, they have been variously estimated from 3,000 or 4,000 feet to several miles. The probability is, that the conditions on which the aurora depends vary in the altitude of their operation; but the truth is, that, notwithstanding the electrician, by his artificial experiments, can imitate the light of the aurora borealis and australis—notwithstanding the prevalence of the phenomena in question near the magnetic poles, seems to point to magnetic agency as the cause—our real knowledge concerning the aurora borealis and australis is very slight.

It may be as well here to present the reader with a summary of the various opinions which have prevailed at different times relative to the phenomenon in question. Many early writers referred the appearances presented to mere optical causes, considering them to be due to the reflection of the sun's light thrown upwards by a mirror of snow and ice, and a subsequent reflection downwards by atmospheric agencies. De Mairan, the observer who, perhaps more than any one else, is entitled to be considered the chronicler *par excellence* of the phenomena of the aurora, attributed them to the penetration of our planet at certain periods into the solar atmosphere. On this supposition it will be remarked, that the solar atmosphere must be assumed to extend to the orbit of our planet, an hypothesis totally irreconcilable with the teachings of optics and astronomy. The celebrated Euler, the philosopher who could deal so satisfactorily with the abstractions of number and quantity, seems to have offered a most crude and improbable theory explanatory of the aurora. Adopting the molecular theory of light, he assumed that the solar rays, striking against the particles of our atmosphere, actually carried particles of the latter up into the heavens to a height of more than four thousand miles—the height at which Euler believed auroras to exist. Some philosophers, of whom Volta may be regarded the Coryphæus, adopted a chemical theory of auroras, referring them to the ignition of hydrogen gas spontaneously generated on the earth, and rising, by its light specific gravity, to the higher atmospheric regions. It was assumed by these philosophers that the evolution in question took place in the tropical regions chiefly, and that it was wafted by the upper current of air—treated of in connection with the trade wind—to the north and south poles respectively.

Fig. 63.



Halley was the first, we believe, who suggested that the phenomena of aurora borealis and australis might be due to the passage of magnetism from one magnetic pole to the other; and the theory of Halley is so far retained, that the aurora is assumed to be in some way connected with electricity and magnetism, but in what manner is beyond the competence of observers to decide.

ON THE PHENOMENA OF THUNDER AND LIGHTNING.—Perhaps no meteorologic phenomena are now so well understood as these; though, before electrical science had been studied by the philosophers of the last century, and the crowning experiment of Franklin performed, the phenomena of thunder and lightning were so mysterious, that even philosophers were content to refer them to the operation of an occult cause.

The intimate study of electrical science opens a field of somewhat abstruse matters for consideration; the field is far too wide and too abstruse to be dealt with satisfactorily here. In the section on Electricity it has been treated in detail; and to this we must refer the reader who desires to know more on this subject than strictly belongs to the necessities of what we may term *practical meteorology*.

With this explanation we shall not hesitate to adopt the term *electric fluid*, although the reader has already been made aware that no such fluid is at all likely to exist. Let us now contemplate the phenomenon of that electrical excitation, the solution of which is lightning, under the simplest conditions that the phenomenon can assume. Let A and B (Fig. 63) represent two clouds, which, being made up of watery vesicles, are electrical conductors; and being surrounded by the atmosphere on all sides, are necessarily insulated. For the sake of our illustration, it will now suffice to assume that neither of the clouds here represented is electrically excited at this period of the description, and hence that the marks + and — are for the present misplaced. Let it now be assumed that the cloud A becomes positively electrified, —that is to say, charged with positive electricity, owing to some natural cause unnecessary here to explain; and let the results of this condition be traced out. Firstly, there is not in all nature, and there *cannot be*, such a condition as that of independent electric excitation; in other words, there cannot be one body *positively* excited without the co-existence of another body *negatively* excited. Hence, if cloud B were away, and cloud A positively excited, the air circumadjacent to A would assume the second or negative function; but if the cloud B is present, it therefore becomes negative, and the two clouds A and B are mutually attracted, because opposite electricities attract each other. Hence, they approach until the space of air, between the two, is insufficient to restrain their mutual electric tension: this condition having arrived, a discharge takes place, precisely analogous to the discharge of a Leyden jar. Under the postulates of our experiment, the discharge, or lightning flash, takes place between the two clouds A and B.

It follows, however, from the consideration of known electrical laws, that just as the two oppositely electrified bodies may be two clouds, as assumed, so also may they be one cloud, and the surface of earth or water, or conductors placed upon either one or the other; under which conditions a downward discharge will take place; and generally, electricity will always take the nearest path between any two bodies oppositely charged, the conducting facilities being equal.

LIGHTNING-CONDUCTORS.—It is almost unnecessary, in these days, to announce that Franklin, in the year 1752, first demonstrated the nature of lightning by drawing electric sparks from the string of a kite, previously caused to ascend into the region of a thunder-cloud. This experiment performed, the connection between lightning and electricity could no longer be doubted, and a means of drawing off a surcharge of the electric fluid by lightning-conductors was immediately suggested. The most important instruments were not adopted, however, until after numerous and varied conflicts. Firstly, the argument was adduced by some, that lightning conductors could not be adopted without impiety, being intended to contravene the will of Providence. An argument so fallacious was no sooner abandoned than lightning-conductors were exposed to another ordeal, founded on an erroneous practical estimation of a truth in theoretical electricity. We allude, as the electrician will perceive, to the contest between the advocates of spherical, and of pointed, terminations for electrical conductors.

Now, regarding the question of points or spheres abstractedly, it is easy to see that preference should be given to the former, inasmuch as points draw off and give issue to the electric fluid in silence; whereas spheres draw off and give issue to electricity in sparks; but, inasmuch as the largest spherical termination ever used, or ever likely to be used, for the upper extremity of a lightning-conductor, is virtually a point in comparison with the enormous surface of the smallest thunder-cloud, the dispute, though violent and prolonged, never had the practical significance which was at one time taken for granted.

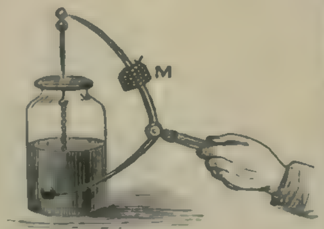
The history of lightning-conductors furnishes a remarkable illustration of the difference between the mere knowledge of a fact, and the confidence or conviction resulting from that knowledge, and justifying its practical application. The whole theory of lightning-conductors was almost as well known half a century ago as now; yet it is only within the last few years, and owing to the unflagging perseverance of Sir W. Snow Harris, that due effect has been given to the theory, and lightning-rods have been fearlessly applied.

Electrical Principles connected with Lightning-Conductors.—The electrical principles on which the efficiency of lightning-conductors depends are few and simple; they all admit of being readily demonstrated by electrical experiments artificially performed, and they have been universally justified by the result of three practical applications:—

(1.) *Electricity, cæteris paribus, follows its course through the best Conductors which happen to be in its path.*—Thus, for example, if a Leyden jar be charged, and the electric connection between its external and its internal coating be completed by three linear substances of equal length—say, for example, silk, wire, and linen thread—thin wire, being the best electrical conductor of the three, will transmit the whole of the electricity, to the exclusion of the silk and the linen thread. It is assumed, however, in the performance of this experiment, that the wire is sufficiently large to convey the whole electric discharge.

(2.) *Provided the Conductor be good, and its Sectional Area adequate, the Electric Fluid or Discharge is conveyed harmlessly away.*—No point in the whole of electrical science can be more satisfactorily established than this. It admits of being illustrated by numerous experiments, among which the following may suffice:—

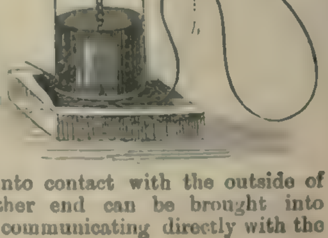
Fig. 64.



The diagram (Fig. 64) represents a common Leyden jar, in the act of being discharged by the ordinary discharging instrument. This is, as usual, of brass—all save the handle, which is of glass, and therefore a non-conductor of electricity. Those who are conversant with the form and construction of the discharger, are aware that its two terminal balls admit of being unscrewed. Assuming one of the balls, viz., the upper one in the diagram, to have been unscrewed, the liberated brass stem to be passed through a marroon, or box, holding gunpowder, and the ball to have been again replaced, the conditions will have been fulfilled which the diagram represents. It is evident that the Leyden jar, as represented, will be discharged. It is, moreover, evident that the whole of the charge will be transmitted through the gunpowder contained in the marroon, yet that gunpowder will not inflame. If, however, instead of the conditions of the last experiment, a very fine metal wire (a steel wire by preference) be passed through the marroon, or rather through some combinations of explosive materials less potent than a marroon, which would now be dangerous, and electricity transmitted as before, the wire, not presenting a sufficient amount of transverse area of surface to convey the electricity, would melt, and the explosive compound be inflamed.

(3.) *Lateral Discharge must be provided against.*—The meaning of lateral discharge will be illustrated by the following experiment:—The diagram (Fig. 65) represents, as before, a Leyden jar ready arranged for being discharged through a metallic wire, one end of which has already been brought into contact with the outside of the jar, while the other end can be brought into contact with the knob communicating directly with the

Fig. 65.



inside of the jar. The hand is represented in the act of holding a glass rod, around which one end of the wire is coiled, and the extremity of the wire is finished off with a ball. All these arrangements, the electrician will perceive, are necessary for giving effect to the efficient discharge of the Leyden jar through the conducting wire. The chief point for observation, however, is the bend of the wire, by means of which one part is caused very closely to approach another part, as represented at *a b*. Now, it is possible by choosing a wire sufficiently small, and causing the two bands to pass sufficiently near, to determine the passage of an electrical spark from *a* to *b*, instead of proceeding through the entire length of the wire, from the internal to the external coating of the jar. This is what electricians call the lateral discharge, and it requires to be studiously guarded against in the construction and arrangement of lightning-conductors.

Application of the foregoing Deductions.—Perhaps the deductions already arrived at, will suffice for practical guidance in the matter of lightning-rods, though these deductions by no means exhaust the science of the subject. The fact may be considered as proved, that all bodies, even the most dangerous and inflammable—all edifices, all living beings, may be shielded from the evil consequences of lightning, by the safeguard of lightning-conductors. The conductors, however, must present a sufficient external area; and the point has been made out by numerous trials, that a copper rod, a square inch in sectional diameter, will convey away the utmost fury of the most highly-charged thunder-cloud ever proved to exist. Copper is one of the best electrical conductors amongst metals; but, by providing a sufficiently increasing sectional area to compensate for inferior conducting power, any metal may be made to perform the function of copper. Whatever be the conductor, its upper extremity should project considerably above the edifice to be protected; and if pointed *theoretically*, all the better; though, practically, the bluntest termination could be only as a point by comparison with the enormous mass of a thunder-cloud. Far from preventing contact between the building to be protected and the conductor, as is sometimes done by the interposition of glass or earthenware guards, a lightning-conductor cannot be brought into too intimate metallic connection with every part of the edifice to be protected. The conductor should branch and ramify over the surface of the building, and should be brought into contact with every important system of metal line work, such as the iron pipe which frequently runs down the side of a wall; finally, the conductor should, at its lower extremity, be brought into contact as efficiently as possible with some good electric conductor, such as the system of gas or water-pipes which run underneath most houses, especially under the streets of most civilised towns. As regards the number of conductors necessary to be supplied to one building, that will depend on the shape of the building, whether it be composed of many elevations, or whether, like a column, it has only one. Perhaps the best practical testimony on this point is gleaned from the fact, that in a ship having three masts, one of which only was protected by a lightning-conductor, the unprotected masts have been shattered by the effects of a thunder-storm, while the other remained untouched. If a column be surmounted by a metallic statue, it is worse than useless to disfigure the head of the statue by a projecting metallic spike as the beginning of a lightning-conductor; nothing more is requisite, in this case, than to provide sufficient metallic conduction for the electricity downwards into the ground. Lightning-conductors, it should be remembered, *do not*, as they are commonly said to do, *attract* electricity. They no more attract electricity, than a gutter attracts water. They merely open a channel for electricity to pass through. Before the demonstrations of Sir William Snow Harris had taken effect, marine lightning-conductors were something more dangerous than lightning itself: consisting merely of chains, which were only elevated aloft after the thunder-storm had come on. Marine lightning-conductors are now fixtures on the masts; they are made of copper, running band-like down the mast, and imbedded in the latter in such a manner, that, whether the masts be elevated or lowered, perfect metallic contact, between any two pair of masts, remains uninterrupted.

RELATIVE PREVALENCE OF THUNDER-STORMS.—The phenomena of thunder and lightning are nowhere so violent or so frequent as in the so-called region of calms; but they are very prevalent throughout the torrid zone, more especially during the rainy season. Thunder and lightning are almost always absent in the polar regions; and even at a spot no farther north than Bergen, in Norway, the annual number of thunder-storms does not average more than six. As the rule, thunder-storms chiefly occur in hot weather, winter thunder-storms being comparatively rare. Iceland and the western coast of North America, however, are remarkable for the predominance of thunder-storms in winter. In Sweden, winter thunder-storms are almost unknown; thus furnishing another example of the circumstance already noted, that the Scandinavian range of mountains effects a remarkable difference between the general climate of Sweden and Norway, though the two, geographically considered, are so close together.

AEROLITES—SHOOTING STARS—METEORIC STONES.*—The beautiful phenomenon of shooting stars is common enough; but at certain periods it is peculiarly remarkable, the whole sky being filled with these fleeting meteors. The beginning of August and the beginning of November are noticeable for their connection with shooting stars; more especially have they been recorded between the 9th and 14th of August. The *bouquet* of shooting stars, observed at this period in North America, has been sometimes called the Shower of St. Lawrence.

For our knowledge respecting the periodicity of the phenomenon of falling stars, we are indebted to Quetelet, Besenberg, and others; but Muschenbroek, so long back as 1762, first directed attention to the so-called *Shower of St. Lawrence*. In addition to the August and November phenomena of the kind under consideration, other periods have been noticed—for instance, in April, and from the 6th to the 12th of December; but these *bouquets* of shooting stars, which thus occur, are less considerable and less regular than the former. Besides these showers, the periodicity of which is well attested, single meteors of this kind are frequently noticed, and they occur at all seasons; therefore, whatever may be the cause of shooting stars, it must be regarded as continuously operating.

Sometimes the luminous meteor attains a large magnitude; observers then speak of it as a fire-ball. The identity of shooting stars and fire-balls is now well established, though formerly they were treated of as distinct. Fire-balls are sometimes seen alone, but more frequently in connection with shooting stars. Their light and their bulk are frequently so considerable, that they can be seen in broad daylight. Their velocity through the heavens, or rather through the upper layers of our atmosphere, is various; but it generally exceeds that of the earth. As regards the nature of shooting stars, we have only theory and analogy for our guidance; but our knowledge of fire-balls is far more accurate, and there seems no reason to doubt that they quite illustrate the nature of falling stars. Numerous fire-balls dart through our atmosphere, become luminous, and disappear, no one knows whither. Others, though passing near to our atmosphere, fail to enter it, and therefore are not rendered visible. A third division not only come within our atmosphere, shine, and burst with a loud report, but they fall; yet, falling either into the sea or upon an unfrequented spot of land, the locality of their fall remains unknown. Whilst a fourth division of fire-balls may be seen to fall, be dug out, and examined.

Masses of this kind are termed aërolites, and their connection with fire-balls has been placed beyond all doubt. Fire-balls have been seen to fall, and aërolites have been extracted from the place whereon they have fallen. Nevertheless, some aërolites have fallen upon the earth without the assumption of a previous appearance of luminosity. Cases, though rare, are well attested of an aërolite suddenly falling from a small cloud, attended with a noise resembling the discharge of cannon; others, again, have fallen silently, and out of the clear air, not the slightest trace of cloud being visible at the time.*

---

* Further remarks on this subject will be found in Chapter V., at the end of this section.

Testimony concerning showers of stars and the fall of aërolites has been handed down to us from all periods; but it is only since the time of Chladni that the occurrence of these phenomena has been placed beyond doubt.

Amongst the best-attested examples of the fall of aërolites are the following:—On the 16th of June, 1794, a shower of stars fell at Sienna; and in the following year, December 13, an aërolite, weighing no less than fifty-six pounds, fell in England. Three years afterwards, and, remarkably enough, also on December 13th, a fire-ball split up and discharged round stones. A very large shower of stones fell April 26th, 1803, near Aigle, in France; the occurrence is particularly interesting on account of its having been noticed and verified by M. Biot. Ten such meteoric showers were observed in France in twenty-six years—*i. e.*, between 1790 and 1815. The meteoric shower at Aigle in 1803, which poured its contents over a surface of two-and-a-half French miles long, by one in breadth, consisted of 2,000 fragments of different sizes, some weighing not more than two drachms, others near twenty pounds. Aërolites are sometimes much larger than this; one fell at Agram on the 26th of May, 1751, weighing seventy-one pounds; but the largest known aërolite fell in Mexico, and weighed between 30,000 and 40,000 pounds.

As to shape, aërolites are generally prismatic, or angular—rarely smooth; and almost always sheathed in a crust of pitchy blackness. Their specific gravity is various, some being sufficiently porous to absorb water with rapidity, others being dense and metallic. Looking at the specific gravity of aërolites in the aggregate, it may be said to vary between 1·94 to 4·28, presenting a mean of about 3·5. All the heavier varieties of aërolites are made up of iron, holding a little nickel; traces also of cobalt, manganese, chromium, copper, arsenic, tin, and other well-known elementary bodies, are found.

ORIGIN OF FIRE-BALLS AND SHOOTING STARS.—Various opinions have been advanced to account for these bodies. One of the earliest, if not the very earliest, of these hypotheses, originated in 1660, and assumed fallen aërolites to be mineral masses originally projected from lunar volcanoes; and calculations were made, having for their object to demonstrate what volcanic force might be sufficient to project aërolites of a given mass into the sphere of attraction of the earth's atmosphere. Unfortunately for the probability of this theory, the moon's surface appears to be altogether devoid of active volcanoes. Then followed the chemical hypotheses, according to which it was assumed that aërolites were nothing more than aggregations of metallic vapours, which had risen to the upper region of the atmosphere, aggregated there, and fallen. The opinion of Chladni is now, however, generally received; he regards aërolites to be of cosmical origin—to be so many planets, or planetary fragments, which revolve in orbits of their own, variously inclined to the orbit of the earth; that our planet encounters periodic shoals of these little worlds, some of which, becoming entangled in the earth's gravitating system, pass into our atmosphere, become heated by friction against its particles, and ultimately fall to the ground. Although the discovery of aërolites is comparatively rare, the meteors, of which they are the final result, are by no means so. It has been calculated that the average annual fall of aërolites is not less than 700, or about two daily.

METEOROLOGIC RESULT OF OCCULT EMANATIONS.—When the utmost powers of a refined chemistry have been applied to the analysis of atmospheric constituents and conditions, much still remains to be unveiled. There are atmospheric causes, whatever they may be, of epidemic and endemic diseases, and perhaps other agencies which our philosophy little suspects or dreams of. We have ventured to include these undetermined agencies under the general expression *occult emanations*. It is not difficult to point out objections to this designation in some of its applications. Perhaps it is not strictly philosophical to speak of emanations thus hypothetically; perhaps this may be only a repetition of the error of assuming the existence of an electric fluid; perhaps the number of influences due to allotropism and to polarity is greater than we imagine; but, at any rate, the term "occult emanations" may be accepted as a rallying-point for a certain class of facts, until the time arrives when their true significance shall be correctly made out.

Without invoking the hypotheses of allotropism and polarity, there are undoubtedly some atmospheric agencies to which the expression occult emanations is applicable, and concerning which, the only thing occult about them is the insufficiency of ordinary chemical examinations to demonstrate their existence, though that existence admits of being demonstrated by extraordinary chemical means. Thus, for example, it is a well-authenticated fact, that the atmosphere of localities in which fever is endemic, usually contains minute traces of hydrosulphuric acid, and an odorous animal matter—substances which ordinary chemical processes fail to detect, but which, nevertheless, by the adoption of refined methods of investigation, can be proved to exist. The late Professor Daniell was of opinion that the much-dreaded fever of Western Africa was augmented by the diffusion, through the atmosphere of that coast, of minute traces of sulphuretted hydrogen. And the circumstances under which African fever originates, are perfectly consonant with the above theory. The disease only prevails now on the coast, its ravages being limited to a small belt, partly of land and partly of sea, Central Africa being comparatively exempt from its inflictions. Now Professor Daniell assumes the hydrosulphuric acid to be the result of decomposition, under a powerful sun, of matter borne seawards by the Niger and other great rivers, in connection with certain sulphates of sea-water. Be this theory true or the contrary, there can be no doubt as to the truth of the assumption which refers fever, when endemic, to a vitiated condition of atmosphere; which vitiation may be generally summed up as consisting of minute traces of hydrosulphuric acid, and of undetermined animalised matter.

Amongst other occult emanations, we can hardly refuse to admit the cause, whatever that cause may be, of intermittent fevers. The ultimate, if not the proximate, cause of this class of disease is so well known, that we may almost produce or banish intermittent fevers at pleasure. Given, heat and moisture continuously; ague almost invariably sets in, and continues its ravages as long as the conditions of heat and moisture co-exist.

What is the occult emanation here? What is the proximate cause of intermittent fever? Are we to attribute the disease to the conjoined evaporation of moisture, and heat *directly*, or to some further emanation to which these conditions give rise? Some pathologists have assumed that light carburetted hydrogen, or marsh-gas, as it is called, determines the disease; but the notion hardly coincides with known facts. The horizontal demarcation of altitude, above which the influence of ague cannot extend, is one of the most remarkable circumstances in connection with the disease; a difference of no more than ten feet in perpendicular height frequently corresponding with the region of fever and the region of salubrity respectively.

The mention of light marsh-gas naturally suggests the curious meteorologic phenomenon called Will-o'-the-wisp, or Jack-o'-lantern; of which gas, ignited, or, according to some, phosphuretted hydrogen gas, it is believed to consist. The Will-o'-the-wisp is not a very frequent phenomenon anywhere; but it is chiefly seen in marshes and churchyards—the latter locality apparently adding to the hypothesis that it is nothing more than ignited phosphuretted hydrogen gas. (See Fig. 66).

---

* A large collection of these curious substances may be seen in the British Museum.—ED.

Fig. 66.

Scarcely less accurately demonstrated than the locality of ague, is the locality of yellow fever, the focus of which may be considered to be Vera Cruz. Strange to say, the yellow fever is totally unknown on the Pacific coast of Mexico; it extends north as far as New Orleans, but rarely further. This condensation, so to speak, of febrile energy, points to some local cause—most probably of atmospheric origin; but chemistry has been unable to determine its nature.

Reflections similar to the above are suggested by the contemplation of several contagious diseases; of which the plague is a notable example. This scourge, although capable of spreading, from its normal focus, into regions wide apart, is in certain spots determined conditionally by the existence of some unknown circumstances; and these are most probably atmospheric. The plague never originates in very hot or very cold regions. Its focus of development is Egypt, Turkey, and the Levant, from which spots it can never be said to be absent altogether; but it only appears with violence at intervals of eight or ten years. Still more extraordinary than any of the preceding, are the varied conditions which give rise to Asiatic cholera. Unlike the plague and the yellow fever, and intermittents, this fell destroyer seems independent of region, recognisable limits, or other conditions of demarcation. From east to west it has extended its ravages, under every vicissitude of season and of clime. Much as there is mysterious in this—absolutely ignorant though we be of the proximate influences by the operation of which cholera and other epidemics are generated, important facts have, nevertheless, been made out; and their consideration tends to allay the extreme fear wherewith epidemics were formerly regarded. The most important fact in connection with this subject is, that epidemic influences, whatever their nature may be, only as a rule prevail over the weak, exhausted, ill-fed, or mentally broken-down individuals of a community; whence it happens, that in our metropolis the medical statician is enabled to lay his finger upon the regions of epidemic virulence, as he would on the locality of a mountain or a coal-field; and with equal satisfaction can he point to localities where epidemics formerly raged, but whence they have been banished by the art of man.

CLIMATOLOGY.—Many of the effects of heat, in its meteorological relations, have already been incidentally considered; but reference has not yet been made to the sources of heat, and to the means of its distribution over the surface of our planet. The term *heat*, as applied to the matter now under investigation, may be regarded as synonymous with elevation of temperature; and inasmuch as such elevation necessarily pre-supposes a condition of antecedent depression, we may, without impropriety, comprehend the meteorological effects of high and low temperatures (heat and cold) under one and the same generalisation.

Central Heat of the Earth.—The hypothesis was first propounded by Leibnitz, that the whole of our planet was once a molten mass, which, by the operation of cooling, uninterruptedly going on in successive ages, has become superficially encrusted over, the crust having become adapted to the necessities of animal and vegetable life. Various circumstances may be adduced in favour of this notion, more particularly the gradual increase of terrestrial heat downwards,* the heat of deep springs, and the evidences of fusion, in what geologists term the igneous rocks. Whether the idea of Leibnits hold good in its entire acceptation—that is to say, whether the centre of our planet be one molten mass or not—there can be little doubt that all positions of the globe, at a sufficient distance below the surface, have at some period been submitted to fusion. Nevertheless, at this time, the earth's central heat may be altogether ignored as tending to influence, in any manner, the climatic temperature of our globe. Primarily, the sun's direct rays determine the climatic temperature; those portions of the world's surface being most strongly heated on which the sun shines vertically—a remark which of course applies to the tropics; while those are least heated on which the direction of solar rays is most oblique—a remark which of course applies to the arctic and antarctic regions. But the latitude of a region has less connection with its climatology than might at first seem probable. The varying conditions of insular and continental sea-level, or elevated table-land, valley, or mountain, and still more the influence of thermal oceanic currents, have much to do with the climatic result. The high table-land of Mexico is strongly illustrative of the effect of mere elevation. The traveller who disembarks first on the Atlantic coast, and wanders inland, soon finds himself amidst all the luxuriance of a tropical forest, and surrounded by all the dangers of tropical existence. Still wending his way inland, he ascends a mountain elevation, well adapted to the growth of wheat, which refuses to grow anywhere in tropical lowlands.

Of all the causes which influence the climate of a region, that attributable to oceanic currents has been hitherto least studied; yet there is none which deserves to be scrutinised more narrowly. Looking at the enormous amount of oceanic surface in comparison with that of the land—taking into consideration the mobility of water, its susceptibility of thermal impressions, and the effect of the configuration of capes, headlands, and lines of coasts—the contemplative observer soon arrives at the deduction, that the ocean presents to him, at least, as wide a field for investigation as the atmosphere, and one scarcely less interesting. "The fauna and the flora," says Maury, "of the sea are as much the creatures of climate, and are as dependent for their well-being upon temperature, as are the fauna and the flora of dry land. Were it not so, we should find the fish and algæ, the marine insect and the coral, distributed equally and alike in all

* Careful observations have not confirmed this idea, as it has been found, in mines not at work, that there is no indication of an increased temperature as a descent is made. It is probable that the increase observed, in mines at work, may be due to the animal heat, lamps, &c., of the miners.—ED.

parts of the ocean. The polar whale would delight in the torrid zone, and the habitat of the pearl oyster would be also under the iceberg, or in frigid waters colder than the melting ice." The particles of water being mobile, the ocean, and indeed aqueous collections generally, are amenable to the same law of convection as was described when treating of the cause of winds. Hot water, being specifically lighter than cold water, must necessarily come to the surface; and for every current in one direction there must be a counter-current in the reverse direction, precisely in the same manner as occurs in the development of a wind.

Contemplating the ocean in its relation to the effects of heat and motion, our original ideas concerning that vast collection of waters are modified and expanded. Instead of regarding the ocean as one shapeless aggregation of briny water, it presents itself to us as an assemblage of many streams—a network of mighty rivers, each following its own course, each having its own temperature, its own flora, its own animals; and though devoid of palpable banks, scarcely less accurately defined on that account. Amongst all these oceanic currents, that denominated the gulf stream is the largest in size—the most important in the functions it subserves. The gulf stream is so far from being an imagining of mere theory, that the dark blue alone of its waters suffices to point out its limits and define its course.

All hypotheses as to the cause of the gulf stream are as unsatisfactory as the direction of the stream itself, and its benign influences are evident. The first idea relative to the gulf stream was, that it originated in the impetus given to the ocean by the disemboguement of the Mississippi; but placing out of consideration the inadequacy of this assumed cause, on account of the comparatively small amount of water which even a river so vast as the Mississippi can pour forth, it follows that, if really the cause of the gulf stream, the whole Gulf of Mexico should, in process of time, be found to contain only fresh, or, at the most, brackish water. This, it is scarcely necessary to remark, is not the case. Franklin advanced the theory, that the gulf stream is referable to the pressure of an inordinate amount of water against the coast of the Gulf of Mexico by the trade winds—an idea which is scarcely more tenable than the last.

Whatever the cause of the gulf stream may be, the direction of its current is obvious. Setting out from the hot regions of the Mexican Gulf and the Caribbean Sea, it proceeds northward to the great fishing-bank of Newfoundland, and thence to the shores of Europe, yielding up its heat to the genial west winds, and thus transferring a portion of the superfluous heat of the tropics to our colder shores. The greatest heat of the oceanic water of the Mexican Gulf is about 86°, or about 9° above the ocean temperature due to latitude alone. After it has ascended to 10° of north latitude, the gulf stream has still only lost 2° of the original heat with which it set out. Ascending northwards a distance of three thousand miles from its first origin, this mighty oceanic river still preserves the heat of summer even in winter time. It now crosses in an easterly direction, in a line coincident with about the fortieth degree of north latitude, spreads itself out, and imparts to Europe a genial temperature; which mere latitude could never give. The gulf stream now pauses in its course; it is split into two divisions by the British Isles, and two gulf streams are formed. Of these, one ends northward in the direction of Spitzbergen, while the second enters the Bay of Biscay—imparting temperature to each, and causing a soft mantle of vapour to arise, which, wafted landward, in its turn disperses the heat of the gulf stream far inland. Very little is known concerning the depth to which the gulf stream extends.

Lieut. Maury, of the United States naval service, assumes that depth to be two hundred fathoms; and, arguing on this assumption, he calculates that the amount of heat led away from the Gulf of Mexico by this oceanic torrent, raises, on a winter's day, the whole atmosphere which hovers over France and the British Isles, from the temperature of 32° F. to about 79°; in other words, from winter-cold to summer heat. But the genial influence of the gulf stream on the British Isles is more than this. Every western breeze that blows towards us crosses the mighty gulf stream, robs it of a portion of its heat, and comes towards our shores charged with warmth and laden with balmy moisture, clothing Ireland in a suit of green, and imparting a mildness to both England and Ireland which can be best appreciated when we consider that the coasts of Labrador, on the American side, and under the same parallel of latitude as England, are rigid with ice. In 1831, the harbour of St. John's, Newfoundland, was closed with ice as late as the month of June; yet the harbour of Liverpool, though 2° further north, is never ice-locked, even in the severest winters. By referring to any chart of isothermal lines, the current of the gulf stream, as just described, may be readily traced.

Although the climatic effect of the gulf stream is so advantageous to Western Europe, more especially to these isles, it is scarcely less advantageous to the regions whence it originates. If the gulf stream be the channel along which an amount of heat so considerable passes eastward, we may speculate on the consequences that would have arisen had the amount of temperature, now conveyed away, remained in the gulf itself. Even now the coast-line of this region is extremely hot and unhealthy; how much more hot and unhealthy would it have been had the gulf stream not existed!

Under-Current of the Gulf Stream.—As the trade winds are only an under atmospheric current, passing in an opposite direction to a current above; so the gulf stream is only the counterpart of an inferior current of cold water flowing back, to compensate for that which has departed. Not only does theory proclaim this, but it is borne out by experiment. At a mean depth of two hundred and forty fathoms, an under-current of water flows into the Caribbean Sea; and the temperature of this current has been found as low as 48°, whilst the surface-water had a temperature of 85°. At the depth of three hundred and eighty-six fathoms the temperature had fallen to 43°; and at the very bottom of the gulf stream the temperature was only 38°; hence the existence of the returning cold current is fully borne out. It comes, there is little reason to doubt, from the arctic circle; presenting the closest analogy to the lower aërial current which constitutes the trade wind.

The course and extent of the gulf stream were not generally known until the celebrated Dr. Franklin drew attention to the subject. The history of this event is worthy of narration, illustrating as it does the discriminating and logical mind of that extraordinary individual.

Happening to be in London in 1770, his opinion was demanded respecting a memorial presented by the Board of Customs at Boston to the Lords of the Treasury, stating that the Falmouth packets were generally a fortnight longer on their voyage to Boston than common traders were from London to Providence, Rhode Island: whence their request that the Falmouth packets might be sent to Providence instead of to Boston. "Franklin could not understand the reasonableness of this request, inasmuch as London was much further than Falmouth; and from Falmouth the routes were the same; so that the difference should have been the other way. Desiring a solution of his difficulty, he consulted Captain Folger, a Nantucket whaler, who chanced to be in London at the time. The whaler explained that the difference arose from the circumstance that Rhode-Island captains were acquainted with the gulf stream, while those of the English packets were not. The latter kept in it, and were driven back sixty or seventy miles a-day; while the former avoided it altogether."—*Maury.*

The manner in which the old whaling captain had been made acquainted with the existence, the extent, and the direction of this gulf stream, is curious enough in its way. His instructors were the objects of his search, *the arctic whales*—animals which, having a dislike to warm water, never enter the gulf stream, though they swim close up to it on both sides.

Franklin having extracted this intelligence from the whaling captain, got him to draw a chart of the gulf stream to the best of his ability. The chart was drawn; Franklin had it printed; and copies were sent to the Falmouth captains. They, however, were foolish enough to pay no heed to its teachings; nor did they profit for many years after by the knowledge of the gulf stream. Though the date of Franklin's discovery was 1775, yet a knowledge of the gulf stream was not generally diffused and acted upon until fifteen years later. Not the least extraordinary fact in connection with the gulf stream, is the sharpness of its line of demarcation. No river imprisoned between two scarped rocky banks could flow in channel more defined. "If," remarked the American author, Jonathan Williams, "these strips of water had been distinguished by colours of red, white, and blue, they could not be more distinctly discovered than they are by the thermometer."—"And he might have added," remarks Maury, "nor could they have marked the position of the ship more clearly."

The notion prevails among sailors that the gulf stream is the great storm breeder of the Atlantic—the father of storms; and, indeed, the tempests which follow in its course, or on its borders, warrant that designation. What are the indications of theory in this respect? Had the Atlantic been still an untravelled waste, and the existence of a gulf stream, such as we now know it, been propounded as the basis of discussion, would not the theorist have predicted that storms must originate in the meeting of the hot, moist atmosphere, which hovers over the ocean tract of seething waters, from the fiery shores of Mexico and the Caribbean Sea, mixed with the chilling blasts of the north? What torrents of water must result from the condensation of the tepid mists—what stupendous electrical force must be brought into operation!

If the gulf stream, by its impulsive flow, sometimes impedes the mariner, and drives his ship from the desired course, it nevertheless affords a compensation, not only in assisting to propel ships sailing in the direction of its course, but in affording a genial climate to the weather-beaten mariner, frozen and benumbed by the shivering blasts of the regions outside its channel. "No part of the world," says the writer, to whom we are largely indebted for much that in these pages concerns ocean currents and ocean climatology—"no part of the world," remarks Maury, "affords a more difficult or dangerous navigation than the approaches of our (the American) coast in winter." Before the warmth of the gulf stream was known, a voyage for this reason from Europe to New England, New York, and even to the capes of the Delaware or Chesapeake, was many times more trying, difficult, and dangerous than it now is. In making this part of the coast, vessels are frequently met by shore-storms and gales which mock the seaman's strength, and set at nought his skill. In a little while, his bark becomes a mass of ice, and his crew frosted and helpless. She remains obedient only to her helm, and is kept away for the gulf stream. After a few hours' run she reaches its edge, and almost at the next bound, passes from the midst of winter into a sea at summer-heat. Now the ice disappears from his apparel: the sailor bathes his stiffened limbs in tepid water; feeling himself invigorated and refreshed with the genial warmth about him, he realises out at sea, the fable of Antæus and his mother Earth. He rises up and attempts to make his port again; and is again as rudely met, and beaten back from the north-west; but each time that he is driven off from the contest, he arises forth from this stream, like the ancient son of Neptune, stronger and stronger; until after many days his freshened strength prevails, and he at last may enter his haven in safety; but in the contest he sometimes falls to rise no more, for it is often terrible. Many ships annually founder in these gales; and we might name instances, for they are not uncommon, in which vessels bound to Norfolk or Baltimore, with their crews enervated in tropical climates, have encountered, as far down as the Cape of Virginia, snow-storms that have driven them back into the gulf stream, times and again; and have kept them thus out for forty, fifty, and even for sixty days, trying to make an anchorage.

Nevertheless, the presence of the warm waters in the gulf stream, with their summer-heat in mid-winter, off the shores of New England, is a great boon to navigation. At this season of the year especially, the number of wrecks and loss of life along the Atlantic sea-board are frightful. The month's average of wrecks has been as high as three a-day. How many escape by seeking refuge from the cold, in the warm waters of the gulf stream, is a matter of conjecture. Suffice it to say, that before this temperature was known, vessels thus distressed knew of no place of refuge short of the West Indies; and the newspapers of that day—Franklin's *Pennsylvania Gazette* among them—inform us, that it was no uncommon occurrence for vessels bound to the capes of Delaware in winter to be blown off, and to go to the West Indies, and there wait for the return of spring, before they would attempt another approach towards their destination.

The gulf stream is the largest known oceanic current; it has been perhaps more fully studied than any other, and its teachings may, therefore, be appropriately regarded as the type of the rest. We have seen how powerful and extensive are its effects; we have seen a few of the purposes to which it ministers. The ocean is full of streams similar to this, each taking its well-defined course, carrying its own temperature, clad with its own fauna and flora, peopled with its own denizens. Thoughts like these prove how false and unfounded is the expression, *ocean waste*, so commonly applied. The ocean has its regions, its valleys, and its mountains—climate and varied inhabitants—no less than the earth.

OTHER OCEANIC CURRENTS.—*The Mediterranean.*—It has long been known that an upper or sailing current constantly sets into the Mediterranean through the Straits of Gibraltar. What, then, becomes of the water of the current? That water must either be dissipated by evaporation, or there must be a second or back-current.

The existence of this under-current was first demonstrated very curiously in 1712. At that time, France being at war with Holland, M. L'Aigle commanded a French privateer, called the *Phœnix of Marseilles.* Near Ceuta, this privateer gave chase to a Dutch ship bound to Holland—came up with her, delivered one broadside, when the Dutch ship went down. A few days later, the sunken ship, with all her cargo of brandy and oil, came to light again; but this took place on the coast of Tangier, at least four leagues westward of the place where the ship went down, and in a direction quite opposite to that of the upper or navigable current. This well-authenticated case was communicated to the Royal Society in 1724.

Currents of the Red Sea.—Precisely similar to the Mediterranean currents, just described, are those of the Red Sea. The necessity of a free change of waters here is even more decided than in the Mediterranean; the sea is not only shallower, and subjected to a more powerful evaporation, but its waters are not freshened by the afflux of any rivers. It has been calculated by Dr. Buist, that, taking into consideration the mean evaporation on every part of the surface of the Red Sea, a sheet of water, eight feet thick, and equal in superficial area to the whole extent of the surface of that sea, is raised in vapour annually. When this enormous rate of evaporation is considered, the necessity for a continuous interchange of water between the Red Sea and the external ocean will be evident. If the Red Sea outlet were choked up, so that ingress and egress were no longer possible, the evaporation of about a thousand years would, it is calculated, completely dry it up.

Currents of the Indian Ocean.—Many thermal currents originate in the Indian Ocean. Amongst the foremost of these is the Mozambique current; another of these currents, first escaping from the Straits of Malacca, and being swollen by warm streams from the Java and Chinese Seas, flows out into the Pacific between the Philippines and the Asiatic shores. Passing thence towards the Aleutian Isles, it ultimately loses itself on the north-west coast of America. Meteoric conditions like those which mark the course of the gulf stream, also mark the course of this. Fogs and mists follow in its track, and storms are also generated on the bank of this oceanic river.

For a fuller account of oceanic currents than is consistent with the limits and objects of these pages, we must refer the reader to treatises which deal with the special matter, and, above all, to the work of Lieutenant Maury, of the United States' service, to whom meteorologists are under deep obligations, for his contributions to their knowledge of ocean phenomena.

In contemplating these oceanic currents, of which the gulf stream may appropriately be considered the type, we cannot fail to be impressed with an evidence of design, where, at first, no design would seem to exist. These oceanic currents originate in, and are determined by, a peculiar conformation of the land. Now, what can be more seemingly irregular or capricious than the shape of land? If dropped down into the ocean at random, or elevated by a subterranean power equally capricious, the crust line of islands and continents, the solid blocks of our planetary crust, could not well be more irregular than they are; and yet how practically harmonious is the relation between land and water: how well adjusted the powers of each—how well adapted to the mutual benefit of mankind! It appears an unimportant matter when, in the map of the world, we skim our eye over the southern hemisphere of the terrestrial globe; there we behold the limits of the African and American continents in their furthest extent; but how terribly would the locomotive faculty of mankind have been impeded had either continent expanded itself to the south pole, or even traversed much further south than is actually the case!

In connection with the subject of ocean currents, the effect of aqueous temperature on the ocean's denizens, deserves a passing word of remark further than has already been devoted to it. In the Caribbean Sea, and other ocean cauldrons, where stores of heat are accumulated for distribution in regions far away—in the hot currents which originate in these tepid sources of oceanic rivers, there are a fauna and a flora: the fauna no less marked than we see on tropical lands. There grows the coral, there swims the shark; and thousands of shelled mollusca, of gorgeous colour and enormous size, revelling in oceanic forests of rank and bulky growth, represent the land forests, and their denizens of corresponding climes. But, though grandeur and beauty be the characteristics of these warm ocean spots—the thermal ocean-tropic (if the propriety of that expression be allowed)—it is the colder oceanic currents which support the form of animal life most useful to man. Strange though the circumstance may appear, it is no less true, that the fish of the hot parts of the world are always indifferent as food. This fact is strikingly illustrated in the Mediterranean. The temperature of the Mediterranean water is usually four or five degrees above the temperature of the external ocean; and what a difference in the fish! Whoever has compared the edible fish of the Atlantic with those of the Mediterranean, will be at no loss to admit the vast superiority of the former. The naturalist does not require to be informed, that not only are Mediterranean fish inferior to those of the Atlantic, but they are, for the most part, of different species.

Let us now take a glance at the locality of the principal fishing regions. Limiting ourselves to two of these, they would unquestionably be the fishing-grounds of Newfoundland and Japan. The former is the better known of the two, though, perhaps, the latter is the more considerable, seeing that the natives of Japan are debarred from the use of animal food by their religion, although the eating of fish being permitted, they are all ichthyophagi; and, notwithstanding the dense population of the Japanese islands, their inhabitants, though fish-eaters, are abundantly fed.

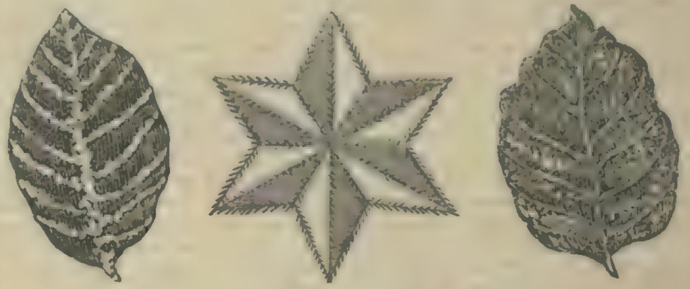
Between the gulf stream and the coast is a narrow band of cold water: here are the fisheries of Newfoundland. Between the China current, as it is denominated, and flowing in an opposite direction, is the cold current, in which the Japanese fisheries are prosecuted. These are the two most prominent examples, and they will be found to present the type of many others.

COLD, AND ITS EFFECTS.—Under the heads of Snow, Hail, and Hoar-Frost, some of the meteorologic effects of cold have been already described. The phenomena due to this powerful agency are, however, so numerous and so important, that it may be well to make the subject of cold a matter of special contemplation. If, casting our eye over the field of nature, we endeavour to select the most prominent results of cold, they will be found to relate to the departure from an ordinary law, which Nature has made in the expansion of water during the act of freezing.

The term *freezing* is but a general expression for the act of solidification by cold. Popularly, the term is only applied to solidified water; but this is altogether a conventional acceptation of the word. We are justified, then, in comparing the act of solidification of water with the act of solidification of any other fluid, and seeing to what extent the conditions which regulate one also regulate the other.

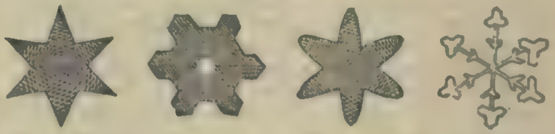
When the temperature falls to 32° F., water ceases to be liquid, and becomes ice; the weather is said to be frosty, and water is said to be frozen. Whatever water be contained in the atmosphere at the freezing temperature, is deposited in the solid form of hoar-frost, the particles not being irregular, but bounded by definite mathematical outlines—frequently giving rise to forms of great beauty, especially on window-panes, blades of grass, and leaves (Fig. 67). These forms are similar, in general contour, to those of well-formed snow-flakes (Fig. 68), but far more beautiful, and, like snow-flakes, prove that frozen water is a crystalline body, and that it crystallises in forms belonging to the rhombohedral system.

Fig. 67.



But the most important point connected with the freezing of water, and without which our globe would cease to be habitable, is this:—Water, during the act of freezing, expands, and thus becomes specifically lighter. Ice, therefore, swims on water; it cannot sink. How stupendous are the consequences of this departure from the law of freezing! Had it so happened that frozen water, like frozen mercury, were heavier than the corresponding liquid material, each frozen sheet of water would sink as soon as formed; and thus, being far removed from the melting influence of solar rays, the production of ice would have been accumulative, and the ocean, long ere this, would have been completely ice-locked.

Fig. 68.



In tracing, hypothetically, an assumed aberration of Nature to its consequences, the mind is speedily entangled and lost in the chaos of jarring effects. The speculative meteorologist finds himself unable to thread the labyrinth of causation here involved. Having shown that the ocean would have been full of ice, had the ordinary law of solidification not been departed from in the case of water, it is perhaps unnecessary to follow the development of our hypothetical case further. That ocean life must have been destroyed is evident; that the sea's liquid highway would have ceased to be, is only a figurative expression for a frozen ocean. But would what is now the solid land have then served the purposes of animal life? Where could the rivers have flown, had the ocean been a block of ice? or would not the rivers have remained frozen too, seeing the vast cooling power of a frozen ocean? It is easy to see that, under such circumstances, our planet would have been totally unfit to be a resting-place for its present denizens had the freezing of water not assumed a departure from a law, though it be impossible to imagine all the consequences that would have resulted.

The same expansive force of water during the act of freezing, by the operation of which it is rendered specifically lighter than water, subserves many important purposes in the world's economy, besides floating the ice. Water percolating into the fissures of rocks, and being subsequently frozen there, displays its irresistible force by splitting large rocks into fragments, and disintegrating their fragments. In this way hard and sterile districts become covered with useful soil, in which low forms of vegetable life can take root; and by their subsequent decay, contribute the elements necessary to the support of higher forms of vegetation.

Relation of Climate to Organic Development.—The naturalist, who, in his desire to see, as in a dioramic picture, the wonderful characteristics of animal and vegetable types, sighs to think that a vision so glorious will never pass in reality before his gaze, may at least console himself with the assurance of that great master of philosophic travel, Humboldt, that it is in the power of man's creative faculty, aided by philosophy, to imagine those striking types in the vividness of their truth, gladdening the closet with ideal images of the living features of Nature.

Even in the narrow region of European travel, the intelligent observer will not fail to see distinctive physiognomies. Passing from the cold green-sward and modest vegetation of our own Isles to the Mediterranean shore, a striking change in the aspect of nature meets the view. The sturdy oaks and elms of our own forests disappear; the absence of smaller grasses removes the green carpet of our meadows; tall graminaceæ spring up; the aloe and the prickly pear bespeak a mixed condition of heat and drought; and the date-palm, barely acclimatised, gives some faint notion of what the characteristics of a tropical forest must be. "It would be an enterprise worthy of a great artist," says Humboldt, "to study the aspect and the character of all these vegetable groups, not merely in hot-houses, or in the description of botanists, but in their native grandeur in the tropical zone. How interesting and instructive to the landscape painter would be a work which should present to the eye, first separately, and then in combination and contrast, their leading forms! How picturesque is the aspect of tree ferns, spreading their delicate fronds above the laurel-oaks of Mexico; or the groups of plantains overshadowed by arborescent grasses! It is the artist's privilege, having studied these groups, to analyse them: and thus, in his hands, the grand and beautiful form of nature which he would portray, resolves itself, like the written works of men, into a few simple elements."

When the meteorologist has exhausted his knowledge in the laying out of climatic groups—when he has placed in correlation, conditions identical, as he thinks, in every respect—the growth of vegetable forms demonstrates his inability to comprehend many hidden secrets of nature, which their delicate organisation makes known. European olive-trees grow luxuriantly at Quito, but they bear neither fruit nor flowers; and a similar remark applies to walnut-trees and hazel-nuts in the Isle of France. In India, the bamboo flowers luxuriantly; but in South America, where it flourishes equally well, so far as general aspect of growth is concerned, so rare an event is the infloration of the bamboo, that during a four years' residence in South America, Humboldt was only enabled to obtain blossoms once. But, perhaps, a still more remarkable example of luxuriant growth, without inflorescence, is furnished by the sugar-cane. The West Indies have come to be considered as the region *par excellence* of the sugar-cane; yet it seldom bears flowers there—nor indeed does it in any part of the American continent; thus furnishing a strong presumptive argument in favour of the theory, which asserts, that no variety of the sugar-cane is indigenous to the New World.

CHAPTER IV.

PRACTICAL METEOROLOGY.

So many amateur meteorologists are now springing up in every direction, that it may be desirable to point out the precautions and reductions necessary, in order to render the raw observations useful to science. The present paper is, therefore, written to enable the amateur, with as little trouble as possible, to reduce his observations to useful results.

To the non-meteorologist, such terms as "adopted mean temperature," "elastic force of vapour," "reduced barometric," &c., unexplained, serve rather to perplex than to enlighten, or point out that care has been bestowed upon the observations, and that the requisite reductions and precautions had been adopted.

The first duty of an observer is to procure good instruments, and to place them in such positions as may be deemed least likely to be affected by local circumstances, such as heat from a fire, draughts round a building, &c. Much time is frequently thrown away by using imperfect instruments. When a person purchases a thermometer, he is too apt to consider it correct; whereas, in many instances, it is far from being accurate. Mr. Hartnup, of the Liverpool Observatory, in his last report, mentions, that among the thermometers used by the captains of the merchant service, an error of 4° or 5° is quite common; even a thermometer fitted up for taking the temperature of water at different depths, and professing to have been made with care, was found to be 8½° in error in one part of its scale. The most curious instance, however, was a barometer which had the following errors:—

At 28	inches	was	— 2·22	inches	of the standard.
At 28½	,,	,,	— 1·88	,,	,,
At 29	,,	,,	— 0·73	,,	,,
At 29½	,,	,,	— 0·30	,,	,,
At 30	,,	,,	— 0·02	,,	,,
At 30½	,,	,,	+ 0·33	,,	,,
At 31	,,	,,	+ 1·07	,,	,,

The whole yearly range of pressure seldom reaches two inches, whilst the range in error of this instrument was 3·29 inches.

Meteorological Observations.—In order to place this portion of the subject in as clear a light as possible, let us suppose that daily observations are made of the barometer and its attached thermometer, of the temperature of the air, of the wet bulb thermometer, of self-registering maximum and minimum thermometers, of the amount of rain, amount of ozone, temperature on the grass and sunshine, state of electricity, amount and class of cloud, direction and force of winds, and state of the weather. Let us further suppose that two observations are taken daily, the hours of observation being 9 A.M. and 10 P.M.

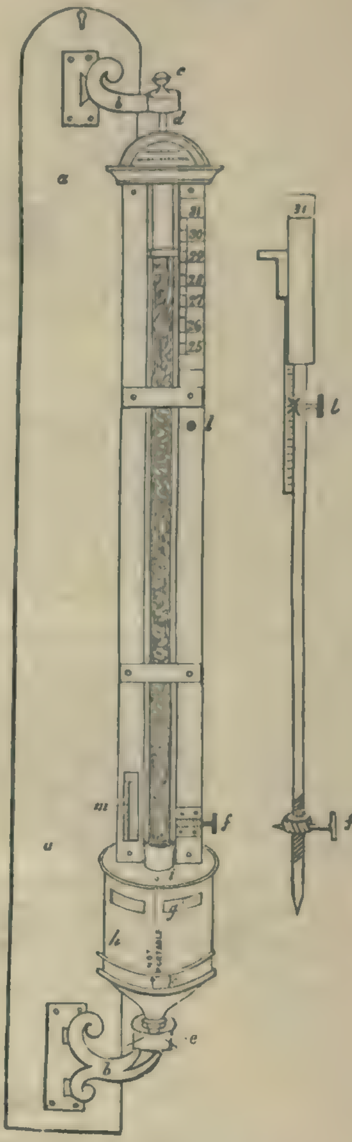
The Pressure of the Air.—The barometer is the instrument by which the alterations in the weight of the air are ascertained. The gravitation of the earth exerts a certain pressure, which would always be alike, were it not that lateral disturbances had the power of removing a portion of that pressure, and adding it elsewhere. Thus, suppose the average pressure to be 29½ inches; if the barometer be seen to rise to 30 inches, it is certain that, in another portion of the earth, a corresponding fall has taken place to account for this change: however, as it is not our object to enter into the physical and local changes of the weather here, we shall at once proceed to describe the reductions that are requisite.

It is essential to correct observation, that the barometer used be a standard instrument. The ordinary instruments are useless, owing to the friction of the mercury against the sides of the glass in small tubes; the impossibility of applying the reduction necessary to *correct*, for the alteration of the height of mercury in the cistern, with the common wheel barometer, owing to a rise and fall in the tube; and, further, because if errors occur in this barometer, they are increased by the circumstance of the index of the wheel barometer being a long arm worked by a small wheel, thus multiplying all the errors.

The Standard Barometer should have a tube of not less than $\frac{4}{10}$ths of an inch in diameter; and the nearer it approaches to $\frac{6}{10}$ths the better, as the correction requisite for the friction against the sides of the glass, rapidly diminishes with an increase in the size of the tube. This is the correction for capillarity, which is additive. The base of the tube should be plunged into a cistern of pure mercury, and the scale of inches should have a rod attached, terminating in an ivory point, so contrived as to be moved by rack-work until the point *just* touches the surface of the mercury. This is requisite, in order that the measurement may be made from the surface of the quicksilver in the cistern. Suppose we either neglect this operation, or that the barometer is one not capable of having it applied; and let us further take a reading without reference to this correction, after a sudden change in the barometer; this reading may be represented as 30·036 inches. On bringing the ivory point down to the mercury, this second reading may be 30·074 inches: thus exhibiting an error, from the want of this precaution, of ·038, or nearly four hundredths of an inch. The thermometer fitted for use should have its bulb plunged into the cistern of mercury, otherwise it will not give the temperature of the mercury itself, but merely show the heat of the apartment in which it is placed. Such an instrument is produced by many of the leading London makers: of similar kind are those made for the Royal Society, Greenwich Observatory, Admiralty, and the British Colonial Observatories.

Description.—*a* (Fig. 69) is the mahogany board to affix against the wall; *b*, brackets which support the barometer, between which it is capable of being revolved so as to observe the light on the surface of the mercury; *c*, a vase, which unscrews, to allow of the socket *d* being removed, to receive the upper end of the barometer; *e*, the adjusting screws for shifting the lower centre, by which the barometer is to be made exactly perpendicular: to accomplish this, the ivory point is to be adjusted to the surface of the mercury; the barometer gently turned between the two brackets; and if, in any position, the point should be elevated from the surface, or depressed into the mercury, the screws must be altered accordingly, until the point coincides in every position; *f*, the key by which the ivory point is adjusted—the ivory point being a termination of the brass scale marked off at the temperature of 32°, and which is adjusted by means of a tangent screw; *g*, the glass part of the cistern, through which the surface of the mercury and ivory point are seen; *h*, the cistern; *i*, the screw, which is to be loosened when the barometer is fixed, to admit the atmospheric pressure; *k*, the movable part of the cistern, on which the index ↗ is engraved; *l*, the key by which the Vernier is adjusted; *m*, the thermometer dipping into, and showing the temperature of the mercury.

Fig. 69.

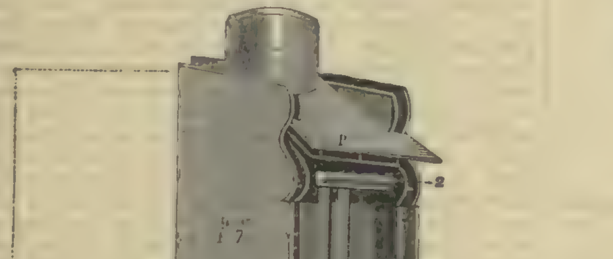


This barometer is necessarily expensive. Modifications of this standard are made by many London instrument-makers; and these are more reasonable in price, answering remarkably well, though possibly not equal to Mr. Newman's standard. Having procured a barometer, it should be compared with the Standard, in order to ascertain its index error. The apartment in which it is kept must not be subject to great changes of temperature; one with a window facing the north is to be preferred; and the instrument should hang where there is a strong light, but an outer wall should be avoided.

THERMOMETERS.—There are various constructions of instruments for ascertaining the temperature of the air; of these the mercurial ones are the best. Thermometers for comparison require to be placed upon a proper stand, as the errors arising from peculiarity of situation, from radiation, absorption of heat, &c., will alter the reading very materially. There are two forms of stand—the one constructed by the late Henry Lawson, Esq., F.R.S.; the other by James Glaisher, Esq., F.R.S.

Thermometer-Stands.—In comparing the readings of one thermometer with any other, it is requisite that each instrument should be placed, as much as possible, in a similar manner; without this uniformity, no deductions can be drawn with any claim to accuracy. In looking to the situation of instruments used by persons who have not been aware of the necessity of providing themselves with a thermometer-stand, some will be found facing the north, others the south, south-east, north-west, and, in short, every point of the compass. Again, some are placed from one to five feet from the ground, others ten to twenty feet; some in the angle of a large building; others exposed to the sun's rays, either during the morning or the evening; some touching a wall, others at a distance from one; in short, the situations vary in as great a degree as the temperature deduced from the observations made by them. To obviate these sources of inaccuracy, the late Mr. Lawson constructed his "Thermometer-Stand," a sketch of which is given below (Fig. 70).

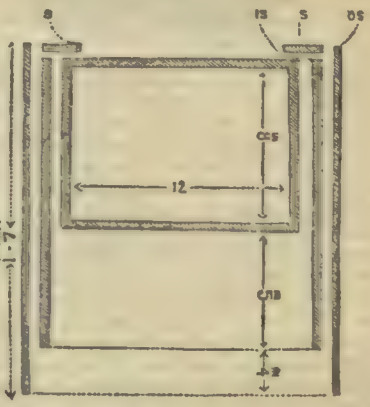
Fig. 70.



This stand consists of a frame, which has been found to answer the intended purpose very well. It is composed of *white deal* boards, and can be constructed by any carpenter. It consists of an oblong trunk T, 12 inches by 8 inches outside measure; to the opposite side of which are nailed boards *b b*, at the distance of three-quarters of an inch, and projecting about six inches from the trunk towards the north. Outside of these are nailed other thin boards *c c*, full half an inch distant, and projecting about four inches beyond the last-mentioned boards, also towards the north. These sides or shades being multiple, prevent the sun from heating the interior of the stand, where the thermometers are placed. The top, or pent-board, P, is made double; and the boards are placed full three-quarters of an inch distant from each other, and come forward so as to overhang, by a full inch, the Night Index Thermometer, placed immediately beneath, for the purpose of preventing rain or dew from falling perpendicularly upon the bulb of the thermometer. The legs, L L, of the stand, are merely the continuation of the sides of the trunk. The board or feet, F F, are loaded or fixed to the ground, to sustain the force of the wind. The interior, T, is blackened to prevent strong reflections of light.

Fig. 71 is a ground-plan of the machine, which will prove sufficiently clear to any intelligent workman for its construction. The sides (and wood-work generally) are of half-inch white deal. The distance or space between the sides of the trunk T and the board or inner side, *i s*, is three-quarters of an inch; and the distance from that board to the outer side, *o s*, is full half an inch. The narrow boards, *s s*, are to be nailed, with studs intervening, to the middle board or side, *i s*, and are for the purpose of preventing the sun from shining between the trunk, and the sides *o s* and *i s*, when near the meridian. The sides are fixed, one upon the other, at the required distance (viz., three-quarters of an inch and half an inch), by numerous wooden studs, about three-quarters of an inch in diameter; and the nails or screws passed through the sides and studs, fix the whole firmly together. The whole is to be painted white, and no other colour, except the face of the trunk T, which may be black, as mentioned already.

Fig. 71.

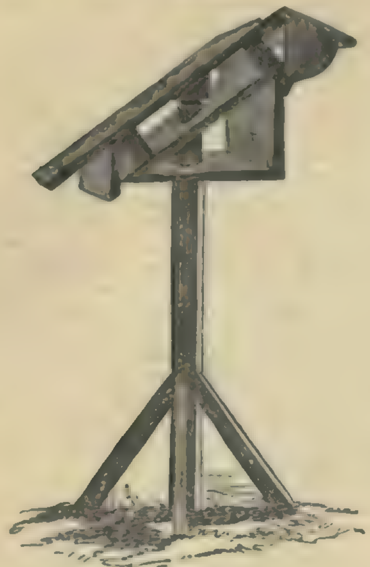


This thermometer-stand can be placed in *any* eligible spot that may suit the convenience of its owner; its four sides should face the cardinal points, commanding therefore a true north and south aspect. It can be visited on every side, and be free from all surrounding objects. The thermometers used can be read off with the greatest facility, and the whole will be at a known distance from the ground. Those instruments placed on the south face will have the meridian sun, and those on the north face will be always in the shade, in consequence of the projecting wings. The arrangement can be employed by any meteorologist, wherever residing; it is of a determinate form, height, and size; it is not costly, but firm, and can be placed on any open spot that may be thought eligible for its use. The instruments may be read off with the greatest promptitude, so as to prevent or reduce errors arising from the person of the observer being too long in the vicinity of the thermometers. By the general adoption of this stand, instruments placed upon it will all be used or observed under similar circumstances, and deductions from them be more correctly drawn than where there is no other used. It follows, that observations made by individuals wherever residing, either in Europe, Asia, Africa, or America, if drawn from instruments thus similarly placed, can be compared one with the other, with far less chance of error than has hitherto been the case.

Mr. Glaisher, F.R.S., has likewise constructed a stand, differing from the one just described, but which is also an excellent contrivance. (See Fig. 72.)

Rutherford's Thermometer.—The mercurial thermometer of Rutherford's construction, pushes a registering-pin before it as the mercury expands by heat; on the

Fig. 72.



air becoming cooler, the mercury contracts, leaving the registering-pin at the point of maximum heat. One objection to this instrument will always be felt—*i. e.*, the pin is not unlikely to become entangled with the mercury, especially if the mercury should oxidise.

It is very desirable to incline Rutherford's maximum thermometer from the horizontal position, so that the bulb shall be slightly the highest, in order that the thermometer may have the assistance of gravitation in pushing the pin forwards. Within the last fifteen years, many of Rutherford's construction have, at the Highfield House Observatory, become useless, owing to the registering-needle becoming entangled with the mercury. Two thermometers, however, of this construction deserve to be noticed—the one purchased of Dollond, and the other of Bennett: they have done their duty satisfactorily, and are at the present time in perfect working order.

Negretti's Patent Maximum Thermometer.—Too much praise cannot be given to this ingenious invention, which, from the circumstance of doing away with the registering-needle, prevents the possibility of the instrument getting out of order. Since the invention, half-a-dozen of these thermometers have been constantly employed by us without any derangement. The principle of the thermometer is this:—A small piece of enamel is pushed into the thermometer tube near the bulb, and the tube is then bent so as to secure it in its place; if the thermometer act once, it will continue to act until the instrument is broken. As the temperature rises, the mercury will flow over this enamel; yet, on the air becoming colder, the contraction will only take place below this point, the whole column of mercury in the tube being left to mark the maximum heat. It is only requisite to turn the thermometer in a vertical position, and give it a gentle shake, when the mercury will descend, and flow over the obstruction, which, in the horizontal position, had prevented it from returning into the bulb of the thermometer.

Phillips's Construction of the Maximum Thermometer.—This, the invention, of Professor J. Phillips, F.R.S., also records without a registering-needle. A small bubble of air is passed down the tube, and a portion of mercury is made to remain above this bubble; as the air increases in temperature the whole column rises; yet, when it cools, the mercury only falls from below where the bubble of air is situated. It is an instrument liable to get out of order in travelling; yet, when once properly fixed, does its work well. In consequence of the bubble of air expanding with an increase of temperature, a slight error will be occasioned, and the thermometer will read a little too high in warm weather, and the reverse in cold.

The Minimum Thermometer, until lately, has been filled with *spirit* instead of *mercury*, with a slender glass pin floating in the liquid. This pin is carried down with it to the lowest point; on the temperature rising, this pin is left behind, and thus marks the coldest point. Like the maximum thermometer, gravitation should be allowed to assist the descent of the pin, which is accomplished by slightly lowering the bulb from the horizontal position. The best that we have received have been from Messrs. Negretti and Zambra; in these the pin is much longer and more slender, and they very rarely get out of order. A disadvantage will always be felt with spirit thermometers, for their action differs from those filled with mercury.

The Mercurial Minimum Thermometer.—Meteorologists have for some time urged the opticians to invent a mercurial minimum thermometer, an invention which long seemed almost to be an impossibility. However, such an instrument now exists—thanks to Messrs. Negretti and Zambra. A thermometer, with a large tube, is placed in a vertical position; in it is a slender, pointed needle, which is brought down to the surface of the mercury; quicksilver, being heavier than the needle, the latter is held above it; yet, the needle being pointed, plunges a small, but sensible, distance in the mercury, which it invariably does by the side of the glass of the thermometer tube. This being the case, the needle will descend to the lowest degree of cold; on the thermometer rising, the mercury presses the needle to the glass, and rises up by the side of it, instead of raising the needle. Four months' working of this thermometer has proved it to be a valuable invention. The instrument must come into general use among meteorologists.

The Solar and Terrestrial Radiation Thermometers are made entirely of glass, the scale being engraven upon the bulb itself. For thermometers continually exposed to damp, the swelling of the wood, and the obliteration of the index thereon, have been felt a great annoyance; consequently, the substitution of glass for wood has been hailed with pleasure by meteorologists, independently of its great improvement in a scientific point of view.

The white enamel placed along the back of the thermometer tube—an invention of Negretti and Zambra's—is now becoming generally adopted; the improvement is at once manifest on inspecting two instruments, the one with, and the other without the enamel.

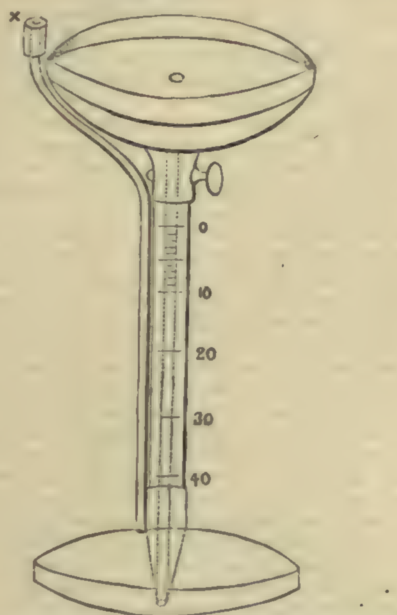
The Wet and Dry Bulb Thermometer.—The dry bulb is the ordinary thermometer; and the wet bulb differs only in having the bulb enclosed in a muslin bag, with a cotton-wick conductor to a cup of water, so that it shall always be wet from the capillary action of the cotton conveying the water constantly to it. If the muslin bag were attached to self-registering, instead of ordinary thermometers, the greatest heat and cold of the wet bulb would be obtained—an important addition to the meteorological instruments, yet one almost unknown. The muslin and cotton should be changed every month.

Bennett's Photographic Wet and Dry Bulb Thermometer is an additional evidence of the close relationship between heat and light. In this most ingenious contrivance, *light* is incessantly writing down the *heat* of the air. It is simply requisite to place a sheet of photographic paper upon the roller once a-day, in order to record every change in temperature of the wet and dry bulb for the twenty-four hours. This is, indeed, a triumph of science.

EVAPORATORS.—Having had constructed gauges of various sizes, we are enabled to speak with confidence as to their working. The water in gauges under eight inches in diameter becomes too warm, owing to the small quantity that can be contained in them; consequently, an excess of evaporation results. There are two gauges to be recommended: the one Newman's, and the other Negretti's. These gauges work well. Newman's is a very convenient and ornamental instrument, having a graduated glass tube. It consists of a short cylinder, twelve inches in diameter, having connected with it, by means of a stopcock, a glass tube graduated to hundredths, and terminating in a lower vessel, which will contain a sufficient quantity of water, to be raised by artificial pressure into the upper one, for exposure to the atmosphere.

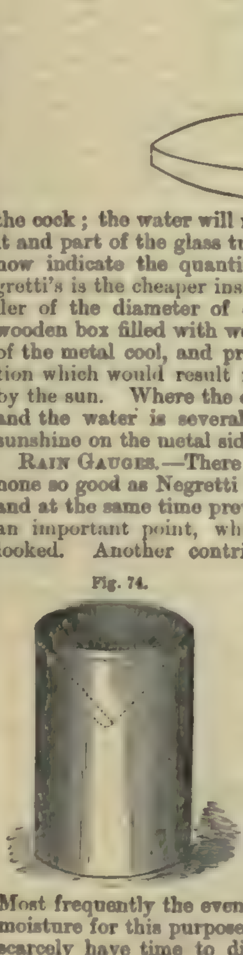
To use the apparatus, pour water into it until it rises to the zero in the glass tube; then, by means of a syringe, force the air through the tube × (Fig. 73) into the lower vessel, so as to raise the water into the upper one to any height you please. Now shut off the stopcock beneath to retain the water in the upper vessel; then, having exposed the apparatus for any length of time required, open the cock; the water will run into the lower vessel, filling it and part of the glass tube, the divisions of which will now indicate the quantity of water evaporated. Negretti's is the cheaper instrument, being simply a cylinder of the diameter of eight inches, which fits into a wooden box filled with wet sand; this keeps the outside of the metal cool, and prevents that excessive evaporation which would result from the heating of the metal by the sun. Where the diameter of the gauge is large, and the water is several inches deep, the effect of the sunshine on the metal sides is not felt.

Fig. 73.



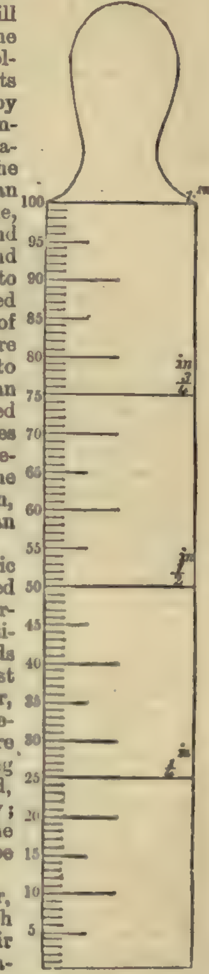
Rain Gauges.—There are several constructions, yet none so good as Negretti and Zambra's, which is simple, and at the same time prevents any loss by evaporation—an important point, which has been too much overlooked. Another contrivance is that of a cylindrical vessel of brass or zinc (Fig. 74); the latter would be the cheapest, and answer all purposes equally well. Into this cylinder, a funnel, with its tube bent, fits tightly: the diameter should be eight inches, and the tube about an inch in length. The object of this bent tube is to prevent evaporation taking place from the surface of rain collected in the rain gauge, for a few drops of water will hermetically seal the opening from the escape of vapour. Most frequently the evening dews will deposit sufficient moisture for this purpose, which the heat of the day will scarcely have time to dissipate, before night brings a fresh supply.

Fig. 74.



The readiest mode of measuring the amount deposited in the gauge, is by procuring another cylindrical vessel, or measure, which is exactly four inches in diameter, and four inches deep: this, when quite full, will just contain an amount equal to the deposit of an inch of rain as collected in the eight-inch gauge. Parts of an inch can be measured by plunging a rule (Fig. 75) perpendicularly to the bottom of the measure, the portion wetted by the water being the decimal part of an inch required. Having made a rule, exactly four inches in length, and divided it into ten equal parts, and each division being subdivided into ten others, a measure is obtained which will read off the hundredth of an inch; and, as the divisions are tolerably wide, it is not difficult to estimate even to thousandths of an inch. Thus, for example, as used in the measure, the rule four inches long, divided into 100 parts, represents one inch of rain fallen; the score at twenty-five, or one inch, represents a fall of a quarter of an inch, and so on.

Fig. 75.



Electrometers. — Atmospheric electricity has been much neglected by meteorologists; it is an important item of meteorological investigation. There are several methods of studying the subject: the most simple is Glaisher's electrometer, which, being portable, should become generally adopted. Where there are the conveniences for having exploring wires, properly insulated, the results are more satisfactory; and when this plan is adopted, the following electrometers should be used:—

1. De Saussure's Electrometer, which consists of two fine wires, each terminated by a small pith ball, their expansion being measured by a graduated scale.

2. Volta's Electrometer, consisting of two thin stems of about two inches in length, and fitted to a metal rod by small rings.

3. Singer's Electrometer, consisting of two slips of gold-leaf. For stronger electricity, a pair of Dutch-gold leaves become a useful addition.

4. Zamboni's Dry-pile Electrometer. It is a single gold-leaf suspended from the conducting-rod between two dry piles, the negative pole of the one and the positive of the other being uppermost. This shows whether the electricity is positive or negative.

For powerful electric storms, the self-registering apparatus belonging to the atmospheric recorder is very useful; whilst a nicely-arranged electrical bell will be a means of warning the observer that his presence is required in the electric-room.

The effect of a thunder-storm, when three or four miles distant, as shown on these electrometers, is exceedingly interesting. It is not only possible to witness the instantaneous convulsion caused by a flash of lightning, at least twenty seconds before the peal of thunder occasioned by it is heard, but it is also possible to know, several seconds before a flash takes place, that one is about to occur.

The beneficial effects of electricity on the vegetable kingdom are of a character so apparent, that any extended researches upon the branch of Meteorology calculated to throw additional light upon the subject is very desirable.

The Gimbal Vane.—This is a wind-vane exactly balanced and hung on gimbals, having vertical fans to carry it in the direction of the wind, and horizontal fans to enable it to tip *up* or *down*, to show the angle at which the air is blowing.

The Rain Angle is a simple contrivance for showing the angle at which the rain descends. It consists of a rod, which moves along a graduated arc.

The Distance Measurer.—A modification of the carpenter's rule, having an elevated eye-hole, fixed vertically in the joint, and a slender pin screwed vertically on each leg of the rule. The rule itself slides on a graduated arc. In order to measure approximately the distance of a peculiar cloud, or other celestial phenomenon, from any fixed object, the legs of the rule are opened until one of the vertical pins covers the object to be measured, and the other the object to which it is referred. The distance will be seen on the graduated arc.

Ozonometer.—A chemical contrivance for ascertaining the amount of ozone in the atmosphere. Ozone was discovered by Dr. Schönbein of the University of Bâle, in the year 1848. Test-papers are hung in a situation where there is a free current of air, but not in sunshine;—the north face of a thermometer-stand is a convenient situation. These papers will remain colourless if there be no ozone present, and will be more or less tinged with blue, as the ozone is more or less powerful. A scale of different tints, marked from 0 to 10, is furnished with the test-papers, to which the slips are referred after exposure to the atmosphere, immediately after immersion in water for the space of one minute.

These test-papers are made in the following manner:—

200 parts of distilled water,
10 „ of starch,
1 „ of iodide of potassium,

boiled together for a few seconds, and then slips of bibulous paper dipped into the solution; when dry, they are ready for use. If there be any ozone present in the air, it seizes on the potassium—the blue colour left being iodide of starch. Other test-papers have been prepared by Dr. Moffat of Hawarden, which do not require to be plunged into water, in order to bring out the proper colour. Dr. Moffat's test-papers must be kept in the dark. They are placed in a box, the bottom of which is perforated with holes for the free passage of air. These test-papers, if kept in the dark, will last for several years, retaining the amount of discoloration.

The Wind-Vane should be so contrived as to move with the least amount of friction; otherwise, in calm weather, the changes will not be seen to take place in the direction of the wind at the proper time.

The Atmospheric Recorder, although too expensive for the ordinary meteorologist, still cannot be passed over in silence. Having had one in work for a year, we can speak of its value. Every change in the atmosphere is written down by pencils at the precise moment of occurrence. It is merely requisite to supply the cylinders with sufficient paper; after which, if the clock be occasionally wound up, and the pencils kept capable of drawing a clearly-defined line, no further care or trouble is needed. This machine is incessantly writing down the force of every gust of wind, the extent of every change in its direction, the commencement and termination of every shower, the quantity of rain which has fallen, and the amount of evaporation and electricity. The temperature of the air, the pressure and hygrometrical condition, are recorded every quarter of an hour. The discussion of these records cannot fail in being productive of much good to meteorologists. Mr. Dollond makes this machine.

The Actinometer.—An instrument for ascertaining the force of solar radiation. It consists of a large hollow cylinder of glass, soldered at one end to a thermometer tube, terminated at the other end by a ball drawn out to a point, and broken off so as to leave the end open. The cylinder is closed at the other end. It is filled with a deep blue liquid (ammonio-sulphate of copper). The cylinder is enclosed in a chamber, which is blackened on three sides. This instrument requires careful manipulation, and is but little used.

Intensity of Light.—The gauge for ascertaining this consists of a long narrow box, with a window at one end facing the north. The box is painted black inside, with a white belt of a couple of inches in width, graduated up to 100. The brighter the day, the further can the figures be seen up this box.

The Transit Instrument is a useful addition. It has been well described by Mr. Breen in the Section on Astronomy. A very close approximation to correct time may be obtained by the use of Dollond's Portable Transit.

A good astronomical clock, with a mercurial pendulum, ought to be found in every observatory, and a good watch in the pocket of every observer; each should be provided with the seconds-hand.

Whewell's Anemometer, invented by the Rev. Dr. Whewell, is an ingenious self-registering anemometer, which gives the amount of horizontal movement in the air. A system of wheels is worked by windmill-sails, according to the velocity of the wind; and these carry a pencil, which is constantly recording the direction and velocity of the wind.

Osler's Anemometer constantly records the force and direction of the wind, and also the amount of rain. An admirable invention. Unfortunately, such instruments as this and Dr. Whewell's are too expensive for the majority of meteorological observers.

The Electrical Observatory at Kew, under the able management of Mr. Ronalds, has become a most important meteorological station, being, in fact, a collection of all requisite electrometers; a brief description of which will be found in Dr. Drew's *Practical Meteorology.*

Daniell's Hygrometer.—An instrument for ascertaining, from direct observation, the temperature of the dew-point. This is an interesting contrivance, as a ring of dew is precipitated at the temperature of the dew-point. It consists of two glass balls, communicating with each other by means of a bent tube. The one ball is of black glass, and the other transparent. A thermometer is fixed with its bulb within the blackened ball; and as soon as three-fourths of this ball is filled with sulphuric ether, it is immersed. The air having been exhausted, the tube is hermetically sealed. The transparent ball is covered with muslin. A duplicate thermometer for ascertaining the temperature of the air, is attached to the stem of the instrument. To find the temperature of the dew-point, all the ether must be made to run into the black ball; ether is then poured from a phial on the muslin: this produces rapid evaporation, and the temperature is cooled down to that of the dew-point; at this temperature, a ring of dew is formed round the black bulb, and at this instant the immersed thermometer must be read off; rapidity of observation being necessary, as the temperature will continue to fall below this point, and the ring of dew also to increase in width. In a few seconds the ring will gradually disappear, and at this moment the thermometer should be read a second time. The mean of the two readings will give the temperature of the dew-point. It is necessary that the ether should be very good.

The results obtained by actual observation and by calculation (from the wet and dry-bulb thermometers) are very nearly identical, as the following illustration will show:—

By Observation.

Daniell's hygrometer, temperature of air . .	56·0°
Daniell's hygrometer, temperature of dew-point when ring was formed	48·1
Daniell's hygrometer, temperature of dew-point when ring disappeared	48·2
Daniell's hygrometer, mean temperature of dew-point	48·1
Daniell's hygrometer, temperature of dew-point below temperature of air	7·9

By Calculation.

Temperature of dry bulb	56·0
Temperature of wet bulb	52·0
Calculated dew-point	48·2
Temperature of dew-point below temperature of air	7·8

Regnault's Hygrometer.—Another instrument for ascertaining the dew-point from direct observation. It differs considerably in its construction. Some meteorologists prefer it to Daniell's hygrometer. Messrs. Negretti and Zambra have constructed a modification of Regnault's hygrometer, and from them it can be procured at the same price as that usually charged for Daniell's hygrometer.

Connell's Hygrometer is a third instrument for ascertaining the dew-point from observation. In this, the temperature is lowered to the dew-point by means of an exhausting syringe. The wet and dry bulb thermometer, however, answers every purpose, and, to the ordinary observer, is not so liable to be incorrectly read off.

The Cyanometer consists of a flat ring, divided into 53 equal parts, and numbered from 0 to 52, the 0 being white, and 52 very dark blue; the other numbers are painted every intermediate tinge from nearly white to deep blue. By its use, the colour of the sky can be comparatively recorded.

GENERAL DIRECTIONS.—The following occasional phenomena require a few words. The most uninstructed observer may give useful information on these subjects with comparatively little trouble to himself, by making known the particular features to be observed. It is desirable to note, in

Thunder-storms, the direction in which they move, the point of the horizon in which they were first noticed, and that in which they disappeared; the time when thunder was first and last heard; the colour of the lightning; the number of seconds elapsing after a flash before thunder became audible (noted at different periods during the storm's continuance); the commencement and termination of rain; the direction of the wind before, after, and during its continuance; the time when the electrical breeze springs up (this is a peculiarly violent breeze noticed in most thunder-storms); whether hail falls; and any other feature that may appear remarkable or be deemed desirable to be recorded.

Aurora Borealis.—Its position amongst the stars, whether merely a low auroral arch, or accompanied by coruscations. If a brilliant display, whether a cupola or dome is formed, a little south of the zenith; and if formed, whether oscillatory among the stars. The hour of its occurrence when seen as a diffused light; if there be floating patches of luminous haze or cloud, &c.

Solar and Lunar Halos.—When visible, the quarter of the heavens where they appeared, and how long they remained visible.

Mock Suns and Complicated Circles of Light.—Their form and position with respect to the sun or moon; whether prismatic.

Meteors or Falling Stars.—Their apparent size, shape, colour, path amongst the stars, velocity and duration; whether accompanied by a streak of light, or separate fragments; if large, whether a streak of light remained after the meteor itself had disappeared; and after bursting, whether any noise of explosion be heard—if so, how many seconds after the meteor itself had burst; the time of appearance, &c. These observations should more especially be attended to from the 6th to the 16th of August, and from the 9th to the 14th of November.*

Gales of Wind.—Their direction, and estimated force; when they commenced and terminated; the height of the barometer during their continuance.

Snow.—When it fell, how deep in inches on the ground, and the form of the snow-crystals. To sketch the crystals, a magnifying glass is requisite.

Hail.—The shape of the stones, &c.

The times of breaking up of long dry periods, and frosts; the termination of rainy periods; the commencement and duration of fogs, wind-changes, &c.

Solar Eclipses.—During their continuance, and before and after, record the temperature in sun and shade repeatedly. Expose for ten seconds, every five minutes, slips of sensitive paper, to ascertain the effect of the diminution of sunlight.

REQUISITE TABLES OF REDUCTION.—1st. *Glaisher's Hygrometrical Tables* (2nd edition). These splendid tables enable the observer, with comparatively little labour, to calculate the temperature of the dew-point; the elastic force of vapour; the weight of vapour in a cubic foot of air; the additional weight of vapour required to saturate a cubic foot of air; the degree of humidity; the whole amount of water in a vertical column of the atmosphere; the weight of a cubic foot of air; and also to separate the pressure due to vapour from that due to the gases, for any temperature from 10° to 100° F. There is also a table for reducing the readings of the barometer to the level of the sea. Mr. Glaisher has calculated this table from the fact determined by M. Regnault, that air expands $\frac{1}{491\cdot13}$th part for every increase of 1° of heat.

2nd. *Tables of the Corrections for Temperature to Reduce Observations to 32° F. for Barometers with Brass Scales*, by J. Glaisher, Esq. It is absolutely requisite to reduce the readings of the barometer to a certain acknowledged temperature, otherwise the true pressure of the air could not be ascertained; for it must be remembered that, besides the pressure of the air on the mercury, the mercury itself obeys the same law which is pointed out to us by the thermometer—*i.e.*, it expands by heat, and contracts by cold. Thus, suppose the actual pressure of the air to be stationary, the barometer will be seen to rise or fall, if there be an increase or decrease in the temperature of the air. In like manner, the metal scale of the barometer is subject to expansion and contraction by an increase of heat or cold; and this, as Mr. Glaisher says, explains the apparent anomaly that, although the readings are said to be reduced to 32° (or the freezing-point), the point of no correction is 28½°. As metal bars will vary in length with every degree of temperature, it is apparent that a certain temperature should be determined upon at which the standard unit of measure must be referred to.

Now this temperature has been fixed at 62° F.; therefore above 62°, as the metal will expand, this will make the divisions on the scale of the barometer too large, and consequently the barometer will read lower than it should do; on the contrary, below 62°, the metal contracting, will bring the index divisions closer together, and the barometer will read too high, unless corrected. Thus, owing to this cause alone, at the temperature of 32°, the barometer is made to reach ·009 of an inch too high.

The great use of the reduction for temperature will be at once apparent, when an example is given: thus, suppose a person has two barometers, one in a room heated artificially, and the other as cold as possible;—

Reading of barometer at temperature of 90° = 30·200
Correction for temperature . . . — 0·165

Reading corrected for temperature . . 30·035 in.

Reading of barometer at temperature of 40° = 30.066
Correction for temperature . . . — ·031

Reading corrected for temperature . . 30·035 in.

The difference ·134 inch between the two readings, being due to the expansive action of heat.

These tables have been calculated trom Schumacher's formula, which is here copied:—

$$-z \times \frac{m\,(t-32^\circ)-s\,(t-62^\circ)}{1+m\,(t-32^\circ)}$$

z = reading of barometer.
m = the expansion in volume of mercury for 1° F. = 0·0001001.
t = the temperature of the mercury and the scale.
s = the expansion of the brass scale in length for 1° F. = 0·000010434 (the normal temperature being 62°).

---

* During these periods, the appearance of "falling stars" is always found to be more frequent than during other times of the year.—ED.

Thus the formula becomes—

$$s \times \frac{0{\cdot}0001001 \times (t-32) - 0{\cdot}000010434 \times (t-62)}{1 + 0{\cdot}0001001 \times (t-32)}$$

3rd. *Table of Corrections to be applied to Meteorological Observations for Diurnal Range*, prepared by the Council of the British Meteorological Society. These tables are of the utmost importance, as they enable an observer, from one, two, or three readings daily, to find from them the true monthly means; in fact, to make his observations represent a reading taken every hour, day and night. Thus, if a reading of the barometer be made daily at 3 A.M. in March, the mean will be ·023 too low, or, at 11 A.M., ·015 too high. The necessity of this reduction becomes very evident from hourly readings of the thermometer; for, suppose the readings are made in June, at 4 A.M., the mean will be 9·3° too low, or, if at 2 P.M., 8·6° too high.

The only correction requisite for the reduction of meteorological observations not found in the three above-mentioned tables is that for capillarity—the capillary action of the tube of a barometer depressing the mercury by a quantity inversely proportional to the diameter of the tube. The following table will be found sufficient for this reduction: it is copied from the work published by the Committee of Physics and Meteorology of the Royal Society:—

Correction to be added to Barometer Readings for Capillary Action.

Diameter of tube. Inch.	Correction for unboiled tubes. Inch.	Correction for boiled tubes. Inch.
0·60	+ 0·004	+ 0·002
0·50	0·007	0·003
0·45	0·010	0·005
0·40	0·014	0·007
0·35	0·020	0·010
0·30	0·028	0·014
0·25	0·040	0·020
0·20	0·060	0·029
0·15	0·088	0·044
0·10	0·142	0·070

The following reductions for meteorological observations will supply examples of every reduction necessary:—

BAROMETER REDUCTIONS.—To find the mean pressure of the barometer for the month of February, 1856 (height above the sea-level, 281 feet).

Sum of all the readings made at 9 A.M., 867640;
at 10 P.M., 867528.
Divide the above by the number of observations.

At sea-level the mean pressure is . .	30·170 in.

$$\text{As } 90{\cdot}7 : \overset{\text{in.}}{0{\cdot}1} :: \overset{\text{feet.}}{281} : = \frac{281 \times 0{\cdot}1}{90{\cdot}7} = 0{\cdot}310.$$

Another method, based upon the theorem of Sir George Shuckburgh and the calculations of Regnault, has been described by Dr. Drew of Southampton, who has constructed a table showing the height, in feet, of a column of air equivalent in weight to a column of mercury one inch in height, at different temperatures, under a pressure of thirty inches of mercury. This table is copied from Dr. Drew's *Practical Meteorology*.

Temp.	Feet.	Temp.	Feet.	Temp.	Feet.
30	865·1	47	895·2	64	925·2
31	866·8	48	897·0	65	927·0
32	868·5	49	898·8	66	928·8
33	870·3	50	900·5	67	930·6
34	872·1	51	902·2	68	932·4
35	873·9	52	903·9	69	934·1
36	875·7	53	905·7	70	935·8
37	877·5	54	907·5	71	937·5
38	879·3	55	909·3	72	939·3
39	881·1	56	911·1	73	941·1
40	882·8	57	912·9	74	942·9
41	884·5	58	914·7	75	944·7
42	886·2	59	916·5	76	946·5
43	888·0	60	918·2	77	948·3
44	889·8	61	919·9	78	950·1
45	891·6	62	921·6	79	951·8
46	893·4	63	923·4	80	953·5

For any temperature above that given in the table, the addition of 1·7 feet for every degree; and for any temperature below that given in the table, the subtraction of 1·7 feet for every degree, will give the factor required.

To work out the addition required to reduce to sea-level, let T represent the tabular number opposite the temperature of the air, s the reading of the barometer at f feet above the sea-level, and x the correction required; then

$$x = \frac{f}{T} \times \frac{s}{30}$$

Dr. Drew gives the following practical example:—The barometer being 29·500 inches, the temperature being 50°, and the height above sea-level 60 feet, what correction will be required?

$$x = \frac{60}{900 \cdot 5} \times \frac{29 \cdot 5}{30} = 0 \cdot 065 \text{ correction required.}$$

∴ 29·500 + 0·065 = 29·565 inches (the pressure reduced to the sea-level).

Thermometer Reductions.—To find the mean temperature for the month of December, 1855, from observations made at 9 A.M. and 10 P.M., and from self-registering thermometers.

Sum of all the readings made at 9 A.M, 10915; and at 10 P.M., 11017.

31)10915(35·2° mean at 9 A.M.
93 + 0·9 cor. for diurnal range.
161 36·1 approx. mean for month.

Approximate mean from observations made at 9 A.M. . . . . . . = 34·5°
Approximate mean from observations made at 10 P.M. . . . . . . = 34·6

Sum of the series . . . . . . 2)69·1

Adopted mean temperature of the wet bulb = 34·5

To find the mean temperature of evaporation.

Adopted mean temperature of the air from dry bulb . . . . . . = 36·0°
Adopted mean temperature of the wet bulb = 34·5

Difference . . . . = 01·5−
Adopted mean temperature of air . . = 35·9

Difference, or mean temperature of evaporation . . . . . . 34·4

To find the mean temperature of the dew-point, the mean dry bulb* being 35·8°, and the mean wet bulb 34·5°.

Example 1.—In the hygrometrical table for 35°.

The dew-point opposite to 34° wet bulb, is	32·4 –	32·4
The dew-point opposite to 35° wet bulb, is	35·0	
Difference on the increase in dew-point for an increase of 1° in wet	2·6.	
Proportional part of increase for 0·5, is		+ 1·3
Temperature of the dew-point corresponding to 35° dry, and 34·5° wet, is		33·7
In the fourth column, the decrease of dew-point for an increase of 1° in the dry bulb, is — 1·5°; the proportional part for 0·8°, is		— 1·2
The adopted temperature of the dew-point for 35·8° dry, and 34·5° wet, is		= 32·5

Example 2.—To find the mean temperature of the dew-point for the month of December, 1855, dry bulb being 36·0°, and wet bulb 34·5°.

In the hygrometrical table for 36°,

The dew-point opposite to 34° wet bulb, is	31·0 –	31·0
The dew-point opposite to 35° wet bulb, is	33·5	
Difference	2·5	
Proportional part of the increase for 0·5°, is		+ 1·2
Mean temperature of dew-point		= 32·2

The same tables, and the same manner of reduction, will find "the elastic force of vapour," "the weight of vapour in a cubic foot of air," "the additional weight required to saturate a cubic foot of air," and the "degree of humidity." To render the tables clear, one example of each will be worked out for a temperature of 35·8° dry bulb, and 34·5° wet bulb.

To find the elastic force of vapour of the temperature of 35·8°, the wet bulb being 34·5°.

In the hygrometrical table for 35°,

	Inch.	Inch.
The elastic force of vapour opposite to 34° wet bulb, is	0·184 –	0·184
The elastic force of vapour opposite to 35° wet bulb, is	0·204	
Difference, or the increase for an increase of 1° in wet	0·020	
Proportional part of the increase for 0·5, is		+ 0·010
Elastic force of vapour corresponding to 35° dry, and 35·5° wet, is		0·194
In the 6th column, the decrease of the elastic force of vapour, for an increase of 1° in the dry bulb, is — 0·010; the proportional part for 0·8°, is		— 0·008
Mean elastic force of vapour		= 0·186

To find the whole amount of water in a vertical column of the atmosphere—*i. e.*, from the surface of the earth to the top of the atmosphere.

This is found by multiplying the elastic force of vapour by the constant 1383, which would give, in this instance, for the whole amount of water in a vertical column of the atmosphere, if precipitated on the earth at one time, a depth of 2½ inches.

To find the weight of vapour in a cubic foot of air. In the hygrometrical table of 35°,

	Grains.	Grains.
The weight of vapour in a cubic foot of air, opposite 34° wet bulb, is	2·1 –	2·1
The weight of vapour in a cubic foot of air opposite 35° wet bulb, is	2·4	
Difference, or the increase in weight of vapour for an increase of 1° in wet, is	0·3	
Proportional part of the increase for 0·5°		+ 0·1
Weight of vapour in a cubic foot of air corresponding to 35° dry and 34·5° wet, is		2·2
In the 8th column, the decrease of weight of vapour for an increase of 1° in the dry bulb, is 0·2; the proportional part for 0·8°, is		— 0·2
The adopted weight of vapour for 35·8° dry, and 34·5° wet, is		2·0

To find the additional weight of vapour required to saturate a cubic foot of air.

In the hygrometrical table for 35°,

The dry bulb being 35·8°, and the wet bulb 34·5°.

	Grain.	Grain.
Additional weight of vapour required to saturate a cubic foot of air opposite 34° wet bulb, is	0·3 –	0·3
Additional weight of vapour required to saturate a cubic foot of air opposite 35° wet bulb, is	0·0	
Difference, or the decrease in amount required to saturate a cubic foot of air for an increase in 1° in wet bulb, is	0·3	
Proportional part of the decrease for 3·5°		— 0·2
Additional weight of vapour required to saturate a cubic foot of air corresponding to 35° dry and 34·5° wet, is		= 0·1
In the 10th column, the increase in the weight of vapour required to saturate a cubic foot of air for an increase in 1° dry, is + 0·3; the proportional part for 0 8°, is		+ 0·2
The adopted additional weight of vapour required to saturate a cubic foot of air for 35 8° dry and 3·45° wet, is		= 0·3

To find the degree of humidity, the temperature being 35·8° and the wet bulb 34·5°, complete saturation = 100.

In the hygrometrical table for 35°.

Degree of humidity opposite 34° wet bulb, is	90 –	90
Degree of humidity opposite 35° wet bulb, is	100	
Difference, or the increase of humidity for an increase of 1° in wet, is	10	
Proportional part of the increase for 0 5°, is		+ 5
Degree of humidity corresponding to 35° dry and 34·5° wet, is		95
In the 12th column, the increase in the degree of humidity for an increase of 1° in the dry bulb, is 9; the proportional part for 0 8°, is		— 7
Adopted degree of humidity for 35·8° dry and 34·5° wet, is		= 88

---

* The hourly readings of the thermometer, which are made at the same time as those of the wet bulb, are called the "dry bulb."

To find the weight of a cubic foot of air, the mean pressure of the barometer being 29·742 inches dry bulb 35·8°, and wet bulb 34·5°,

	Grain.
In the hygrometrical table for 35°.	
In column 13, the weight of a cubic foot of air (the barometer being 29·0 inches) opposite 34° wet, is	543·4
In column 14, the decrease of weight for an increase of 1° in dry, is −1·1°; the proportional part for 0·8°, is	−0·9
	542·5
In column 14, the increase of weight for an increase in the reading of the barometer for one inch, is + 18·7° grains.	
Opposite 7 in the table, under 18·7° in last column, is	13·1
Opposite ·04 in the table, in right-hand corner of the page, is	0·7
The adopted weight of a cubic foot of air is .	556·3

To find the mean pressure of dry air, or that due to the gases when separated from the water contained in the air.

Subtract the adopted elastic force of vapour (which is the pressure of the water contained in the air) from the adopted pressure of the barometer.

Example.

If the mean pressure of barometer be	= 29·742 inches,
And the elastic force of vapour is .	= 0·186 inch,
The pressure of dry air (of that due to the gases) will be	= 29·556 inches.

To find the monthly range of temperature, &c., deduct the coldest temperature from the hottest observed during the month. Thus—

Hottest temperature . . .	50·8°
Coldest temperature . . .	12·0
Monthly range of temperature .	38·8

To find the mean daily range of temperature, deduct the mean of all the readings of the minimum thermometer, from the mean of all the readings of the maximum thermometer.

Mean maximum temperature . .	41·0°
Mean minimum temperature . .	30·4
Mean daily range of temperature . =	10·6

To find the amount of terrestrial radiation, deduct the reading of a minimum thermometer, placed on the grass, from that of a minimum thermometer, placed four feet above the grass. Thus—

Greatest cold four feet above the grass	36·5°
Greatest cold on the grass . .	27·8
Amount of terrestrial radiation . . =	8·7

To find the amount of solar radiation, deduct the reading of a maximum thermometer (with a blackened bulb) placed in full sunshine from the greatest heat in shade. Thus—

Greatest heat in sunshine . . =	59·3°
Greatest heat in shade . . . =	34·1
Amount of solar radiation . .	25·2

To find the greatest heat and greatest cold of the wet bulb thermometer. This is obtained by attaching the muslin and cotton conductor to *self-registering* thermometers, instead of to the ordinary thermometer. Thus—

Greatest cold of dry bulb . .	34·0°
Greatest cold of wet bulb . .	32·5
Difference	1·5
Greatest heat of dry bulb . .	46·7
Greatest heat of wet bulb . .	42·8
Difference	3·9

To find the range of temperature of the wet bulb thermometer, deduct the greatest heat from the greatest cold recorded. Thus—

Greatest heat.	42·8°
Greatest cold	32·5
Range of wet.	10·3

To find the mean amount of cloud.

This, by practice, is accomplished very accurately by estimation, 10 being considered an overcast sky, and 0 a cloudless sky. It must be remembered, in making the estimate, that, with a partially covered sky, the forms of the clouds, and the space they cover, are only correctly seen in the zenith; the nearer the horizon we approach, the more obliquely do we look upon them; and, consequently, near the horizon, the sky will appear to be more overcast than it is in reality. The observer's judgment should, therefore, be more especially confined to the upper half of the sky.

Observations made at 9 A.M. and 10 P.M., December, 1855.

Sum of all the estimates at 9 A.M., 2158; and at 10 P.M., 2024.

31)2158(6·96° mean at 9 A.M.
186 − 0·10 cor. for diurnal range.
298 6·86 corrected amount.

190
186
. . 4

31)2024(6·5° mean at 10 P.M.
186 + 0·2 cor. for diurnal range.
164 6·7 corrected amount.
155
. . 9

Corrected reading at 9 A.M.	6·9°
Corrected reading at 10 P.M.	6·7
Sum of the two series	2)13·6
Adopted mean amount of cloud . .	6·8

CLASSES OF CLOUDS.—Mr. Luke Howard, the well-known meteorologist, was the first to classify the clouds; and these classes have been very conveniently abbreviated by Mr. Glaisher. They are—

Cirrus	= ci. . . .	feathery-looking, the most lofty cloud.
Cumulus	= cu. . . .	mountainous looking.
Stratus	= st. . . .	the ground-cloud—forms at sunset, and disappears at sunrise.
Cirro-cumulus	= ci.-cu. .	rounded masses, or woolly tufts.
Cirro-stratus	= ci.-st. .	horizontal masses.
Cumulo-stratus	= cu.-st. .	an accumulation of cumuli, sometimes fungus-shaped.
Nimbus	= ni. . . .	rain-cloud.
Scud	= sc. . . .	broken, flying nimbi.

The cut at page 1141 gives an idea of the general appearance of each kind of cloud just mentioned.

In recording the class of clouds, the interest is increased by also recording the direction in which the clouds are moving, the colour of the clouds, and their height and velocity. The height may be conveniently estimated by supposing 6 to represent very high clouds, and 0 those floating along the ground; the velocity, by supposing 6 to represent those moving at the greatest speed, and 0 those motionless.

To find the mean daily amount of rain. Whole amount of rain collected during the month of December, 1855, 0·764 of an inch.

31)0·764(0·025 of an inch being the mean daily amount.
62
——
144
155
——
— 11

To find the mean daily amount of evaporation for December, 1855. Whole amount evaporated, 0·610 inch.

31)0·610(0·0197
31
——
300
279
——
210
217
——
— 7 Therefore, ·0197, or, in even numbers, 0·020 inch is the daily amount.

To find the amount of evaporation in rainy weather.

Suppose 1·000 inch of water is placed in the evaporator, and that a rain-gauge, of the same diameter as the evaporator, and placed at the same level, has recorded 0·510 inch of rain since last observation, whilst the evaporator is found to contain 1·444 inches. Then

1·444 inches the amount in evaporator.
0·510 amount of rain.
——
— 0·934 difference.
1·000 amount of water placed in the evaporator.
——
0·066 of an inch is the amount due to evaporation.

To estimate the force of wind.

Anemometers being expensive, the majority of meteorologists estimate the wind's force. It is recommended that 0 represent a calm and 6 a hurricane, for this estimate is easily converted into 1 lb. pressure on the square foot; the square of the estimate will represent the lb. pressure on the square foot; viz.—

0 = 0 lb.
1 = 1
2 = 4
3 = 9
4 = 16
5 = 25
6 = 36

By practice, a near approximation to the truth can be obtained.

Mr. Belville, in his *Manual of the Barometer*, gives the following concise table of factors for deducing the temperature of the dew-point, from the temperature of the air and that of the temperature of evaporation: this table originally appeared in the *Greenwich Magnetical and Meteorological Observations for* 1844. The dew-point, deduced in this manner, is a close approximation to that obtained by Glaisher's hygrometrical tables.

Temperature.	Factor.	Temperature.	Factor.
28° to 29°	5·7	40° to 45°	2·3
29 „ 30	5·0	45 „ 50	2·2
30 „ 31	4·6	50 „ 55	2·1
31 „ 32	3·6	55 „ 60	1·9
32 „ 33	3·1	60 „ 70	1·8
33 „ 34	2·8	70 „ 80	1·7
34 „ 35	2·6	80 „ 85	1·6
35 „ 40	2·4	85 „ 90	1·5

Multiply the difference between the wet and dry bulb, by the factor corresponding to the temperature of the dry bulb, and subtract the product from the latter, which will give the temperature of the dew-point. Thus, let T be the temperature, W wet bulb, f factor, x the product, and D the dew-point, then

$$x = T - W \times f$$
$$\text{and } D = T - x$$

Example.—Temperature of dry bulb 50°, and wet bulb 45°,

$$50 - 45 = 5$$
$$5 \times 2{\cdot}1 = 10{\cdot}5$$
$$50 - 10{\cdot}5 = 39{\cdot}5^\circ \text{ the dew-point.}$$

By Mr. Glaisher's tables this dew-point is 39·7°.

RECOMMENDATIONS AND PRECAUTIONS.—Preserve, as much as possible, the continuity of the observations. It is desirable not to change the positions of the different instruments, nor even to alter the method of reading and registering. As it is probable, when two persons are employed in taking observations, that each will read slightly different, a series of simultaneous readings should be made, in order to find the personal error of the observers. If, from any cause, the continuity of the register should be broken, on no account attempt to fill the blank so caused by estimation. Be punctual to the hours determined upon for observations, and read off the instruments in the same way every day; by doing this, it is less likely that an observation of any one instrument shall be overlooked. It is convenient to rule and mark off the form of observation upon a slate, to be transferred to the observatory book, after the whole observations have been made. Before calculating the means, it is recommended to examine each column, to ascertain that no evident error of entry has been made;—an inch in the reading of the barometer is a common error. The maximum reading of the thermometer is also sometimes entered in the wrong column, being placed in that of the minimum; and *vice versâ*. Decimal arithmetic should always be used.

Before fixing the barometer, it should be ascertained that the space above the mercury is free from air. Incline the instrument slightly from its vertical position: if the mercury, in striking the upper end of the tube, produce a sharp rap, the vacuum is perfect; if the tap be dull, or not heard, there will be air above the mercury, which must be driven into the cistern by inverting the instrument and then tapping it gently. If the observer do not succeed in producing this sharp report by tapping, the instrument will require the aid of the maker. In fixing the barometer, adjust the tube vertically by the aid of a plumb-line. In reading the instrument, place the eye on the exact level of the top of the column of mercury, so that each side of the index, and the top of the column, shall be in the same horizontal plane.

The thermometers should be protected from rain; and in making a reading, the observer should do it quickly; and whilst doing so, avoid touching, breathing on, or in any way warming the thermometer by the near approach of his person.

Sir John Herschel recommends that every meteorologist should take an observation every hour throughout the twenty-four, on four stated days in the year; viz., March 21, June 21, September 21, and December 21, excepting when one of these days occurred on Sunday, then to substitute for this date the 22nd. The observations to commence at 6 A.M., and terminate at 6 A.M. next morning.

Thermometers should be frequently compared with a standard instrument, in order to ascertain whether the freezing-point has remained at the temperature as marked off on the scale. It is a well-known fact, that the zero point moves; this has been ascertained from the circumstance that, after a great change in temperature, the glass requires a considerable time to enable it to return to its normal condition.

NEWMAN'S STANDARD BAROMETER form of Rutherford's thermometer differs in the following manner from that already described:—A platinum tube is drawn over a steel wire, which is said to prevent the index from fixing by oxidation. Not having had this instrument at work, we are unable to speak of its advantages from practice. A good improvement has also been accomplished with Negretti and Zambra's rain-gauge. We conceived it was liable to have the water in the canal surrounding it emptied into the graduated glass with the rain to be measured. At our suggestion this has been altered; the canal is now placed much lower down the gauge, and there seems no possibility of an erroneous measurement. The gauge may, therefore, be now said to be perfect.

Of late years two new barometers have appeared—viz., the *Aneroid* and *Burdon's*. They are both good indicators of atmospheric pressure, but cannot take the place of a Standard barometer. In the first place, the metal is influenced by temperature; and in the second, there is a chance of the box of the *Aneroid* and the tube of the *Bourdon* losing their vacuum. As a household instrument, when extreme accuracy is not essential, they are preferred to the common wheel barometer.*

At the time of the Great Exhibition of 1851, when the jury were examining the meteorological instruments, a remark was made that a more perfect maximum and minimum thermometer was required, both of which should be *mercurial*; and on the council medal being presented to Messrs. Negretti and Zambra, their attention was called to this suggestion. Not many months had elapsed before the *patent maximum* was produced, and within four years the *patent minimum*. The latter was sent for trial to a few meteorologists about that time, and one of these instruments came to the Beeston Observatory. The experiments made with it have been perfectly successful; indeed, so much so, as to have astonished all who have used it. The ordinary minimum thermometers do not work uniformly with this new instrument, owing to the alcoholic vapour contained in the upper portion of their tube, and which is more or less developed according to the temperature. Two such important improvements have not taken place since the invention of the thermometer; and it is creditable to them that both should have emanated from the same persons who invented the enamelling of fine tubes.

Professor C. P. Smyth, the Astronomer Royal of Scotland, has caused the electric telegraph to work in meteorology. A wind dial at the one extremity of a wire, is made to turn another simultaneously at the other extremity. The time will come when all large towns will have buildings devoted to these observations, and in which dials will be seen in every direction, some labelled "Edinburgh," others "Liverpool," "Dublin," "London," "Paris," "York," &c., and where the public will be enabled to see the direction of the wind at the same instant at most remote places. The benefit to the farmer and the navigator will be great from such an arrangement. Were such stations to be thickly scattered throughout the country, every change of wind, and every shower, could be traced and recorded, and a knowledge imparted, the benefit of which could not be sufficiently appreciated.

To be enabled to announce the approach of a thunderstorm, however, at a time when the sky is free from clouds, and to ascertain its speed so as to foretel when it may be expected in any given place, would afford the farmer an opportunity of so benefiting by the information, that he would gladly pay a small rate in order to take advantage of it. The world is slow in appreciating any new invention until its usefulness is experienced: let us, however, hope that such invaluable stations may speedily be established, and we venture to predict that, at no very distant period, every conspicuous eminence will have its *road station*, to impart the information collected at the principal establishments, where the electric wires are made to record the changes as they occur. Of late years considerable progress has been made in this direction. Admiral Fitzroy has accomplished much by the "forecasts" he has daily published; and has largely benefited our seafaring population, by "warnings" communicated to the various seaports. (See following chapter).

It is a common expression that nothing is more changeable than the weather; yet that all these changes are governed by certain laws, is as certain as that gravitation binds the heavenly bodies together. Were there no laws to keep the changes within certain limits, we should at one period experience cold, and at another heat so intense, that existence would be intolerable; the earth would be deluged with rain, and anon parched up with drought; the sky would be cloudy for months, perhaps years together, and then cloudless for as long a period; in short, the laws which govern the weather, keep the extreme changes within proper bounds.

As the more complicated machinery of a meteorological observatory cannot be expected to be found except in our principal establishments, it will be requisite to mention what instruments are absolutely necessary for the ordinary observer. These are—A standard barometer; a wet and dry bulb thermometer; a maximum and a minimum thermometer; a rain-gauge; an evaporator; a thermometer-stand; a wind-vane. These would cost from £17 to £30, according to which barometer is selected. The following additional instruments are also desirable (the expense would be £4 or £5):—The solar and terrestrial radiation thermometers; Glaisher's electrometer; an ozonometer; and an extra rain-gauge.

SNOW-GAUGE.—The gauge used at Beeston observatory consists of a thin metal cylinder, eight inches in diameter, and twelve inches deep, graduated upon one side to a quarter of an inch. This cylinder will penetrate through the snow, scarcely disturbing it, and the depth in inches is at once seen. By careful manipulation, if the cylinder be turned round, all the enclosed snow can be lifted from the ground. It is desirable to melt it in a wide-mouthed bath, the gauge being previously kept corked to prevent evaporation. It frequently happens that snow is blown out of the mouth of the rain-gauge before it has had time to melt; consequently, the result of melted snow, as shown by the rain-gauge, will be too little in amount.

CALENDAR OF NATURE.—Every meteorologist should endeavour, as much as possible, to record the arrival and departure of migratory birds, the dates of trees coming into and losing their leaves, the blooming of plants, the ripening of fruit and seeds, the building of birds'-nests, the first appearance of various insects, diseases amongst animals and plants, the appearance of abundance or otherwise of crops of fruit, corn, &c. If such registers were extensively kept and carefully recorded, the effect of the weather upon the animal and vegetable kingdoms would be well seen. It is extremely desirable that every precaution should be taken, in order that, year after year, the same object should be the special one on which the remarks are based, and that one species be not mistaken for another. The following examples will show that it is essential to use the utmost care:—

First, "the elm is said to lose its leaves on a certain date." Such an observation is useless. It is requisite to mention the particular kind of elm; thus, the broad-leaf elm is the first tree to become leafless, which it frequently does in September; the Siberian elm, on the contrary, will remain green after all other trees have become leafless—sometimes it is in leaf as late as December. It will also be found that the same species, in a group whose boughs touch each other, will come into leaf at different dates. In no tree is this more strikingly exhibited than in the beech: two beeches growing close together may be seen to vary a couple of weeks in their period of coming into leaf. The age of the tree also causes a difference to occur. In the different kinds of lilacs and laburnums, there will be a range of some days in their time of coming into bloom. Amongst herbaceous plants, none that have been transplanted should be the objects of record. Respecting the observations on the ripening of fruits, the strawberry will serve as an example: the variety called Black Prince will be ripe before Kean's seedling; Kean's seedling before British Queen; and British Queen before the Elton Pine.

---

* See Mr. Glaisher's report in the next chapter.

CHAPTER V.

WEATHER-FORECASTS—BALLOON OBSERVATIONS—CLIMATOLOGY, ETC.

[THIS Chapter has been added by the Editor, as in part supplementary to subjects already treated on, and also to afford information on various matters, pertaining to Meteorology, which have not hitherto been noticed. Amongst such are—Admiral Fitzroy's Weather-Forecasts; Polar and Equatorial Currents; Cyclones; Rules for predicting the Weather; Animal Instincts; Free Electricity, and its Phenomena; Mr. Glaisher's Balloon Ascents; Shooting-Stars and the Aurora; Meteorological influence of Drainage; Ozone; Determination of Heights; Weather Registration; Gaseous Radiation; Snow-line; Distribution of Heat; Rainfall; Plants and Animals as affected by Climate; Meteorology and Ethnology; Endemic and Epidemic Diseases; Tables of Mean Temperature, &c.]

IN the preceding pages, the student, or general reader, will find an ample disquisition on the laws of Meteorological Phenomena, and some useful advice and aid, should he be desirous of pursuing the subject practically. Within the last few years, an idea has prevailed in scientific circles, that it is possible to predict the probable kind of weather which may occur within certain limitations. Such an object is of the highest importance to us as a seafaring nation, losing, as we do, annually, an immense sum by the wreck of vessels near our coasts. The Meteorological Department of the Board of Trade is devoted to obtaining observations, and in generalising them, with the hope that the laws governing excessive changes of the weather may thus be discovered. To Admiral Fitzroy we are indebted for a great amount of untiring exertion and unequivocal success. Under his direction, telegrams are daily forwarded to all our ports, intimating the weather which may be expected to occur; and a system of signals has been arranged, by which vessels, near our coasts, can be warned of an impending storm.

We present our readers with the following epitome of the results arrived at by Admiral Fitzroy, and the principle on which he proceeds; and are indebted to the pages of the *Athenæum* for the *résumé*. The remarks are founded on a Report which was furnished by the admiral, during the summer of 1862:—

"The Report is highly valuable, for it contains the first-fruits of the measures taken by government to utilise our knowledge of meteorology, with reference more particularly to storm telegraphy. The system at present in use was organised in 1857; when it was arranged that simultaneous observations should be made daily at various localities in the British Islands, also in and around the Atlantic, and at stations on the European continental coasts. By combining these observations in synchronous charts and otherwise, it was discovered, that though the weather and wind appeared to be quite irregular, yet that there was much uniformity and similarity of character in successive variations. It was further ascertained, that by means of a comparatively small number of observations made daily at a few selected stations sufficiently far apart, and by the use of a self-registering barometer at a central station—to which meteorological telegrams are sent from the outlying stations—distinct intimation of marked changes of weather, and warning of dangerous storms, might be communicated to the centre, and from thence to all other points of any telegraphic combination.

"Some years were spent in bringing the system to working order; and on the 6th of February, 1861, the first warnings of portending storms were given. The value of this notice was particularly marked by the circumstance that a fleet of vessels became disabled or wrecked on the 8th or 9th, which were lying off Shields, and whose captains disregarded the timely warning. The misfortune was, however, a singularly pertinent example of the truth of the homely proverb, that 'it is an ill wind that blows no one good;' for since that event, Admiral Fitzroy states that, 'whether from having appreciated these storm signals, or from other reasons, the *fact is*, that very few wrecks occurred on our coasts during the notoriously tempestuous weather of February and March, 1861; and comparatively few since.'

"It is gratifying to find that the aid afforded by the government offices is not confined to British ships, and that a considerable demand for the publications emanating from Admiral Fitzroy's department, has been made by foreign nations. It has been truly observed, that one of the greatest evils of meteorology, hitherto, has been the practice of incessantly making observations without any very definite objects in view, with the vague hope that eventually they may become of value. The aim of the Government Meteorological Department is to correct this evil, by not only instituting observations of a strictly scientific nature, made with scientific instruments, but also in turning the observations to practical account.

"Admiral Fitzroy considers that the phenomena accompanying storms are now so readily explicable by the light thrown upon them by Dove's theory of polar and equatorial currents, which has been translated and published by the Board of Trade, and they are so marked by barometers, that it is quite inexcusable to undervalue their warnings. The principal phenomena connected with storms may be thus summed up. Great and important changes of weather and wind are preceded, as well as accompanied, by notable alterations in the state of the atmosphere; approaching storms are usually shown by falls in the barometer exceeding one inch, and by differences of temperature exceeding about fifteen degrees. A tenth of an inch an hour, is a fall indicating a storm or very heavy rain. The more rapidly such changes occur, the more risk there is of dangerous atmospheric commotion. These circumstances show the necessity of frequently observing the barometer, and the advantages of a self-registering instrument.

"As all barometers often, if not usually, show what may be expected a day, or even days, in advance, rather than the weather of the present or next few hours, and as wind or its direction affects them much more than rain or snow, due allowance should always be made for days as well as for hours to come. Admiral Fitzroy recommends that the following table of average temperatures between 8 and 9 o'clock A.M., near London, should be used to assist in foretelling the direction and nature of coming wind and weather:—

January . . .	37°	July . . .	62°
February . .	39	August . . .	61
March . . .	41	September . .	57
April . . .	46	October . .	50
May . . .	53	November . .	43
June . . .	59	December . .	39

"The thermometer (shaded and in open air), when much higher between 8 and 9 o'clock A.M. than the average, indicates southerly or westerly wind; but when considerably lower, the reverse, or northerly currents of air *approaching*, if not present. It is important to observe that the foregoing table of temperatures must be corrected for other places.

"Careful observations have now proved, that, although England is generally visited by one or more storms during the year, each of which is accompanied by terrible local disasters, yet all these tempests (be they ever so remarkable) are so much alike in character, and have been preceded by such similar warnings, as to warrant our reasoning inductively from their well-ascertained facts, and thence deducing laws. Indeed, all investigations into the characteristics of storms show the same results. Gales from the south and west are followed by dangerous storms from the north and east. Those from the west and south come on gradually; whereas those from the north and east begin suddenly, and often with extraordinary force. The barometer, with these north-eastern storms, does not give direct warning upon this coast, because it ranges higher than when the wind is in the opposite quarter. But though the barometer does not give much indication of a north-east storm, the thermometer does; and the known average temperature of the locality affords the means of knowing, by comparison, whether the wind will be northerly or southerly. Besides the familiar weather signs, Admiral Fitzroy considers that the following special peculiarities, previous to great atmospheric commotions, should be observed:—A great fall of rain or snow, much lightning, unusual cold, or excessive heat, invariably precedes high winds or strong gales.

"Admiral Fitzroy is cautious in advancing any opinion respecting the connection between electricity and storms. It is certain that, although many eminent men do not think that magnetic storms, or even auroras, are directly connected with atmospheric currents, or have any special relation to storms, many facts on record seem to point to a different conclusion. We can only notice one; but this is most important. On the evening previous to the *Royal Charter* storm, a brilliant meteor was seen; and during the previous week, blood-red streamers of aurora were very prevalent.

"We need hardly say that Admiral Fitzroy regards any faith in change of weather at the moon's quartering as utterly illusory, being based merely on deductions from coincidences, and not on any philosophical basis. It is, however, most remarkable how this unsound theory keeps its place among men even of high education. An amusing instance recurs to us. At one of the horticultural *fêtes* this summer, we met a gentleman who was loud in his indignation because, it being a wet day, he had ascertained that the Council of the Horticultural Society had fixed their shows regardless of the moon's quarters; whereas, as he stoutly maintained, had proper attention been paid to the lunar changes, wet weather would have been avoided. We apprehend that the indignant member has seen by this time, that the weather, during this summer, at all events, is not influenced by the moon.

"Although the great working instruments of the meteorologist are the barometer and thermometer, which should be of the highest order of excellence, we are glad to hear that Admiral Fitzroy makes use of an instrument called a storm-glass, which was much more common formerly than it is now. We have long been acquainted with this glass, and can speak confidently of its value in aiding, with the barometer and thermometer, in forecasting weather. Admiral Fitzroy has observed this instrument with great closeness, and these are his conclusions respecting its indications:—When a storm-glass, filled with the proper chemical mixture (camphor, nitrate of potass and sal-ammoniac, partly dissolved by alcohol, with water and air in an hermetically sealed glass bottle), is fixed undisturbed in free air, and not exposed to radiation, fire, or sun, the mixture varies in character with the *direction* of the wind. As the atmospheric current veers toward, comes from, or is approaching only from the polar direction, the mixture grows like fir or fern-leaves, hoar-frost, or crystallisations. As it tends to the opposite quarter, the lines or spikes—all regular, hard, and crisp features—gradually vanish. Before, and in a continued southerly wind, the mixture sinks gradually downwards in the bottle till it becomes shapeless, like melted sugar. Before or during the continuance of a northerly wind the crystallisations are beautiful. The glass should be wiped gently occasionally, care being taken not to shake the contents. While any hard or crisp features are visible below, above, or at the top of the liquid (where they form for much north wind), there is *plus* electricity in the air; a mixture of polar current co-existing in that locality with the opposite or southerly. When nothing but soft, melting, sugary substance is seen, the atmospheric current is southerly, unmixed with, and uninfluenced by the contrary wind.

"In August, 1861, Admiral Fitzroy commenced publishing single 'forecasts' of the weather. Twenty weather reports are received each morning, and ten each afternoon, besides five from the continent. Double 'forecasts' (two days in advance) are now published, and are sent to the daily papers. As these 'forecasts' have created considerable interest, Admiral Fitzroy explains the principles on which they are made.

"A barometrical height of 29·50, with about 60° of temperature, may be considered to indicate (if continued a certain time) fresh south-west wind and mild air, probably cloudy, perhaps rainy; about 30·50 inches, with 50° temperature, or less, would foretel and accompany north-easterly wind, dry weather, and usually a clear sky. Again, a high or rising barometer in the north-west, with low or falling temperature, while in the south and east the pressure is low or diminishing, indicates a north-west wind, either extending generally, or checked and deflected according to the diminution or increase of the temperature in the south-east.

"Objection has been taken to such forecasts, because they cannot be always exactly correct for all places in one district. It is, however, considered that general comprehensive expressions, in aid of local observers, who can form independent judgments from the latter, and their own instruments respecting their immediate vicinity, may be very useful as well as interesting; while, to a person unprovided with instruments, an idea of the kind of weather thought probable cannot be otherwise than acceptable.

"Certain it is, that although our conclusions may be incorrect, and our judgment erroneous, the laws of nature and the signs afforded to man are invariably true. Accurate interpretation is the real deficiency. There is no doubt, that attentive observation to the meteorological laws will enable us to interpret them better, and that, with increased knowledge and experience, 'forecasts' of the weather will be even more worthy of credence than they are now. But it is quite evident that enough is already known to enable an attentive observer, with good instruments, to acquire a useful foreknowledge of the weather during the coming day or two, or even three following days; and the utility of Admiral Fitzroy's weather warnings is amply illustrated by the fact, that notwithstanding the extremely stormy weather that prevailed in the North Sea during the first three months of 1862, the coasts of Durham and Northumberland have had a fortunate immunity from shipwreck, there having been no serious shipping disasters on that line of coast since November, 1861."

The preceding account of the progress made by the Admiral and his staff in 1862, will doubtless prove interesting to many of our readers: and we shall next call attention to the more developed and mature results, obtained since that date; detailing, also, more particularly the laws which are supposed to govern the production of storms, or unusual atmospheric disturbances.

In a communication with which we were favoured by Admiral Fitzroy, he especially draws attention, as the basis of his plans, to the following meteorological facts and phenomena: viz.—"A limited depth of atmosphere," as the region in which the phenomena occur, "not exceeding fifteen miles; horizontal motion of its several superposed or intermixed currents (like streams of water); their opposition, or, at times, combination; and their perennial progress, bodily (in mass), toward the east, in the temperate zone." These he considers as the most useful facts on which inferences may be formed, and the discovery of law can be educed, in dealing with questions relating to the forecasts and warnings to which we have already alluded.

With respect to the movements of the atmosphere, "accumulated facts have induced the conclusion that winds move in parallel currents, or circulate around a centrical area;" and that a uniform law of circulation or gyration exists, equally on the large scale as in the polar and tropical currents, and descending to the slightest aërial disturbance of any kind, with but rare and limited exceptions. The distinction between perennial trade-winds and local cyclones, seems to arise simply in the very circular direction of wind in the cyclone storm; whilst in the ordinary trade and similar winds, the direction is of a less curved, and consequently more constantly direct, character. The direction and force of the polar current are, of course, affected by the rotation of the earth, it becoming equatorial as that region is arrived at. The current, in its return, moves eastward towards each pole, and loses its momentum gradually, from gravitation and various local causes. It has been proved that storms, and all the greater circulations of the air, have an eastward motion bodily, while circulating around a centrical area, between the tropics and polar regions; whilst, within the tropics, the direction is westward until the currents recurve. To the circulation of these polar and tropical currents, often in parallel directions, and the effects of heat, moisture, &c., on the atmosphere generally, are assigned the cause of what are called "atmospheric waves," which are attended with a rise and fall of the mercury in the barometer, under certain limitations.

"Such currents, prolonged and excessively broad, are always flowing in nearly opposite directions, and always moving eastward, at an average rate of about five miles an hour, in our latitude." If near the earth's surface, they may be side by side or parallel; but if overlapping, or entirely superposed, they then cross in various directions, and more or less impinge on, or intermingle with, each other. Hence arise intermingling cyclones, which, affecting each other, apparently in opposition, but really in accordance with these laws, have, from our previous ignorance, much hindered the progress of our deductions, and frequently thrown doubt on the anticipatory predictions which have been made as to their occurrence.

Without detailing the entire known chain of causes which tend to produce the results, and which have, more or less, been already considered in the previous chapters of this section—it may be remarked, with respect to the polar current, that "the sensible result on the whole system of circulation, must be a continual easterly progression in the temperate zones; a general motion of the atmosphere towards the east, over the earth's surface; while, in the lower latitudes, and (perennial) trade-winds, its motion is different from that in higher latitudes, being towards the west. . . . . The normal state of our atmosphere appears to be a regular alternation, or circulation of currents, between polar and tropical regions—the polar usually, but not always, advancing along the earth's surface; the return current (*i. e.*, from the equator) "generally above, at higher elevations." The electrical characteristic of the polar current is generally that of positive excitement, with cold, great specific gravity, and dryness, except over a warm ocean; whilst the tropical current is generally negatively electrical, the positive state being rarely, if ever, observed.

These remarks are intended to explain what we may term the normal state of our atmosphere. The phenomena to which we have drawn attention may be considered as the natural condition of the gaseous envelope of the surface of the earth, undisturbed by local and abnormal influences. When, however, we descend to regions of comparatively slight elevation above the earth, then we find a vast number of other causes coming into operation, such as radiation, the physical character of country, as mountains, plains, swamps, seas, &c.; all of which tend to break-up the main currents of which we have been speaking, and thus to produce that diversity of wind and weather so proverbial in many parts; but especially in insular places, like our own country. In such situations, the study of atmospheric currents becomes a question of great complexity; and our readers may more fully understand its extent, when we remind them, that it is by no means an uncommon occurrence to find the wind blowing in every possible direction of the compass, at the same moment, in different parts, round and within our own coasts. It will be easily seen, after a careful perusal of our Section on Heat, and the earlier chapters of the present one, that an even-flowing current arriving from any direction at our shores, must immediately impinge, in some places, against cold mountain heights; in others, on warm and moist plains, &c.; and thus be broken into an immense number of smaller currents, which, re-acting on each other, afford about as difficult a problem for study as any within the range of philosophical investigation. The establishment of the primary currents, however, tends to assist us in explaining the cause of those of a secondary nature; and as we are assured that nothing occurs by chance, but follows certain definite, although possibly obscure laws, we are constantly encouraged to pursue these investigations, and, by observations and deductions, gradually arrive at the object of our researches.

In explaining the causes of barometric disturbance, Admiral Fitzroy relies chiefly—1st, on the effects of a rapid horizontal current, which tends, by producing a partial vacuum at the place of observation, to depress the mercury: 2ndly, on the presence of aqueous vapour, which diminishes the specific gravity of the air; and, 3rdly, on the expansion of the air by heat, which has precisely the same effect. As regards the influence of atmospheric waves on the rise and fall of the barometer, he is disposed to consider that their action is chiefly of a secondary character. It will hence be seen, that any change of wind and weather, whilst depending on a vast variety of causes, must *always* be attended by an increase or decrease of temperature, and moisture; and, consequently, accompanied with a variation in the height of the mercurial column. The barometer, thermometer, and hygrometer, are, therefore, *par excellence*, the instruments, taken together, on which the meteorologist essentially depends for unravelling the complex character of the winds, &c.

A popular illustration of these statements may be readily presented by referring to the experience of weather-changes in our own country. With a north-east wind, which is always dry, of great specific gravity, and low temperature, a rise of the mercury occurs, both at the moment, and shortly preceding the advent of this wind. On the other hand, the south-west wind, loaded with moisture, of a comparatively high temperature, and consequently low specific gravity, is always ushered in, and attended, by a fall of the mercury. Between this point and the north-east, as the wind veers northerly, the barometric column generally rises; whilst, as the wind travels southerly, from north-east, a barometric fall gradually occurs in most cases. These facts are palpable to the most cursory observer of the barometer; and those who object to the truth of forecasts, admit them tacitly, and condemn themselves practically, whenever they rely on barometric changes to predict, for a few hours, a change of the weather. The philosophic observer differs from such in arguing on a broader basis: he not only notes the barometric variations, but associates with them the *antecedent* changes of temperature and hygrometric condition, which, by experience, he has found invariably to occur. Thus his deductions have reason and fact for their basis, whilst the hasty weather-wise simply follow an empiric and uncertain method of indication. The use of the telegraph, in assisting weather prognostications, will be easily made apparent. Supposing, for instance, at a central station in England—say Wolverhampton—telegrams are received, respectively, from Bristol and Shields, the one noting the existence of a strong S.W. wind, and the other one from the N.E. It is evident, that if these currents meet, the hot, moist S.W. will, on coming in contact with the cold dry N.E., be condensed; and, in some places, where the difference of the temperature and moisture is greatest, their mutual impact *must* cause rain. On either side of this position the winds may modify each other's character; the S.W. will part with a portion of its moisture to the dry N.E., and the latter will, of course, become more hygrometric. Under such conditions clouds may be formed, but rain may not fall; and thus the weather may promise a change, whilst none of importance immediately occurs. It will thus be evident that the rain-tract, produced from causes just mentioned, may be surrounded with another, in which the moisture is not precipitated. By extending the same reasoning for the whole of our country, after being in full possession, by telegraphic reports, at the same moment, of the actual direction of the winds, their temperature and moisture, and remembering that our storms are usually of a cyclonic character—it will be plain, to the most unpractised observer, that forecasts *may* be made with every probability of a successful result, provided that the reports furnished afford data of all the various circumstances, on which, as we have already shown, the occurrence of the phenomena depend. With respect to the method of observing barometric and thermometric changes, in combination with each other, the reader will find a table of temperature averages at a previous page, which will guide him for each month in the course of the year.*

Few persons, without carefully reflecting, can gain an adequate idea of the multitude of minor occurrences, which, unheeded in most cases, give warning of impending atmospheric changes. The indications to which we are about to refer, depend mostly on the increase or decrease of atmospheric moisture. Thus, the long ribbon sea-weed becomes damp as moist weather approaches; so does common salt, to a slight extent: the painted walls of our apartments, and the iron rails in the garden, likewise become moist, for precisely the same reason as does the wet bulb of the hygrometer†—namely, the deposition of moisture from the heated air on a cooler surface. Stairs creak or are quiet as the hygrometric state of the atmosphere varies. With a dry wind, the back of the cat affords bright electric sparks when stroked; but none when the air is moist, because the damp conducts away the electricity. The approach of the S.W. wind, in winter, after a cold N.E. wind, is immediately indicated by the paving of our streets, and the tiles and slates of our roofs becoming moist; our window-frames and doors "stick" for similar reasons; ropes, loosely stretched, become tight, owing to the absorption of moisture, and the consequent contraction of their fibres: hence, the frequent annoyance to the housewife from the sudden break-down of the posts, between which clothes have been hung out to dry. The steam from the locomotive blast-pipe seems abundant in the moist air on a damp day; whilst in fine dry weather it is scarcely visible, being rapidly absorbed by the surrounding air; and, for similar reasons, any wet article hung out in damp weather, dries but slowly, because the air already surcharged with moisture can absorb no more. Our space does not permit us to enlarge on these interesting subjects; and we have only suggested the above as instances of which almost every one has some knowledge, and frequently use, who have any pretension to the name of what is commonly termed a weather-prophet.

In concluding these remarks on the laws of storms, &c., we cannot do better than transfer to our pages the "resulting impressions" which Admiral Fitzroy affords. They are as follows:—

1. The gyratory movements of wind, usually called cyclones, are consequences of the meeting of great air-currents.

2. When so caused, in any part of the world, they rotate, as eddies, during a certain time—more or less limited; not exceeding four complete days and nights without interruption, but usually for a much shorter period.

3. That cyclones originate on one side of the Atlantic, and traverse to the other, is a fallacy, which has arisen from an *insufficiency of facts*, and consequent erroneous combination of the details of various successive gyrations, *since* proved to be *frequent*.

4. When such an atmospheric combination happens, it is not usually an isolated occurrence, but one of many such, similar in nature and origin, though unequal in extent, duration, and force; not taking place at exactly the same time, necessarily, but prevalent in a certain zone or region of the world during a few days or weeks, or a season.

5. The conflicting action of two currents, opposed in much peculiarity as well as in *direction* (a feature connected with electricity?), not only originates a cyclone, but tends to continue its striking qualities, of a wet warm side and a dry cold one, owing to the continued access and addition of air from each of the currents (between which it is the eddy), as place is made by immense precipitation of vapour in rain, hail, or snow, supplied from the vaporous side as speedily as precipitated, or absorbed by the chilling and drying influence of the antagonistic current from a polar direction.

6. These cyclones, originating in *opposition* of currents otherwise caused, are different from local whirlwinds, occasioned by rarefaction or by *electrical* action, as in the sand-columns of the desert, and water-spouts.

7. When opposing currents meet, their masses must *continue* in motion a certain time, either rotating or ascending, or going onward horizontally, in *combination*.

8. Masses of air, either of polar or tropical origin (so to speak), *returning*, when driven back by stronger opposition, at first, and for a certain time, retain the characteristics of their peculiar and very different natures.

9. During the prevalence of northerly (polar) currents of air, electricity, positive or plus, is more active or developed. On the contrary, with a southerly (tropical) current there is no such action, no electricity in excess, no positive or plus, and but little, if any, of negative or minus free electricity.

This *résumé* of the, at present ascertained, laws on which the system of forecasts is founded, will enable the student to arrive at some general idea of the insight which we now possess into those previously hidden laws by which, so far as we can now judge, so many atmospheric phenomena are governed. It must be admitted that our knowledge is still extremely limited, chiefly because our means of observation are confined to within so short a distance from the surface of the earth. In a subsequent portion of this chapter, we shall give an account of many interesting particulars which have been arrived at by means of balloon ascents, undertaken at the instance and expense of the British Association, by Mr. Glaisher. Perhaps, to a certain extent, the preceding remarks and deduced laws may be modified by the results that Mr. Glaisher has obtained, and which certainly do not encourage, at first sight, that assumption of *regular* current forces to which we have so frequently alluded. It must be borne in mind, however, that at the utmost height which has been attained by the balloon, the observers have barely been beyond the sphere of action of purely local causes. Hence, the results necessarily cannot be relied on as bases on which to build a safe theoretical superstructure. Repeated observations, under constantly varying circumstances, will be needful, before we can safely trust ourselves to an unreserved acknowledgment of the truth of many deductions hitherto made. In every branch of philosophical investigations, dependent on experiment, it is safer to doubt than hastily to credit; but in meteorology, which is as yet the most uncertain branch of science, such a principle must be acted on without the least hesitation, if we would not commit ourselves to crude theories, and, possibly, to positively dangerous inferences.

---

* See *ante*, p. 1172.

† See *ante*, p. 1146.

To the general inquiry, "On what meteorologic conditions or changes are the forecasts based?" Admiral Fitzroy replies in the following terms:*—"They depend on considering the atmosphere as a lighter ocean, having currents; elastic expansibility; equilibrium; momentum or inertia; chemical alterations, and extreme sensibility to heat or cold, its *chief motors;* and on knowing the statical condition of the air, in the oceanic envelope at many places simultaneously; likewise, again similarly after certain intervals of time, by which inter-comparisons are made, showing the relative conditions and causations, whence dynamic effects originate. These dynamic motions are proportional to disturbances of level, like those caused by a head of water; to inequalities of temperature, and consequent *chemical* changes, with more or less electric action. They are our winds, and may be soft or gentle, or as heavily boisterous as in a *tempest;* of which differences, through all degrees, instrumental means and telegraphy now give available information. To utilise their indications adequately, a central office should know the natural and general atmospheric movements, with their disturbing causes, even as a pilot knows the varieties of streams and eddies in a wide estuary.

"The whole map of a region (say the British Islands) should be outlined in the mind, as the estuary, with its shoals, is mentally visible to the pilot. The normal tendency of the whole atmosphere (in our latitudes) to *move eastward*, while crossed or variously interfered with by polar or tropical currents, that in course of seasons cause every variety of wind and weather, should be always considered; and then, with due allowances made for gradual advances from westward, for effects of land and differences of temperature, good forecasts may be generally drawn."

Hitherto we have referred solely to the *principles* on which the meteorologist should be guided; but we shall now afford a number of practical instructions, for the use of those who desire to undertake weather-forecasting. The following rules are chiefly selected from the *Barometer Manual*, published by the Board of Trade; a work which, whilst of trifling cost, will be found an admirable compendium, and a guide for making observations and registering results. It is highly possible that some who peruse these pages, reside in localities where the observations of an intelligent person may be of great use to those whose livelihood is obtained at sea, &c.; and a careful attendance to the following suggestions, with the possession of a good barometer and thermometer, may be of essential service. Care must be taken to correct the results obtained, for elevation above the sea-level, temperature, &c., if they are to be compared with those of other observers. Rules for these corrections have been already given in the preceding chapter.

RULES FOR PREDICTING CHANGES IN THE WEATHER.

1. If the mercury, standing at 30 inches, rise gradually whilst the thermometer falls, and dampness becomes less, N.W., N., or N.E. wind; less wind; or less rain and snow may be expected.

2. If a fall take place, with a rising thermometer, and increasing dampness, wind and rain may be expected from S.E., S., or S.W.: a fall in winter, with a low thermometer, foretels snow.

3. An impending N. wind, before which *the barometer often rises*, may be accompanied with rain, hail, or snow, and so forms an apparent *exception* to the above rules, for the barometer always rises with a north wind.

4. The barometer being at 29½ inches, a rise foretels less wind, or a change of it northward, or less wet. But if at 29 inches, a fast *first* rise precedes strong winds or squalls from N.W., N., or N.E.; after which, a gradual rise, with falling thermometer, indicates improving weather; with a steady or rising thermometer, a S. or S.W. wind will follow, especially if the rise of the barometer has been sudden.

5. A rapid barometric rise indicates unsettled, and a rapid fall, stormy weather, with rain or snow; whilst a steady barometer, with dryness, indicates continued fine weather.

6. The greatest barometric depressions indicate gales from the S.E., S., or S.W.; the greatest elevations foretel wind from N.W., N., or N.E., or calm weather.

7. A sudden fall of the barometer, with a westerly wind, is sometimes followed with a violent storm from the N.W., N., or N.E.

8. If the wind veer to the S., during a gale from E. to S.E., the barometer will continue to fall until the wind is near a marked change, when a lull *may* occur. The gale may afterwards be renewed, perhaps suddenly and violently; and if the wind then veer to the N.W., N., or N.E., the barometer will rise, and the thermometer fall.

9. The maximum height of the barometer occurs during a N.E. wind, and the minimum during one from the S.W.; hence these points may be considered as the poles of the wind. The range between these two heights depends on the direction of the wind, which causes, on an average, a change of half an inch; on the moisture of the air, which produces, in extreme cases, a change of half an inch; and on the strength of the wind, which may influence the barometer to the extent of two inches. These causes, separately or conjointly with the temperature, produce either steady or rapid barometric variations, according to their force.

Allowances should invariably be made for the state of the barometer and thermometer, for *some days* as well as *some hours previously* to forecasting, because sudden changes are always indicated antecedently to their occurrence. The longer and steadier a change is in coming, the longer the expected weather, either wet or fine, will last.

Sometimes severe weather from the S., *not lasting long*, may cause no great fall, because followed by a duration of N. winds; and, occasionally, the barometer may fall during N. winds and fine weather, because a continuance of S. wind is about to follow.

The table of average temperatures, *corrected for the place of observation*, but given for *Greenwich* at page 1172, is to form the standard of comparison with the actual temperature at the time of observation, in connection with the barometrical indications. If, at 8 or 9 A.M., the thermometer is much higher than the corrected average of the place, a southerly or westerly wind (tropical current) may be expected; if considerably lower, then a northerly wind (polar current) is indicated.

The preceding rules, of course, solely refer to observations with instruments; but the following external signs (chiefly selected from the *Manual*) of impending changes should be taken collaterally, because they will frequently serve as interpreters of obscure indications given by the barometer, &c. In connection with the following, our remarks on well-known phenomena, depending on the moisture of the atmosphere,† may also be read; and the general observer can employ both, when the ordinary meteorological instruments are not accessible. It will be seen that the objects are purely natural, and that the effects noticed really depend on certain influences, which, affording the phenomena as signs, are also their producing causes.

Clouds.—The following appearances depend chiefly on the refractive power of vapour, either of the cloud, or suspended invisibly in the air,‡ and, occasionally, on its comparative or nearly entire absence.

A rosy sky, at sunset, presages fine weather; an

---

† See *ante*, p. 1175.

‡ The student may read, with this, the articles on Refraction and Colour, in the Section on Light. See pp. 45, 49, *et seq.*

Indian-red tint, rain; a red sky in the morning, bad weather, or much wind or rain; but a grey sky, fine weather; a dawn high in the sky, wind; if low, fair weather; soft or delicate-looking clouds indicate coming fine weather; hard-edged, oily-looking clouds, wind; a dark, gloomy, blue sky, wind; a bright blue, fine weather. The softer-looking the clouds, the less wind may be expected; the harder, more rolled, tufted or ragged, the stronger the coming wind. Inky-looking clouds foretel rain; light scud clouds, driving across heavy masses, foretel wind and rain; but if alone, wind only. High upper clouds, crossing the apparent face of the sun, moon, or stars, in a different direction to that of the lower clouds, or the wind felt below at the moment, foretel a change of wind toward their direction; streaks, curls, wisps, &c., of cloud, in a clear sky, increasing into general cloudiness, indicate coming rain or wind—perhaps both. The higher and more distant such clouds may be, the more gradual, but general and lasting, will be the coming change. Fine weather is usually accompanied with undefined clouds (if any), of delicate, quiet tints or colours; whilst hard, defined clouds, with gaudy or unusual colours, foretel rain, and probably strong wind. Misty clouds, forming or hanging on heights (commonly seen about bushes on the tops of hills, &c.), show wind and rain coming, if they remain, increase, or descend. If they rise, or disperse, fine weather may be expected. Dew and fog generally indicate fine weather; whilst remarkable clearness of the air, unusual twinkling of the stars, indistinctness of the moon's horn, haloes, the rainbow, &c., are, more or less, significant of increasing wind, and possibly of rain, either with or without wind.

It often surprises persons accustomed to reside in towns, how accurately those living in an open but especially hilly country, can predict the weather. In numerous instances, however, certain local phenomena interfere with regular predictions, of which we have met with several instances in various parts of England and Scotland. In journeying, for instance, northward from London, for about 100 miles, a great breadth of land extends between the German Ocean on the east and the Irish Sea on the west: proceeding still further northward, the breadth of coast rapidly narrows, until the width across Cumberland and Durham is little more than 80 miles. In the former case, the currents of air, arising from the surrounding seas, spread over a greater area of land, and more gradually part with their moisture in the form of rain; whilst in the north, the warm westerly and cold easterly winds speedily meet, and give rise to frequent and rapid showers or storms of rain. In the mountainous tracts of Scotland, &c., sudden storms of wind and rain are of constant occurrence; and, owing to the rapid eddies or small cyclones, and the narrowness of the land, the traveller may soon find his knowledge, acquired in other districts, of no practical value whatever. On the west of Scotland the Gulf-stream impinges; and we speak from an experience of some years, in remarking, that whilst staying, during the winter, at Rothesay, in Buteshire, we have never seen snow on the ground, at nearly the sea-level, more than an inch in depth, and no ice; whilst in London, the winter was, at the same moment, and had been for some time previously, most severe, with ice from eight to ten inches in thickness. From Hull, in Yorkshire, to Wick, in the north of Scotland, the winter is generally far more severe than between the same points on the western coasts, owing, doubtless, to the absence of the warm water of the Gulf-stream, and consequently of the heated superincumbent air accompanying it. Instances of this kind might be greatly multiplied; but we mention these only as cautions for persons who, living at places similarly circumstanced, may attempt, without modification, to avail themselves of the rules we have laid down in the preceding pages.

Animal Instincts.—That animals are by some means made acquainted with coming changes of the weather, is a fact supported by universal experience. The annual migration of birds alone is sufficient proof; but those creatures who are domesticated with us, afford more constant and evident signs of possessing a certain amount of weather-wisdom; and we may profitably instance a few facts respecting them, as indications to be used collaterally with those already mentioned. There can be little doubt that temperature, moisture, barometric variations, and electrical influences, may be taken, collectively, as the causes of uneasiness frequently experienced by ourselves, as well as by the lower creatures; for the similarity of the animal constitution, functions, and organism, can point out no other solution of the question.

Without trenching on the subject of physiology, we may shortly investigate the relation subsisting between animal sensation and meteorological phenomena; and, for this purpose, we must avail ourselves of the effects noticed on our own bodies, to explain the indications which the habits and instincts of animals afford us. Commencing with the lungs, it is evident that a decrease of atmospheric pressure must be attended with a diminished supply of the oxygen taken in at each inspiration, because the volume of air is inversely as the pressure. A diminished supply of oxygen immediately influences the process of digestion, by diminishing the rapidity with which the carbon and hydrogen of our food are converted, by combination with atmospheric oxygen, into carbonic acid and water. The blood consequently becomes, to a certain extent, vitiated, and the various humours suffer simultaneously. The common complaint of "dullness," experienced during wet weather with a southerly direction of wind, is thus readily accounted for; whilst precisely the opposite feeling, experienced during northerly winds and dry weather, is explained as the result of an increased atmospheric pressure, a quicker and larger supply of oxygen, and a more rapid oxygenation of the blood. With a southerly warm and moist wind the appetite decreases, to be renewed with full vigour when the brisk breezes of the northerly currents set in. Again, the fluids permeate all parts of the body, which is pressed on, on every side, by the weight of the atmosphere, amounting to some tons in the case of a man of ordinary size. If the barometric column diminish, the pressure is diminished on these fluids also, and hence the sense of "fulness" experienced under such circumstances, and the reverse when the atmospheric pressure again is increased. The skin of the body is alike sensitive to the effects of variable temperature and moisture; extending with an increase of them, and contracting with a decrease; and thus influencing our sensations to an extraordinary extent, as is well known by comparing our feelings experienced respectively during winds blowing from the S.W. and N.E. Electrical action, although more obscure in its effect, is not less decisive; and those who possess thin fine hair, may readily perceive a decided action on the organs of sight, and the nerves of the face, when positive electricity is present or absent: in the latter case, dimness of sight and neuralgia become exceedingly prevalent.

Now, whatever changes we experience, we can readily provide for, in various ways; for extra clothing, fires, &c., may, to a large extent, modify the ill effects to which we have alluded. But the lower class of animals, deficient, or perhaps destitute, of what we call "reason," can make no such provision; and hence, although feeling all the inconveniences we experience, they are compelled to bear with them until a favourable change occurs. Unprovided with external clothing, except that of Nature's affording, and which itself is part of their bodies, they are very sensitive of atmospheric changes, and therefore *sooner* feel them. They thus become indications to us of the coming bad weather, and their uneasiness continues until, again perceiving, *sooner* than ourselves, a coming but more favourable change, they equally foretel its advent. Besides, the hair, wool, and feathers of quadrupeds, and birds, rapidly radiate heat and electricity, and thus accelerate the *prevision* (if we may so call it) which we have just named. What we here *reason* upon is a matter of *blind experience* to persons of limited education, but necessarily of extended observing powers; and thus shepherds, farm labourers, seamen, and others, often depend on the instinct of the lower animals for what is, generally, indubitable evidence of an approaching change in the weather.

It would be beyond our limits to enumerate the various methods by which birds and animals indicate a sense of atmospheric change. Sea-birds, such as gulls, invariably fly inland in search of food on the approach of stormy weather; and some years ago, during a very severe winter, they were seen flying between London and Blackfriars bridges. Wild water-birds, of the geese and duck kind, forsake their marsh haunts, and approach nearer to towns, under similar circumstances. Swallows and rooks fly low, and keep near home, both preceding and during bad weather; and the petrel is always associated with the idea of its predicting coming storms, by its presence. Frogs are unusually noisy before rain; worms and leeches generally appear at the surface of the ground; moles throw up much earth; and ants close up their nests, to preserve their larvæ. The four-footed animals all exhibit considerable restlessness before rain; sheep and cattle huddle together, near bushes and trees; whilst horses and asses frequently assume a ludicrously thoughtful or meditative aspect. We need not, however, further extend these illustrations, as the experience of many of our readers will readily furnish them with additional instances; but the observance of the habits of animals, under such circumstances, is well worthy of the student's attention.

Many indications of coming change for wet or stormy weather have been already noticed; but there is one which we have repeatedly observed, and have long regarded as an infallible sign. It is that peculiar blue tint which distant objects in the landscape gradually assume; perhaps more perceptible to some persons than others. It is also remarkable, that better photographs can often be taken, in such circumstances, than when the air is clear—possibly owing to the presence of this "blueness." We have already noticed the vast variety of colours observable in clouds; and it may be safely presumed, that some peculiarity of action of the invisible aqueous vapour on the rays of light, may be the cause of the predominance of this colour: possibly it may arise from a species of epipolic dispersion.* At times, the gradual approach of the blue tint may be distinctly noticed, especially in a change from frosty weather to damp or thaw; and, on the contrary, as the weather improves, a greyish colour, succeeded by a brownish tint in the distance, is equally observable. As a last instance, drawn from inanimate nature, we may mention, that still water in ponds, &c., generally becomes muddy as wet weather approaches, owing to the diminished atmospheric pressure permitting the escape of gas, which, in ascending, carries up a portion of the fine dirt with each bubble from the bottom.

ELECTRIC PHENOMENA.—Before proceeding to examine the interesting results which Mr. Glaisher has afforded by the balloon ascents made in different parts of England, for meteorological purposes, we may call attention to some curious facts in reference to free electricity, occasionally present in great excess, under certain circumstances. It will have been noticed, that Admiral Fitzroy has been extremely cautious about admitting the electric action into any share in producing ordinary atmospheric phenomena. There is much prudence in such a course, because we know so little on the subject; and what information we do possess has been almost entirely derived from, and confined to, the extraordinary case of thunder-storms. It has, however, been already stated, that a northerly, or polar current, with cold and dryness, is generally associated with the presence of free positive electricity.† This is by no means a matter of surprise to the electrician, for he at once will remember that such circumstances are exactly those which would favour the development of free electricity. Whilst experimenting with the hydro-electric machine (described at page 172, in the Section on Electricity), we have been frequently put to extreme inconvenience by the large amount of free force pervading the surrounding atmosphere during a dry N.E. wind. Occasionally, the hair and whiskers of our audience, seated at a distance of thirty or forty feet from the machine, have been acted on to an extraordinary extent by electric repulsion. Under just such circumstances—only on a much larger scale—the following curious effects of redundant free electricity were noticed by several persons whilst visiting the Jungfrau, in 1863.

Mr. Watson, who headed the party, gives the following relation:—"On the 10th of July, I visited the Col de la Jungfrau, from the Æggisch-horn, in company with my wife, and Messrs. John Sowerby and W. G. Adams, of Marlborough College. We had with us, as guides, J. M. Claret, of Chamouni, and a young man from the hotel. The early morning was bright, and gave promise of a fine day; but, as we approached the Col, clouds settled down upon it; and, on reaching it, we encountered so severe a storm of wind, snow, and hail, that we were unable to stay more than a few minutes. As we descended, the snow continued to fall so densely that we lost our way, and for some time we were wandering up the Lötsch Sattel. We had hardly discovered our mistake, when a loud peal of thunder was heard; and shortly after, I observed that a strange singing sound, like that of a kettle" [the usual noise of a powerful electric discharge from a point], "was issuing from our alpen-stocks. We halted, and finding that all the axes and stocks emitted the same sound, stuck them into the snow. The guide from the hotel now pulled off his cap, shouting that his head burned; and his hair was seen to have a similar appearance to that which it would have presented had he been on an insulated stool, in connection with a powerful electrical machine.‡ We all of us experienced the sensation of pricking or burning, in some part of the body, more especially on the head and face; my hair, also, standing on an end, in an uncomfortable, but most amusing, manner. The snow gave out a hissing, as though a heavy shower of hail were falling; the veil on the 'wide-awake' of one of the party stood upright in the air; and, on waving our hands, the singing sound issued loudly from the fingers. Whenever a peal of thunder was heard, the phenomena ceased, to be resumed before the echoes had died away. At these times we felt shocks, more or less violent, in those portions of the body which were most affected. By one of these my right arm was paralysed so completely, that I could neither use nor raise it for several minutes, nor, indeed, until it had been severely rubbed by Claret; and I suffered much pain in it, at the shoulder-joint, for several hours. At half-past twelve the clouds began to pass away, and the phenomena finally ceased, having lasted twenty-five minutes. We saw no lightning; and were puzzled, at first, as to whether we should be afraid or amused. The young guide was very much alarmed; but Claret, who is devoid of fear, and who had twice before heard the singing noise (though without any of the other symptoms), laughed so heartily, that we joined him. No evil effects were felt afterwards, beyond the inconvenience arising from the burning of our faces, which, though we had no sun, were almost livid in hue when we arrived at the Æggisch-horn."

The above narrative, whilst exceedingly interesting, is of much importance in a meteorological point of view, as showing an instance in which free electricity was observed, in a surprising quantity, at a great elevation, with all the usual characteristics of its presence. In no balloon ascent, to a similar height (10,000 to 12,000 feet), have such phenomena been noticed; but this may readily be explained on account of the non-connection of the machine with any conducting body. It, in fact, would be isolated in the midst of such a development; whilst the travellers on the mountain would act as conductors, by means of their bodies standing on the ground. The great shower of hail and snow is another very noticeable feature; and should such observations be repeated, under similar circumstances, it is probable that some confirmation would be given to the theory which ascribes electricity as the cause of those phenomena. It is, however, just as possible that snow and hail may be the cause of the electrical development; for we may satisfactorily and independently account for them as arising from the loss of heat and moisture which damp air would sustain in such elevated regions, where the capacity of the atmosphere for heat is so much greater than near the sea-level. The moisture would be suddenly frozen into hail or snow; and the rapid transition, and loss of heat, thereby occasioned, may be supposed to be attended with a disturbance of the electric equilibrium, as can be readily demonstrated to occur by experiments on the small scale, conducted on similar principles.

---

* See *ante*, p. 54.

† See *ante*, p. 1174.

‡ See *ante*, p. 175.

Numerous attempts have been made to collect free atmospheric electricity, developed during storms, &c.; and perhaps the most successful have been those of Mr. Crosse, to which we have alluded in the Section on Electricity.* On the small scale, this is constantly done by the electrometer used at observatories, but the amount thus collected is insignificant, and not more than sufficient to affect pith-balls or gold leaves. An electric kite† may be employed: it has, however, the disadvantage of inconstancy of flight, and may be productive of danger to, if not the cause of the death of, the operator. We have often purposed to employ a small silken balloon, well varnished, and attached to a hempen string, enclosing a thin metallic wire to act as a conductor. This string should run through the balloon, and terminate at the top with a bunch of metallic points. Such an apparatus, if filled with hydrogen,‡ and properly ballasted, so as to ascend vertically, might be arranged, for the purpose of observation, in a similar manner to that we have suggested for the electric kite, and almost any degree of elevation might be attained; whilst the operator could pursue his experiments safely on the electricity as conducted to him by the metallic thread. We but suggest such an arrangement, having never tried it; yet we believe, with a little precaution, it might be usefully employed. Of course, there would be no chance of the hydrogen igniting, and thus putting an end to the experiment, because the conducting wire would pass in unbroken continuity through the balloon, to the apparatus below: the only annoyance would be that of strong winds blowing away the balloon; this, however, might easily be provided against. Such an experiment should be conducted in a large field, free from trees, and the balloon should be left aloft until every sign of dangerous cloud, mist, &c., had disappeared. For experiments on the presence of electricity, when expected in but small quantities at moderate elevations, a fine wire, or string with a fine copper wire inclosed in it, may be attached to an arrow, whilst the other end is in contact with an electroscope. If the arrow be then shot from a bow, as it ascends, the gold leaves or pith-balls will diverge, more or less rapidly, in proportion to the amount of free electricity present. A metallic ball, if connected with the string, and thrown upwards by the hand, may be used instead of the arrow, and is often a convenient arrangement.

With respect to the cause of free atmospheric electricity, many theories have been proposed; but the question is still involved in much obscurity. The air is, perhaps, never absolutely destitute of its presence; hence this constant evidence of its existence must be connected with a chain of causes, equally constant in their action. If we inquire into these, we must depend chiefly for explanation on the variable quantities of atmospheric moisture, change of temperature, and friction of masses of air in motion. There seem, however, no exact indications afforded as to when we may expect a redundant or deficient state of electrical action. Thus, in winter time, it is well known that free positive electricity is most abundantly noticed, especially during cold, dry, N.E. winds; and yet, during the moist and hot periods of summer, we observe the most extraordinary instances of electrical disturbance—as in the thunder-storms, which attain their maximum effects in the hot regions of our globe. These facts, at first sight, present many difficulties. It must be remembered, however, that although the surface of our earth may be heated and moist, as in summer, there is always over us, at certain elevations, strata of air, of a temperature far below freezing point—perfectly dry, and, therefore, most probably surcharged with free electricity. As we progress from summer to winter, or from low to high latitudes, the intervening stratum of hot and moist air gets thinner and thinner, until the region of perpetual snow and free electricity becomes on a level equal to that of the sea. Now, in summer time, the earth, hot air, and superincumbent cold air, present an analogous case to that of the Leyden jar, which we have already explained;§ whilst in winter, the intervening hot air is absent, and the conditions just named are also wanting. From these facts we may thus see how it is that thunder-storms are most prevalent in hot weather; and, at the same time, why free electricity may be more readily noticed in winter than in summer; the former (or winter) involving a question of *conduction*, and the latter of *induction*, in respect to the laws of electrical science.

In assigning any probable cause of the constant presence of free electricity, we are in the predicament of not being able to reproduce on the small scale, in our laboratories, the same circumstances as transpire on the large scale in nature. Nothing is easier than to afford free electricity by the friction of glass, or other solid bodies; but to perform the same operation on either dry or moist air, so as to be able to draw intelligible and decisive inferences, has yet to be accomplished. By analogy, we may suppose that two currents of air passing parallel, either horizontally or vertically, and in opposite directions or together, at unequal velocities, may, by their friction, like that of silk and glass,|| develop free electricity: or again, that the difference of heat between two currents, in impact or parallel contact, may produce it in a manner similar to that of the Thermo-electric battery.¶ Separately, or conjointly, both these causes may be called into operation; for we frequently notice, during a thunder-storm, that the clouds move in contrary directions, indicating the existence of opposed air-currents, whilst, at the same time, we find that extremes of temperature simultaneously exist, as shown by the hail-shower in the midst of the hottest summer day.

As meteorological science becomes better known, and more extensively cultivated, we may hope for the establishment of observatories, where the electrical state of the atmosphere at different heights, at the same time and place, may be observed and registered, after the manner that is now adopted with the barometer and thermometer. We shall then have another and most important element added, in enabling us to study atmospheric conditions now involved in obscurity; and perhaps may succeed in unravelling the connection which subsists between them.

MR. GLAISHER'S BALLOON ASCENTS, Etc.

If our atmosphere were ever at rest, and unaffected by heat, moisture, &c.; or, in other words, were it merely a mixture of the two gases, oxygen and nitrogen, and solely acted on by the laws of gravitation, then its density would gradually diminish upwards, its capacity for heat would increase, and the sensible temperature fall. To ascertain how far these laws are disturbed by the abnormal conditions into which the lower mass of our atmosphere is thrown, becomes, therefore, a matter of deep scientific interest.

Some time ago, the British Association voted a sum for the purpose of defraying the expense of balloon ascents, by which meteorological observations, at various heights above the surface of the earth, might be carried on. We need scarcely remind our readers that no other mode exists of carrying out such observations, except that of ascending high mountains; and, in this way, the difficulties met with, and the inconvenience to which the observer is subjected, are almost insuperable. No such objection can arise when balloons are employed. In the course of a few minutes after leaving the earth, the

¶ See *ante*, p. 241.

observer can reach any altitude he may desire; he can ascend and descend as he pleases; his attention need be diverted by no object; and he is put to no personal inconvenience. Several ascents have been made; and we select the following account (furnished by Mr. Glaisher, of the Royal Observatory, Greenwich) of one made on July 30, 1862.

"Mr. Coxwell having planned an ascent with his large balloon, from the Crystal Palace, I availed myself of the offer of a seat in the car, for the purpose of taking a series of observations upon the variations of temperature, and the several hygrometrical states of the atmosphere at moderate elevations, and which I had failed to do in my recent ascent from Wolverhampton.

"The instruments necessary for these investigations were in the hands of Messrs. Negretti and Zambra, and were those which were broken and injured in my recent ascent with the same balloon, and confided to them for renewal and repair, and which they had executed in a very satisfactory manner, these gentlemen having, at all times, expressed an earnest desire to promote the experiments required by the British Association. All the other instruments are at Wolverhampton, ready for the next high ascent. The instruments used on this occasion were two aneroid barometers, dry and wet bulb thermometers, and a Daniell's dew-point hygrometer. As it is of essential importance that the thermometers should be so sensitive that they readily acquire the temperature of the surrounding air, they were of necessity very delicate.

"The air was in very gentle motion, which enabled Messrs. Negretti and Zambra carefully to fix the instruments before starting, so that I at once began to observe, which in my former ascent I was unable to do until I was the greater part of a mile high.

"The balloon left the earth at 4h. 40m., laden with thirteen gentlemen, and a large amount of sand for ballast, and, under the influence of a moderate breeze, bore away slowly nearly S.E., passing successively Eltham, Dartford, to the village of Singlewell, near Gravesend.

"The heights of the balloon, successively, were as follows:—At 4h. 43m. it had attained the elevation of 1,340 feet above the level of the sea; at 4h. 49m. that of 3,700 feet, increasing slowly, till, at 5h. 17m., it was about 5,300 feet. It then, by 5h. 20m., fell 200 feet. On throwing out sand it rose to 5,500 feet by 5h. 24m.; and to 6,600 feet by 5h. 43m. Some gas was let out, and it sank to 5,700 feet by 5h. 47m. Some sand was then thrown out, and it rose to 7,350—the highest point reached—at 6h. 1m. At 6h. 6m. it fell to 6,700. Some sand was thrown out, and it rose to 7,100 feet by 6h. 12m. At twenty minutes past six it descended to 5,300 feet, and slowly to 2,100 feet at 6h. 25m., and to the earth a little after half-past six o'clock.

"Between 4h. 46m. and 5h. 1m., the altitude and azimuth of the balloon were observed at the Royal Observatory, Greenwich, by E. J. Stone, Esq., M.A. If any similar observations have been taken at another place, I should be glad to be favoured with them, as furnishing the means of an independent determination of the elevations of the balloon, and thus checking those made by means of the variations of temperature and barometric pressure.

"The temperature of the air was 68° at the Crystal Palace. At 1,000 feet high it was 62°; at 3,700 feet it was 51°; it continued at this reading nearly till the height of 4,500 feet was reached. At 5h. 4m. it varied between 48° and 50°, till the height of 5,700; it decreased from 48° to 43½° between 5h. 31m. and 5h. 38m.; the height at the latter time being 6,100 feet. At the height of 7,350 feet the temperature was 41°, being 27° lower than on the surface of the earth. After this the temperature rose gradually as the balloon descended, and was 47° at 6h. 20m., 50° at 6h. 24m., and 68° on reaching the ground.

"The temperature of the dew-point, or that temperature at which the moisture in the air, in the invisible shape of vapour, is deposited as water, upon the objects cooled down to this temperature, were successively as follows:—In the gardens of the Crystal Palace this deposit of water took place when the temperature of the bulk of the hygrometer was reduced, by the action of ether, to 50°; at the height of 1,300 feet the bulb was bedewed at 43°; between 3,000 and 4,500 feet, at 40°; then up to 6,000 feet, at temperatures gradually decreasing; at about 7,300 feet, at a little below 32°; and it afterwards increased to 47° on reaching the surface of the earth. When the air is saturated with moisture, as in a wetting fog, the temperature both of the air and dew-points is the same. On this occasion, on the earth, the latter temperature was 18° below the former, and at the highest elevation was 9°, so that the air was nowhere saturated. From a knowledge of the temperature of the dew-point, we know the amount of water then present in a certain mass of air; this amounted, in the grounds of the Crystal Palace, to 4 grains in a cubic foot; at 1,300 feet high, to 3 grains; at 5,000 feet, but 2½ grains; and at 7,300 feet, there were about 2 grains in a cubic foot of air.

"As the amount of aqueous vapour in the air necessarily decreases with the temperature, the changes of the hygrometric condition of the air, at different elevations, may be better understood in speaking of the relative humidity of the atmosphere, by considering air as saturated with moisture represented by 100, and air without moisture by 0.

"The humidity of the air thus expressed was, on the surface of the ground, 50°, showing an unusual degree of dryness. It increased as we left the earth to 63° at 3,000 feet, to 66° at 4,000, and to 70° at 7,300; and the air gradually became less humid on approaching the earth. At no point, therefore, was complete saturation met with, as before noticed. The weight of a cubic foot of air varied from 526 grains on the ground, to 429 grains at the greatest height reached.

"Similar and simultaneous observations were taken at the Royal Observatory, Greenwich, from which we learn that the temperature of the air, on the surface of the ground, varied from 67° to 68°; that of the dew-point from 49° to 51°; that there were about 4 grains of water in a cubic foot of air; the degree of humidity was about 50; and the weight of a cubic foot of air was 526 grains: therefore the differences at the highest elevations, from these values, are due to the elevation alone.

"Test ozone papers were not coloured at all; and no ozone was noticed in the ascent from Wolverhampton.* We were never in the clouds, although rocky cumuli—which, it will be remembered, are the fine massive clouds of day—were at a lower elevation all round, and cumulostrati at a higher elevation than ourselves. The sky was free from clouds in the zenith, and of a deeper blue than as seen from the surface of the earth. At times there was a great mist, and, generally, the horizon was hazy and obscure; the shadow of the balloon was seen both on the ground, as well as on the surface of the clouds.

"A horizontal magnet occupied a somewhat longer time to perform a certain number of vibrations, both in this as well as in the previous ascent, than it did on the surface of the earth. This is contrary to the result obtained by Guy Lussac in 1804.

"At 5h. 24m. a gun was heard with a sharp sound; at 5h. 25m. a drum was heard; at 5h. 26m. a band was heard; at 5h. 38m. a gun was heard; and at 6h. 10m. a dog barking was heard; and the working of the engines on the Dover and Chatham Railway was distinctly heard.

"I have to thank W. F. Ingelow, Esq., for kindly reading one barometer for me, and for rendering considerable assistance in noticing the first appearance of dew on the black bulb of Daniell's hygrometer, enabling me thereby greatly to increase the number of my own observations. The gas furnished must have been of good quality to have raised so great a weight to such an elevation."

---

* Mr. Glaisher states, subsequently, that this was owing to the paper-tests being of bad quality.

The preceding extracts, from Mr. Glaisher's description of his aërial voyage, afford our readers a general idea of the scope and objects which the British Association had in view when they first adopted balloon ascents, for the investigation of meteorological phenomena. Before stating the results which Mr. Glaisher has obtained, we may properly call attention to the variety of subjects which might be elucidated by observations carried on at a considerable height from the surface of the earth, and under circumstances in which numerous locally interfering causes would be absent.

In astronomical observations, it is of the highest importance that the proper refraction for any altitude of a star should be ascertained. The nearer the horizon, the greater is the refractive effect of the atmosphere on the apparent position of a heavenly body. Again, the *amount* of refraction depends not only on the altitude of the body, but also on the varying density of the atmosphere, its humidity, temperature, &c. Some of the effects of these accidents on terrestrial objects, have been already described in connection with the phenomena of the *Mirage*, &c.;* and the consideration of them will point out how essential an accurate estimation of their nature and amount is to the practical astronomer.

In estimating the force of gravity at any point on the surface of the earth, the pendulum is universally employed; and according to the number of its vibrations, in a given time, so the intensity of gravitating force is indicated for the place. In a similar manner, the vibrations of the magnetic needle may be made a measure of the increase or decrease of magnetic force, at any two altitudes when compared together. This subject is of extreme importance in connection with the philosophy of the Undulatory Forces, and one to which we have already directed attention in the Section on Magnetism. Our knowledge of the force of *gravitation*, may be enlarged by considering the attracting power, or perturbing forces, which each and all of the planets mutually exercise; whilst with respect to the *Magnetic forces*, our investigations are necessarily limited to the phenomena exhibited, on, a little beneath, or a short distance above, the surface of our globe.

The *theoretical* constitution of our atmosphere has been determined with comparative precision; but its *actual* composition, at various altitudes, must necessarily depend on local disturbing causes. It is but reasonable to suppose, that the neighbourhood of large towns would present an atmosphere tainted with the impurities produced by manufacturing operations, furnaces, and a crowded population. The *fact* of the air, in such localities, being deteriorated, has long been familiarly known; but the *amount* of impurity dissolved in the air, under such circumstances, and at varying heights, has not been even approximately measured until recently. The presence or absence of ozone, affords us a means of testing the respirable qualities of the air, as has been already pointed out at a previous page.†

In the article on Photography, we explained the peculiar effects of the actinic rays of light on salts of silver, &c.‡ Now the daily experience of every operator teaches him, that considerable difference in the power of the actinic rays is constantly occurring. A change of atmospheric humidity, amount of cloud, &c., is instantly attended with an increase or decrease of actinic force; and hence the varying time required to take a good photograph, especially in landscape effects. We also find, that within the tropics, at the level of the sea, it is difficult to get a good impression on the sensitive plate in the camera, although, in the same region, excellent views are produced at considerable altitudes.

Thus, in connection with Astronomy, Magnetism, Chemistry, and Photography, we must perceive, that investigations carried on in the upper strata of our atmosphere, can but result in an accession to our knowledge; for, at a height of a few thousand feet, we are, to a large extent, removed from irregular and accidental disturbing causes, the presence of which vitiate accurate observations and successful experiments in any of the branches of science to which we have referred. It will be unnecessary to urge similar considerations on those who have read the previous pages in this section, in connection with meteorological phenomena, which are almost invariably produced at heights above 1,000 feet from the surface of the earth. Clouds, hail, snow, rain, lightning, meteors or aërolites, &c., all owe their origin to atmospheric disturbances, occurring, in many cases, far above the reach of man, if unaided by the balloon. Science has provided us, in this machine, with a means by which, Dædalus-like, we may fly in the air, and, at our leisure, note phenomena of the utmost importance to the existence of our race. The *cui-bono* inquiry usually entertained in reference to most investigations of a purely scientific nature, may be readily answered, in the case of balloon ascents, by remarking, that if, through our present limited knowledge, obtained by observations on the surface of the earth, we have been enabled to forewarn the mariner of a coming storm, and save him and his vessel from shipwreck,§ how much more successful may we hope to become, if we venture into those winds, clouds, and storms which he dreads, and investigate their causes, connection, &c., in their own regions, under circumstances so essentially fitted for our purpose.

Having thus pointed out the value of balloon ascents, in a scientific and practical point of view, we proceed to give an analysis of the results which Mr. Glaisher has obtained.

The chief objects which were sought after in the balloon ascents of 1862, were as follows:—

1. The ratio of increase or decrease of the temperature, and the amount of aqueous vapour in the air, at heights within five miles (26,400 feet) above the sea-level, in this country.
2. To compare the readings of aneroid and mercurial barometers.
3. To ascertain the electrical state of the atmosphere at various elevations.
4. To discover the amount of free ozone.
5. To register the number of vibrations of a magnetic needle at increasing heights.
6. To find the relation of the temperature of the air and that of the dew-point, at heights corresponding with those of high lands in India, and other places; and to compare the indications of the dry and wet bulb-thermometers with those of Daniell's and Regnault's hygrometers.
7. To collect air at different elevations.
8. To note the height, kind, thickness, density, &c., of various strata of clouds.
9. To ascertain the rate and direction of atmospheric currents.
10. To make observations on the intensity, &c., of sound.

Besides the above particulars, it was intended to note any phenomena which might casually present themselves during the progress of the observations indicated above. The usual kind of meteorological instruments were employed—each, however, having been specially prepared for the purpose. Owing to occasional accidents, many of them were broken during descents.

Eight ascents, in all, were made in 1862; viz., three from Wolverhampton, which was chosen as a central position, and because it afforded a good breadth of land, without the danger of a voyage over the sea; four from the Crystal Palace at Sydenham; and one from Hendon, which was, in fact, a re-ascent from the spot at which the voyagers had alighted on the previous evening. The dates of the ascents were all in the summer months, being from July 17 to September 8, inclusive.

The greatest height attained was on September 5, in an ascent from Wolverhampton. This was estimated to be at least 36,000 feet; but as Mr. Glaisher became unconscious, owing to the high degree of atmospheric rarefaction, the precise elevation was undetermined. In the ascent of July 17, a height of 26,177 feet was attained; and "in the descent, a mass of vapour, 8,000 feet thick, was passed through. This was so dense that the balloon was not visible from the car."

---

* See *ante*, pp. 1147, 1148. † See *ante*, p. 1122. ‡ See also *ante*, p. 57.

§ See *ante*, p. 1173.

Mr. Glaisher prepared the following table, which shows the mean temperature of the air at each 5,000 feet above the level of the sea, on the dates named, selecting those in which the highest ascents were made.

Height above the Level of the Sea.	Mean Temperature of the Air.					Decrease of temperature for an Increase of Height of 5,000 feet.
	July 17.	August 18.	August 21.	September 8.	Mean.	
Feet.	Deg.	Deg.	Deg.	Deg.	Deg.	Deg.
0	61·2	69·6	62·0	62·2	63·8	...
5,000	39·7	48·0	43·3	41·4	43·1	20·7
10,000	28·0	40·7	32·0	31·0	32·9	10·2
15,000	31·0	31·1	19·0	21·0	25·7	7·2
19,500	42·2	...	...	...	...	...
20,000	33·0	25·9	...	10·6	23·2	2·5
25,000	16·0	23·9	...	0·0	13·3	9·9
30,000	...	...	...	–5·3	...	...
Decrease of Temperature for an Increase of Height of 25,000 feet.	44·9	45·7	...	62·2	50·5	...

On these facts Mr. Glaisher remarks—"The results of July 17 are perfectly anomalous. Up to 10,000 feet the decrease accords with the other days of experiments; but from 10,000 feet, the results are perfectly surprising, and continue so up to more than 20,000 feet. Above 25,000 feet, they are again accordant. If we suppose that up to 10,000, and again at 25,000 feet, the results are not abnormal, by continuing the curve joining these two portions, and then reading, we should have the following readings: viz.—

"At 0 feet, mean temperature = 61°·2
" 5,000 " " " = 39°·7
" 10,000 " " " = 27°·5
" 15,000 " " " = 22°·7
" 19,500 " " " = 20°·0
" 20,000 " " " = 19°·5
" 25,000 " " " = 16°·3

"Then the measure of disturbance would be as follows: viz.—

"At 10,000 feet . . . . = 0°·5 in excess.
" 15,000 " . . . . = 8°·3 "
" 19,500 " . . . . = 22°·2 "
" 20,000 " . . . . = 13°·5 "
" 25,000 " . . . . = 0°·3 in defect.

"The numbers, in the last column of the table, show that the average decrease of temperature, in the first 5,000 feet, exceeds 20°, and, in the next 5,000 feet, is but little more than 10°. The numbers, in the lowest line of the table, show that the average decrease of temperature for 25,000 feet, is 51° nearly. From these numbers, it seems that two-fifths of the whole decrease of temperature, in five miles, takes place in the *first* mile; and, therefore, that the decrement is not uniform with the increment of elevation."

So far, our attention has been confined to the results which Mr. Glaisher obtained during the highest ascents he effected. In the following table the temperature is given for each 1,000 feet of elevation, between the earth and 5,000 above it, for each ascent made during the summer of 1862. It will be seen that the temperature decreases 21° in the 5,000 feet, and that the rate is not uniform. (See also Tables at pp. 1215 and 1216).

Height.	July 17.	July 30.	August 18.	August 20.	August 21.	Sept. 1.	Sept. 5.	Sept. 8.	Mean.	Effect of 1,000 feet.
Feet.	Degrees.	Degrees.	Degrees.	Degrees.	Degrees.	Degrees.	Degrees.	Degrees.	Degrees.	Degrees.
0	61·2	70·0	69·6	66·8	62·0	67·0	62·2	69·7	66·1	...
1,000	57·0	63·0	62·0	62·0	58·0	59·8	57·8	65·0	60·6	5·5
2,000	52·6	56·8	56·5	57·0	54·0	53·2	53·0	60·4	55·4	5·2
3,000	48·3	52·2	53·3	52·7	50·3	49·2	48·7	55·7	51·3	4·1
4,000	44·0	49·8	50·4	49·0	46·9	47·7	45·0	51·5	48·0	3·3
5,000	39·7	47·0	48·0	45·0	43·3	46·0	41·4	48·4	44·8	3·2
Effect of an Elevation of 5,000 feet	21·5	23·0	21·6	21·8	18·7	21·0	20·8	21·3	21·3	...

With respect to other objects of inquiry, it was found, that the electricity of the air was generally positive, diminishing in amount as the elevation increased; that ozone was present in large quantities; that the vibration of the magnet was longer at high elevations than on the earth; and that sounds varied, in the distance at which they could be heard—the barking of a dog being noticed at a height of two miles, whilst the shouting of a multitude was not heard at one mile high.

The general results deduced were—

1. That the temperature of the air does *not* decrease uniformly with an increasing elevation above the surface of the earth; a fact bearing strongly on the refractive powers of the atmosphere, in relation to astronomical observations.

2. That an aneroid barometer may be correctly read to one, and probably to two, places of decimals, when indicating a pressure equal to five inches of mercury in the barometer. (See Table at page 1214.)

3. That the atmospheric humidity decreases rapidly to a height of five miles, where its amount is extremely small.

4. That the readily accepted theory, as to the prevalence of a settled west or north-west wind, was not confirmed.

5. That the opinion of the clouds assuming a counterpart of the earth's surface, and that they rise and fall like hills and dales, was not countenanced by the appearance of their upper surface.

The following interesting description of the appearance of the clouds, as observed on the date named, is quoted from the *Athenæum*, to which periodical we are indebted for many of the facts we have adduced. The balloon had descended on the previous evening at Hendon, and had been anchored for the night, preparatory to an ascent on the following morning.

"Before sunrise, on August 21, all the instruments were replaced, and the balloon left the earth: it was a warm, dull, cloudy, morning; clouds were reached at the height of 5,000 feet; the light rapidly increased, and gradually the balloon emerged from dense clouds into a basin surrounded by immense black mountains of cloud, rising far above. Shortly afterwards there were deep ravines of grand proportions below, bounded with beautiful curved lines. The sky was blue, with cirri. The tops of the mountain-like clouds became silver and golden: at the height of 8,000 feet we were on their level, and the sun appeared, flooding, with golden light, all space for many degrees both right and left, tinting with orange and silver all the remaining space. It was a glorious sight. As the sun's rays fell on the balloon we rose more rapidly, each instant opening to us ravines of wonderful extent, and presenting elsewhere a mighty sea of cloud. Here there were shining masses in mountain chains, some rising perpendicularly from the plains, dark on one side, and silvery and bright on the other, with summits of dazzling whiteness: some there were of a pyramidal form; a large portion undulatory; and, in the horizon, Alpine ranges bounded the view. A height of nearly three miles was reached."

In reference to the ascent of September 1, Mr. Glaisher remarks—"When at the height of three-quarters of a mile over London, the whole course of the river Thames was visible from its mouth; and parallel to it, and bounded by its banks, a cloud or fog-bank extended the whole distance, following all its sinuosities. For half-an-hour before its descent, near Woking, in Surrey, the balloon was under one stratum of cloud, and above another: the upper surface of the latter was remarked as bluish white; the middle portion the pure white of the cumulus; and the lower surface a blackish white, and from it, rain was falling on the earth. The balloon descended to a height of 1,300 feet, but was still above the clouds. It was afterwards learnt that rain had been falling from these clouds all the afternoon."

In the following year (1863), Mr. Glaisher made fifteen ascents; and the results obtained agree, in the main, with those already detailed. The weather, during the summer, was generally calm, and comparatively little rain fell for some months. It will be unnecessary for us to present, in a tabular form, the results obtained; but we shall conclude our notice of the ascents by giving some of the most interesting particulars of the last, which was made on September 28. The object in this one was chiefly to observe the effect due to the influence (if any) of the autumnal equinox on atmospheric phenomena.

The balloon rose from the earth at 7h. 43m.; in two minutes afterwards it was at a height of 500 feet; in four minutes, at 1,000 feet; in nine minutes, at 2,000 feet; 2 miles high at 8h. 30m.;. 2½ miles at from 8h. 45m. to 9h. 8m.; 2¾ miles from 9h. 15m. to 9h. 23m.; and at 3½ miles, the highest point, at 9h. 33m.: it then descended to 2¾ miles at 9h. 52m.; 2½ miles at 9h. 59m.; 2 miles at 10h. 4m.; 1½ mile at 10h. 9m.; 1 mile at 10h. 13m.; 3,000 feet at 10h. 15½m.; 1,000 feet at 10h. 23m.; reaching the earth at 10h. 30m. The temperature of the air at 7 o'clock was 43°, and it became 48° when the balloon left the ground at 7h. 43m.; at 1,000 feet elevation it was 45°; at 3,000 feet, 40°; at 5,200 feet, 34°; at 8,000 feet, 27°; at 10,500 feet, 21°; and at 13,000 feet, 12°. The temperature varied irregularly with the rising sun, increasing to 16° at a height a little above 2½ miles. On descending, the temperature, which varied from 7° to 15° at the height of 2¾ miles, gradually increased to 35° at 5,000 feet; 40° at 3,000 feet; 53° at 1,000 feet; and the same amount was noticed on reaching the ground.

The temperature of the dew-point* was 44° on the ground; 35° at 2,000 feet high; 25° at 5,200 feet; 20° at 13,000 feet; ranging, at this level, between 20° and 12°; sometimes being at the same temperature as that of the air, and, therefore, indicating complete saturation in some places. Above this level, the dew-point decreased to 10° below zero, approaching more nearly to saturation than had been noticed, at that height, in previous ascents. On descending, the dew-point rose till it attained 46°, which was the temperature at which it was produced at the time of reaching the earth. On the ground, the air contained 3½ grains of aqueous vapour in the cubic foot; at 2,000 feet elevation there were 2½ grains; at 5,200 feet, 1½ grain; and at the height of 17,000 feet, there was less than half a grain in a cubic foot. Presuming the greatest amount of moisture which could be present at the then temperature of the air, to be divided into 100 parts, it would have been, on the ground, and up to a height of 1,000 feet, equal to 90 parts; at 5,200 feet, 72; and varied, between 70 and 100, up to the highest point reached.

In comparing the decrements of temperature during the ascent, and the increments as the descent was effected, it will be evident that no regularity could be noticed. If the results, again, are compared with those given at page 1182, the discrepancy is still more apparent. But this might have been expected, from the circumstances under which the observations were made. The ground was below the ordinary temperature at the early hour of starting; for, immediately the sun rose, the temperature was also raised. Of course, during the ascent, every stratum of air passed through would be similarly affected by the absorption of the heating solar rays; and hence any observations would be incomparable, in a practical point of view, with others preceding or following them. Instead, therefore, of the temperature decreasing, in a regular ratio, as a greater elevation was attained, the solar influence quite prevented such a result; and, in the descent, similar irregularities would be met with. Comparing the observations up to one mile elevation, we have a temperature at—

		Ascent.		Descent.
0 feet	. of .	41°	. of .	53°
1,000 „	. „ .	45°	. „ .	53°
3,000 „	. „ .	40°	. „ .	40°
5,200 „	. „ .	34°	. „ .	35°

Whence it would appear that the influence of local causes, such as terrestrial radiation, convection of heat upward from the surface of the earth, &c., greatly affected all the observations made up to a height of about one mile—a result similar to that mentioned at page 1182.

Although, for purely scientific purposes, these observations afford no certain data, we may yet gather valuable hints from them in a sanitary point of view. It is plainly evident that our atmosphere will be considerably and unequally affected at times, with respect to its purity, if it be so in regard to its temperature; because a normal atmosphere, acted on by the simple physical laws of pressure and expansion alone, would certainly decrease in its sensible heat in definite ratios depending on the altitude. But, from actual observations in this island, we find that there exists an extensive strata, just touching the earth's surface, which cannot be proved to obey this law in an equable manner; and this seeming exception arises solely because the effects are masked by accidental, and, therefore, local causes. Mr. Glaisher has, more than once, noticed the smoke, &c., from large towns (especially London), to reach a mile in height; just, in fact, the elevation beneath which the law of the temperature, being in the inverse ratio of the altitude, appears to be stopped in its action. From the numerous observations made, it has also been shown, that the stratum of air, within a mile over the earth, is that most readily affected by storms—a result which we should fully expect, from the abnormal state into which it is thrown by the variety of disturbing causes to which its lower mass is subject.

Let us, for a moment, direct attention to the various affections to which the atmosphere existing over large towns is liable. Thousands of fires in private dwellings; furnaces in the various manufactories; heat from the bodies of the inhabitants; radiation of previously absorbed solar heat, from the materials of the houses, paved roads, &c., &c.;—all tend to cause an enormous up-draught of heated air, which rises as if produced from an immense furnace. A spectator, situated at a short distance from any of our large towns (especially London), if on an elevated position, and in the absence of all wind, will observe an immense body of smoke, &c., rising vertically, and spreading itself, like a canopy of darkness, over the under-lying city. This smoke, or vapour, embodies every volatile impurity produced by all possible causes; and so long as it has a higher temperature than the atmosphere, it remains suspended over-head. If a purely normal atmosphere, uninfluenced by external disturbing causes, were perpetually surrounding such a district, every gas, and particle, of greater specific gravity than itself, would, on gaining the temperature of the air, be precipitated on to the place whence it had arisen—a very common occurrence, indeed, as is seen in the little "blacks" that so abundantly fall during heavy weather, in large towns, and which result from the aggregation of the carbon, &c., in the smoke. Hence, the inhabitants of such a place would live in an atmosphere completely stagnant, and daily becoming more impure; the culminating effect of which would be disease and death. *Locally*, on the small scale, this is constantly occurring in narrow streets, alleys, and crowded dwellings; and, *generally*, whenever the air has become still, and unaffected by moving causes.

---

* See ante, p. 1146.

But the very irregularity in the physical constitution of an atmosphere such as ours, is productive of the most beneficial results. Never at rest in itself—which it would be if in its normal condition—it is ever susceptible of external influences; hence the refreshing breezes that course down our streets, or the boisterous March and November winds, which, scavenger-like, cleanse our fever-stricken courts and alleys. The very characteristic which seems to prove it an exception to that regularity of law prevalent in nature, is that which forms one of its most valued qualities, making it life-giving in its energy, whilst its stability of position would be synonymous with death.

Reverting, after this brief digression, to the results obtained by Mr. Glaisher, we may notice the actinic observations made during the ascent. By Herschel's actinometer, the force of the sun's rays was shown, at 11 A.M. (at the Wrottesley Observatory), by 48 divisions in one minute; and at 5 P.M., by 25 divisions, the sun being then low. At 9h. 8m., during the ascent, the increase was, with a bright sun, 5 divisions in one minute; at the height of 13,000 feet (at 9h. 29m.), it was 7 divisions; at 16,000 feet, the increase was about 7 or 8 divisions; at 10h. 7m., or 8,000 feet elevation, it was 20 divisions; at 10h. 19m., and at a height of a little over 1,000 feet, it was 25 divisions; and on the ground, at 10h. 45m., the number was 48. With respect to solar radiation, a delicate blackened-bulb thermometer, at heights varying from 13,500 to 1,000 feet, in the descent, showed a variation not exceeding 4° to 8° beyond that of the shaded thermometers: at the height of three miles, although the sun shone brightly, the blackened bulb showed an excess of but 2° to 4°; whilst, on the ground, that became 30°. The observations, during previous ascents, had proved that a self-registering blackened-bulb thermometer, in vacuo, with its bulb always in the beams of the sun, never read so high as before leaving the earth; and on being re-set, indicated a reading but little beyond that of the shaded thermometers. This result very possibly arose from the great capacity that rarefied air has for heat, which would cause the immediate loss, by radiation, of nearly all the caloric absorbed by the bulb during its exposure.

A sky spectrum, with the lines visible from B to G,* was observed, from 7h. 58m. to 9h. 4m., at heights varying from 3,000 to 13,000 feet; from 9h. 22m. to 9h. 43m., and at heights between 15,000 and 18,000 feet, the spectrum extended from A to H, at which latter point it became extremely dark, whilst the lines in the violet end were very numerous. We have already remarked that the actinic rays were most active at high elevations; and Professor Piazzi Smith, during the British Association Meeting of 1863, furnished some very interesting facts, which we may conveniently give, as verifying the observations of Mr. Glaisher. He stated that, in 1856, the chief object of astronomical experiments made on the Peak of Teneriffe, which has a height of 12,000 feet, was to ascertain the degree of improvement in definition, obtained whilst using the telescope at great elevations. It was found—the air being so dry and clear—that stars, when viewed by powerful instruments, always gave clear and well-defined discs, surrounded with regularly formed rings, even when a high magnifying power was used. He had recently magnified some of the photographs taken on Teneriffe, in 1856, at various elevations, and found that their clearness and definition depended on the elevation, and that they remarkably confirmed the results of telescopic observation. Near the sea-level a photograph could never be taken which would show clearly the detail on the side of a distant hill, however brightly the rocks or cliffs were illuminated by strong sun-light; the microscope only brought out a broad, faint, and nearly uniform tint. On the other hand, photographs taken at high elevations, exhibited clearly, and well-defined, the most minute detail; even bushes on a hill-side, distant four-and-a-half miles, were distinctly marked.

With respect to the amount of ozone, which was observed in the last ascent of Mr. Glaisher, it appeared that none was shown by papers freely distributed about the car; but ozone powders, made of wheat-starch and iodide of potassium, were slightly tinged when first exposed; were unchanged at a height of one mile; but when noticed at 9h. 57m., at a height of about 13,500 feet, they indicated an amount of colour equal to four, when compared with a scale whose maximun is ten.

We have thus put our readers in possession of the leading facts obtained during the scientific balloon ascents of late years. Whilst they have largely added to our knowledge of meteorological conditions, with regard to the temperature, moisture, quantity of ozone, actinism, &c., of the atmosphere immediately over the earth, they have entirely dispelled the illusive theory which was long indulged in—that the decrement of temperature was in inverse ratio of the altitude. In a purely theoretical point of view, such can only be the case in an atmosphere entirely unaffected by solar radiation and the convection of heat, and in the absence of purely local disturbing causes. These conditions cannot be present in our atmosphere, within any elevation approachable by man, above the surface of the earth. Beyond a distance of five or six miles, it is impossible that the observer could exist: indeed, in one of the ascents, this elevation was attained, and nearly proved fatal both to Mr. Glaisher and Mr. Coxwell; the former entirely losing all consciousness, whilst Mr. C. lost the control of muscular action, and was all but a passive observer of the nearly inevitable destruction of himself and companion.

There could scarcely have been chosen any situation in Europe in which so many disturbing causes to normal atmospheric conditions are presented. Surrounded by the sea; of narrow breadth; situated between the warm Gulf-stream on the west, and the cold polar currents on the north and east—our island presents almost a uniqueness of condition in respect to meteorological phenomena. If circumstances permitted, ascents made in regions less liable to such extraordinary interfering causes, might give some interesting results; and many parts of continental Europe afford such opportunities. At present, the proper mode of managing the balloon is but little known, and confined to but a few individuals, who possess sufficient practical skill. On frequent occasions, the lives of both the aeronauts were in imminent danger; and it is a matter of great surprise, that so many valuable observations could have been made under circumstances in which the majority of persons would have only exerted themselves for their own safety, and regardless of the interests of science. There can be little doubt that a constant repetition of these experiments will afford a much larger quota of results; for as, on each ascent, the external conditions of our ever-changeable atmosphere may be expected to vary, new phenomena will present themselves, whilst previously acquired experience will be prepared to seize on each novelty, and assign to it a proper place in the departments of meteorological science.

LUMINOUS METEORS, AND THE AURORA BOREALIS.—During the last few years, considerable attention has been devoted to the study of meteors, the appearance of which has become more frequent, or, perhaps, more noticed. In 1862 and 1863, several large luminous bodies were seen; and, amongst them, one was observed, simultaneously, in the middle and southern districts of England, and in the north and centre of France—an evidence that it must have travelled at a considerable height above the surface of the earth. In the early part of August, 1863, the usual annual meteoric display was exceedingly great, attaining the maximum on or about the 11th of the month, when as many as 200 "shooting stars" were noticed in about three hours. In the constellation of Cassiopeia, we perceived, at 9 P. M., an incessant discharge *south-westward*, lasting for above an hour, none of the balls having a great size, and the distance travelled by each being from three to five degrees: the elevation above the surface of the earth seemed to be great, judging from the comparatively small velocity and apparent magnitude of each meteor. Most observers remarked, that the paths of the meteors, about that date, chiefly lay from north-east to south-west. We observed but few instances in which any tail was shown, although the evenings were generally favourable for observation.

---

* See *ante* p. 56.

The extremely rapid course of these bodies renders it very difficult either to calculate their elevation, or to use means of testing the nature of the light they emit, as can be done with the sun, &c., by spectrum analysis.* Two observers at distant stations, may, by chance, simultaneously observe one; but such an occurrence seldom presents itself; hence the varying estimates which are made respecting their height. There can be little doubt, from their periodicity, that they are solid bodies, and not of electric origin, as was formerly supposed—on, perhaps, the slightest possible grounds. The different theories which have been suggested, to account for these meteoric phenomena, have been already alluded to in an earlier portion of this section; and we regret that, at present, nothing of a more definite nature has been arrived at.†

With respect to the Aurora Borealis, which has also been spoken of, there can scarcely be a doubt as to its origin. Its great altitude, fleeting nature, and general appearance, all bespeak an electric origin. Few persons residing southward of Scotland can have any idea of the beauty of this phenomenon, which may be seen in great perfection, even in our own isles, during the winter season. In the western and northern districts of that country, we have often observed the entire heavens illuminated; the north, north-western, and north-easterly parts shining, of course, with the greatest brilliancy. Occasionally the coruscations proceed from those quarters extending far beyond the zenith, in a southerly direction, so that the whole sphere overhead is brilliantly lit up. At other times, but more rarely, the zenith itself seems to be the centre of action, and, ray-like, thousands of broad sheets of flame, of many colours, dart on all sides. Generally speaking, when an Aurora is thus developed, the flames assume a lambent or phosphorescent appearance, are comparatively ill-defined, and rarely more dense in one place than another. At times we have seen a lake, five miles long, and four broad, illuminated from the northern side by an Aurora, to an extent quite equal to that it usually presented under the full moon, and the shadows from the over-hanging mountains were deeply cast on the water. During several years' observations, often carried on nightly, we noticed that the Aurora was always better seen inland than near the sea; our places of observation ranging between the east and west coast of Scotland, on a line extending north of the Clyde and Forth rivers, as far as the counties of Ross and Cromarty.

In the experiments which we undertook, some years ago, on the spark in vacuo, from the Rhumkorf coil, and which are related at a previous page,‡ we frequently noticed the peculiar effect resulting from the introduction of a minute quantity of various vapours into the highly exhausted receiver. So long as the remaining atmospheric air was pure, the colour of the spark was a rich reddish purple, becoming bluer in proportion as the exhaustion was increased. A more dense state of the air, effected by its gradual admission, only made the spark of a redder tint. If, however, the vapour of bisulphide of carbon were passed in, in exceedingly minute quantities, a sudden flash of delicately whitish-yellow light was produced, exactly resembling that of the diffused Aurora we have shortly before alluded to. Without describing a great variety of experiments, we may remark, that every tint of the Aurora may thus be produced by choosing proper vapours (chiefly of ethers), and simultaneously regulating the vacuum, which should vary, in the air-pump, from about 27 to 29 inches, the external air having a barometric height of not less than 29·30.

Now a repetition of such experiments cannot fail to suggest, to any one who has seen the Auroral phenomena we have just described, their great similarity, or, to us, identity of appearance. If electricity be assumed as the cause of Auroræ, precisely such circumstances may occur, in the elevated regions of the atmosphere, as we refer to in the above remarks—namely, a minute quantity of solid colouring matter, diffused in a highly attenuated atmosphere. Rapid chemical combination would constantly occur, attended with the production of flame, between the solid matter and the oxygen of the atmosphere; and if it be objected that the quantity of oxygen present would be excessively small, we reply, that the results obtained in the air-pump receiver, are produced under exactly similar conditions; for the vacuum very nearly approaches that existing in the regions in which the Aurora is supposed to exist, assuming that to lie within the limits of our atmosphere.

Whilst offering this as an explanation of certain Auroral appearances, we do so under the conviction that it can be but a suggestion, the value of which is dependent on analogy alone. It is by no means certain that the Aurora is at all caused by electric action; indeed, such is only inferred from the disturbance of the magnetic needle generally attending the displays of Auroræ; and, again, the relation of this fact to electrical science is also one of inference, depending on the knowledge we possess of the mutual production of the electric and magnetic forces, so far as our experimental determinations have carried us.

THE METEOROLOGICAL INFLUENCE OF DRAINAGE.—We have incidentally spoken of the various local causes which influence the meteorological character of some districts, and we shall devote a short space to the consideration of that subject; more especially in reference to the great advances which have been made in the drainage, &c., of some parts of this country, and to the permanent improvement of extensive tracts of land, in a meteorological, agricultural, and sanitary point of view.

It is familiar, in the experience of every one, that a low, flat, and marshy tract of land is generally a region of fog, and often of rain. In England, for example, the land between the Thames and Boston Wash—a length of about 100 miles, and of variable width—is chiefly of this kind. The superincumbent air is loaded with moisture, and, as far as our experience has gone, there is a greater frequency of thunder-storms, and, for the moment, heavier showers of rain, than in the districts flanking it. The same remarks are equally applicable to extensive tracts in France, Holland, Russia, India; Africa, as at Sierra Leone; Florida, Georgia, and various places in North and South America; with many others too numerous to mention here. The meteorological characteristics we have just referred to, of course vary, according to the annual average temperature; being in excess in low latitudes and about the equator, and gradually diminishing as we approach the pole, where the moisture of the air arrives at its minimum. If these local peculiarities were due solely to the presence of water, then the ocean should be equally liable to them; but that such is not the case is well known; and the cause of the difference is easily explained.

In the Section on Heat, we called attention to the different radiating powers which bodies possess; pointing out that those of a rough nature radiate quickly, whilst polished surfaces are poor radiators.§ Now just such a difference subsists between the surface of the ocean, or any extensive sheet of water, and that of land saturated with moisture; the constituent particles of the latter radiating heat rapidly, whilst the former does so but very slightly. Generally speaking, good radiators greatly promote rapid evaporation, just as we find in the case of the ordinary porous wine-coolers, from the surface of which moisture is quickly carried off. In precisely a similar manner, the extensive surface of sodden earth, in swampy and marshy lands, absorbs heat during the daytime, and as readily radiates it at night. Evaporation is quickly carried on; but being attended with a cooling effect, the moisture conveyed into the air becomes partly condensed, and hence the mists and fogs, so common in the damp and fenny portions of Essex, Cambridgeshire, Lincolnshire, and other parts of our own country. For similar reasons, and arising from the same causes, we may often, in summer time, notice a deep haze coating a valley beneath us, as soon as the sun sets, if we are standing on some moderate elevation. The depth of the haze or mist will depend on the amount of moisture which has been evaporated during the day, and the fall of temperature at night—presuming, of course, that the air is perfectly still, and that various circumstances, to which we need not here allude, are favourable to radiation.*

§ *Ante*, p. 26.

Such, therefore, being the causes of the superabundant moisture, haze, fog, &c., of damp grounds, we may proceed to notice their general effect on animal and vegetable life; and here we may observe, that the natural constitution of the subject will materially influence the effect, prejudicially or beneficially. Many plants can only vegetate in an exceedingly hot and moist air; and their healthy existence, in any place, is highly indicative of the surrounding climate. Even human beings can be so inured to a particular region, as to live, without serious inconvenience, in places where others would find an untimely grave. Many parts of the coasts of Africa, North and South America, &c., illustrate this; and even our own fenny districts, in which ague is so prevalent, are inhabited by individuals whose families have long resided there, and being acclimatised, are comparatively free from diseases which a casual or temporary visitor is sure to suffer from. It is not only, however, in the districts themselves, in which such meteorological phenomena are common, that danger to health may arise; the surrounding country is equally liable to be affected: and hence every method should be adopted which may possibly remedy the evil. The usual effect of too moist a climate, is that of a general depression of the nervous system, and, consequently, a liability to impression of diseases, especially those of the low febrile class, as the typhoid, &c. Most endemics partake of this character; but they are frequently accompanied with others, in which diarrhœa is usually a characteristic. In some cases, a peculiar fever becomes endemical: as an instance of which we may cite New Orleans, where yellow-fever is a regular and periodical visitant. It is stated, however, that the rate of mortality is not above the average, for those born and brought up in the city; and that the fever is chiefly fatal to visitors. This most likely arises from want of precaution on the part of the latter, who are likely to expose themselves to the dangerous influence of the climate, which the regular inhabitants prudently avoid.

In most marshy places, but especially in warm or hot climates, vegetable growth and decay proceed rapidly, being stimulated by the heat and moisture together. This is remarkably the case on the west coast of Africa, and in many parts of Italy, of which the Pontine Marshes are a well-known example. In such districts pestilence is always to be found, arising from the abundant miasmatic vapours which are generated. The Niger is too well known as a most dangerous locality for Europeans; and its pestilential effects are readily traced to the presence, in immense quantities, of poisonous gases, which are given off from the rich tropical vegetation as it undergoes decomposition, caused, and rapidly promoted, by the hot and moist air.

Of late years these facts have received the earnest attention of all classes, and the principles of meteorology have been studied in reference to the best method of detecting, avoiding, or ameliorating such conditions. The hygrometer has been of great use for the examination of the atmosphere in suspected localities; because, as the dew-point is formed at a temperature which differs from that of the air, just in proportion to the dryness of the latter,† it follows, that the lower the dew-point average is in any place, the drier, and therefore the more salubrious, is the country for a permanent residence. One of the objects which Mr. Glaisher carried out in his balloon ascents, was that of acquiring information on this matter, which might subsequently be of service in directing the choice of stations for our troops in India and other tropical countries.

In attempting to improve the climate of marshy places, of course drainage must be had recourse to; and as the practical part of this belongs more especially to engineering science, it will not fall within our scope to discuss it in its mechanical details. Not only does the withdrawal of the surface-water of swamps, marshes, &c., lessen, and, if complete, expel standing fogs and mists, but it also diminishes the rain-fall, on the average, throughout the year. The reason of this is twofold: first, there occurs a diminution of superincumbent moisture, which, in part, causes the rain; and, secondly, through that, the addition to rain falling from high regions (due to the presence of moisture at a lower level), is avoided; for, as we have already seen, more rain falls, in any spot, as we approach the surface of the earth, because of the drops gathering additional moisture from the air they pass through.‡ The application of a good drainage system has, therefore, the effect of removing the moisture itself, and, simultaneously also, the cause of its continued production. Occasionally, even the geological character of a country may be judged of by its meteorological characteristics. Thus we generally find that clayey soils, which will not allow the water on their surface to drain away, are covered with mists; and the temperature is usually lower than that of a surrounding but better drained country. Such soils are generally termed "cold" by the farmer, who, apart from any scientific theories, has discovered, by long experience, that their temperature, superabundant moisture, &c., unfit them for producing many kinds of crops. A few years ago, such places were left in their natural state, but that enterprise which commenced in our manufacturing districts, has infused itself gradually amongst the agricultural portion of the community; and many thousand acres, considered by our forefathers as irreclaimable wastes, now teem with excellent crops; and also have become places fit for residence, where formerly they were little better than sources of pestilence.

It has been discovered, that where land is in course of being well drained, and cleared of timber and brushwood, the annual fall of rain soon diminishes in amount. Of all other countries, America has furnished the most striking examples of this fact. There nature has done everything on the large scale; immense forests spread over surfaces exceeding in area some of the larger states of the old world: but as civilisation has gradually spread, the necessities of the colonists have encroached on the domains of forest-land; trees have been felled over extensive areas; and it has been found that, gradually, the amount of precipitated moisture is lessened. This result proceeds from the removal of those objects which radiated the heat of the earth, &c., and tended to produce rapid evaporation and subsequent condensation; for the branches and twigs of trees have an astonishing effect in precipitating rain, and of holding passing mists. We have often watched such flying over an extent of plain country, yet parting with but little, if any, of their moisture. The moment, however, they came in contact with a plantation of trees, they were stopped in their course, and the previously suspended moisture fell in copious showers, owing to the radiating and cooling action of the trees amongst which the mists had been caught. This singular and interesting phenomenon may be frequently noticed in Derbyshire, Yorkshire, and in some of the southern counties, where plains or downs, and moderate elevations, covered with trees, alternate on the face of the country. A familiar instance of this action on suspended moisture is seen in our gardens, during a November mist, when each twig is dripping with water: this may also be noticed on the edges of the hair and whiskers of any one hastily walking in the open air, under similar circumstances. So universal is the action of the radiating power of plants, that we may consider the moss, lichens, heather, grass, brushwood, shrubs, and trees, as specially adapted to rob the air of its suspended vapour, and thus to become the chief means by which our rills, lakes, and rivers are constantly fed. We may add, that the blades of grass, straw, and similar objects, have been found to rank amongst the best radiators of heat and electricity. Perhaps from some partial knowledge of this fact, has arisen the idea, prevalent in many country places, that a straw-wisp is an excellent "lightning conductor;" and it is often employed by farmers at the gable ends of thatched cottages, and on wheat and haystacks, for that purpose; whilst by others, it is, perhaps, merely added as a finishing touch.

---

* See our remarks on radiation, the formation of dew, &c., at p. 26, in the Section on Heat.

† See *ante*, p. 1146.

‡ See *ante*, p. 1143.

Before concluding these remarks on the influence of drainage on meteorological conditions, we must distinctly state that they have referred solely to local influences. We need scarcely observe, that fogs may be so general and extensive as to cover vast areas both of land and ocean surface: indeed, the major part of these islands may frequently be enveloped in one general mist, which even yet falls far short of those that are seen near the island of Newfoundland, and in many other parts of the Northern Atlantic ocean. Such proceed from entirely different causes, and are due to the intermixture of currents of hot-moist, and cold air, which, immediately on impact, cause a condensation of aqueous vapour, on a scale commensurate with their extent of area. In a paper read by Dr. Gladstone, before the British Association in 1862, it was stated, that there was greater uniformity of distribution of fogs over the surface of the sea, than on the land around the British Isles; and that certain years were decidedly more foggy than others, in nearly all localities. These facts, however, do not affect the truth of the observations which we have made in reference to the production of *local* fogs and mists.

OZONE, &c.—It is but recently that the presence of ozone in the atmosphere has been made a subject of registration, in connection with wind and weather reports: in fact, so little is known of this element (if such it be), that it has rarely attracted the attention which its importance as a chemical agent demands. Of late years, many investigations have been made into its general characters and relations; and we may here add a few facts to those already given respecting it.[*]

The action of oxygen on many bodies is a matter of constant experience, as in the case of combustion, breathing, rusting, &c. Now the results of these processes are considered to arise simply from the chemical union of the oxygen with such bases as carbon and hydrogen, in the two former instances, and with metals in that of metallic oxidation. But ozone is evidently so far connected with oxygen, that they are only simultaneously developed; the former having never been detected, separately, from oxygen in any way whatever. The artificial generation of ozone we have already mentioned at the pages previously referred to; and we have also found that its effects generally resemble, or are just such as those we should, from our previous knowledge of the properties of oxygen, expect to arise when that element enters into combination. But ozone, also, somewhat supplements these: thus, putrefaction goes on more rapidly when free ozone is present with oxygen; it acts as an irritant on the animal tissues, which oxygen does not; and, moreover, it seems to have an affinity to free electricity, which is singularly indicative of its character. This is amply illustrated during the decomposition of water by voltaic electricity; the excitation of electricity by friction, as with the ordinary electrical machine, &c. To these we may add another and singular instance, which we noticed during a violent thunder-storm that visited the neighbourhood of London in the early part of September, 1863. Whilst watching the storm, and noting the interval between the lightning and the claps of thunder, a brilliant flash occurred, apparently just over the spot of observation, and accompanied with a loud peal of thunder. Less than half a second of time intervened between the two; hence the locality of the discharge could not have been more than 600 feet, if so much, in distance.[†] Almost immediately afterwards, the air smelt so strongly of ozone as to produce pain in the nostrils, showing that a large amount must have been set free, evidently by electrical action. Precisely the same result was noticed during the storm described at page 184, in the Section on Electricity: in that case, however, the entire body of air in the house which was "struck," was affected. These are, certainly, extraordinary instances of the development of free ozone; but others frequently occur, and may be especially noticed in large towns, where the smell of ozone is easily recognised, in contrast with the smoke usually so prevalent in such places. For instance, at certain periods of the year, we have noticed, in the centre of some of the largest squares in the metropolis (Russell Square, Lincoln's Inn, &c.), a strong smell of ozone, accompanied with a temporary cool and refreshing air, which unscientific companions have denominated, at the moment, a rich "country smell." Such instances, doubtless, arise from sudden down-draughts of cooler air, which open spaces frequently permit, even in crowded neighbourhoods. These facts would indicate that ozone is present continuously in the higher regions of the atmosphere, when positive electricity is redundant—a circumstance of frequent occurrence, as we have already pointed out.[‡] We looked with great interest for the results of Mr. Glaisher's observations on the presence of ozone in the higher regions of the atmosphere; but, generally speaking, whilst they noted an increased amount of this agent at great elevations, the indications have been so varied and uncertain, as to have added but little to our knowledge of the subject.[§]

The causes and presence of free ozone are matters of extreme interest in a sanitary point of view. It is remarked, that its redundancy in a free state in the air, occurs chiefly with cool northerly breezes, and is attended, in some respects, with a more salubrious state of the atmosphere. But, whilst it evidently has the tendency of purifying the air, by, perhaps, removing the animal and other noxious gaseous impurities, and thus of improving the general health of the community in respect to diseases of a zymotic character—such as the typhoid, &c.—yet a large amount of ozone may prove extremely harmful to those who suffer from irritation of the bronchial tubes, affections of the lungs, and other complaints of that nature. We are, indeed, almost tempted to suggest, whether the increased mortality, which frequently accompanies north-easterly winds (so prejudicial to the health of persons suffering from diseases of the organs of respiration), may not in some degree be due to this cause. We offer this as a suggestion only, recommending it as worthy of close observation to those whom circumstances may place in situations for carefully acquiring information on the subject.

The detection of ozone by prepared papers and powders, containing the iodide of potassium and starch, has been already described. But for those who may wish to become accustomed to its smell, we may also suggest, that if a few sticks of phosphorus be placed in a bottle containing water, so that the phosphorus may be only in part covered with the liquid, and the bottle be corked, the smell of ozone may be recognised on removing the cork after a few minutes have elapsed; and an occasional smelling of it, as produced after this method, will enable any one to detect it, even in minute quantities, when it occurs in the atmosphere in a free state.

[†] See *ante*, p. 276.

[‡] See *ante*, p. 1178.

[§] See *ante*, pp. 1130 and 1164.

We have alluded, at page 315, to the presence or absence of ozone in crowded localities, as a test of their sanitary state; and we may urge on our readers the great advantage which will arise from an extension of experiments of that kind. We there stated, that ozone tests were variously affected, according to the proximity, or otherwise, of crowded dwellings. The presence of animal matter in the atmosphere seems to entirely prevent any action on the test-papers; and this would confirm the idea that a chemical relationship, or affinity, subsists between ozone and the carbon, hydrogen, or nitrogen which gases, emitted from the animal body, contain. For such purposes, the salts of manganese[*] are more delicate as ozone tests, and are, therefore, to be preferred, in many cases, to the iodide of potassium and starch papers. In observing the effect of ozone on such tests, the depth of colour produced, as compared with a standard, is to be noticed: it is, therefore, desirable that specimen papers should first be procured; and they are sold at most of the instrument-makers. Any quantity of the test-paper may afterwards be easily made, by following the directions given at page 1164; and in using them, the direction of the wind, whether it may have blown over a town before being tested, or arrived in an unchanged and non-vitiated state, with all other circumstances which might modify the action of the free ozone, should be carefully noticed, otherwise the observations would be worse than useless, and be only calculated to mislead. We have no doubt that many curious particulars might be gathered by the medical profession, in relation to endemic and epidemic diseases, if this interesting subject were more fully understood. Such persons would have frequent opportunities, both in the localities and the sick room they visit, of making valuable additions to the facts we already possess.

BAROMETRIC DETERMINATION OF HEIGHTS.—Rules for determining the heights of mountains, &c., by the barometer, have been already given;[†] which, for some comparative results, will suffice: we may, however, here mention certain points which require careful attention, if extreme accuracy be required.

After a perusal of the pages devoted to a description of the ascents of Mr. Glaisher, the reader will perceive that the ordinary rule, of an equal decrement of temperature occurring at equally increased elevations, does not always hold good; and therefore, that heights, determined on the assumption of the correctness of that rule, must necessarily be erroneous. There are also other causes of error, which must be taken into account, and which were ably pointed out by Mr. Ball, in a paper read before the Physical Section of the British Association, in 1862. We shall avail ourselves of the report given in the *Athenæum*, for the purpose of laying the leading facts before our readers.

The author remarked, that serious errors are involved in the ordinary process of reducing barometric observations, for hypsometrical purposes. This process involved two assumptions; first, that the volume of a column of air, unequally heated, is nearly the same as that of an equal weight of air of the same mean temperature; secondly, that the mean temperature of the column or stratum of air, between the stations of observation, corresponds to the mean of the readings of thermometers standing in the shade, at each station. The error involved in the first assumption is not very considerable; that arising from the second, is, on the contrary, highly important. M. Bravais was the first to propose a practical plan for applying a correction to the assumed mean temperatures of the air, depending upon the hour of the day, and the season of the year, at which observations are made; but it is to M. Plantamour, the distinguished astronomer of Geneva, that we owe the fullest investigation of this important subject. Having ascertained, by careful levelling, the true height of the Great St. Bernard above Geneva, M. Plantamour finds that the mean of all the barometric observations made during eighteen years, deviates by fourteen feet, English, from the true height; and he attributes this deviation, with great apparent probability, to an abnormal depression of the mean temperature of Geneva, owing to the neighbourhood of the lake. The readings of the barometer and thermometer, at the observatories of Geneva and the St. Bernard, are taken daily at nine hours or epochs. M. Plantamour assumes that, on an average of a long period of years, the mean of the observations taken at any one epoch in the twenty-four hours, should give the true difference of height between the two stations, with an error due to the difference between the mean of the readings of the thermometer, at both stations, at the same epoch, and the true mean temperature of the air in the intervening stratum. Calculating, then, the height of the St. Bernard by the elements corresponding to each epoch of the day, during the four summer months, from June to September, he obtains a series of measures differing from the true height; those corresponding to the hottest hours being in excess, and those appertaining to the coldest, in defect of the true height. He then ascertains the amount of correction, which being applied to the mean sum of the readings of the thermometer, at each epoch in each of those months, would bring out the true height. In this manner he obtains a table, showing what he calls the *normal correction* for each of the epochs of the day, during the four summer months.

There is good reason to believe, that in reducing barometric observations, which are to be compared with those of Geneva and the St. Bernard, the application of the normal correction, ascertained in the manner above stated, will, in general, give truer results than those where it is not applied; but as it is obvious that the conditions of temperature, at the moment when a given observation is made, are constantly varying from the mean of the corresponding day and hour—it follows that a further supplemental correction should be made on this account. To apply this further correction is a matter of no small difficulty; but the method employed by M. Plantamour is as follows:—He obtains from the observations at Geneva and the St. Bernard, by interpolation when necessary, the elements corresponding to the day and hour of the observation which is sought to be reduced; and from these he calculates the height of the St. Bernard. The height so obtained, when compared with the measure, which is derived from the mean of the readings of the same day and hour (as shown in his table of normal corrections), furnishes a criterion by which to judge of the conditions, with respect to temperature, of the moment when the observations to be reduced were made. M. Plantamour thinks it not difficult to infer, from the observations themselves, and from the general state of the weather of the time, whether the moment was one of atmospheric equilibrium, or the reverse. In the latter case, the observation is treated as one of inferior utility, to which a lower value should be assigned in the final calculation. Supposing, on the contrary, the observations not to betray a disturbance of equilibrium between the two stations, the deviation of the height, as calculated for that particular moment, from the height derived from the corresponding means, is the measure of the amount, and sign of the supplemental correction corresponding to the moment of observation.

These facts acquaint us with a peculiar and local cause of error, which adds another difficulty to the method of measuring heights by means of the barometer. To some extent the sources of error are analogous to those we have already pointed out, when speaking of the variety of causes which affect a normal atmosphere in the neighbourhood of, or immediately over, large towns; but they differ, in being more constant, and therefore more easily determinable in their character. Many of our readers may imagine that the method of finding the elevation of accessible heights by the rules of trigonometry,[‡] would be sufficient for all purposes, and render us independent of the barometrical method; but the trigonometrical plan is not at all times possible; for,

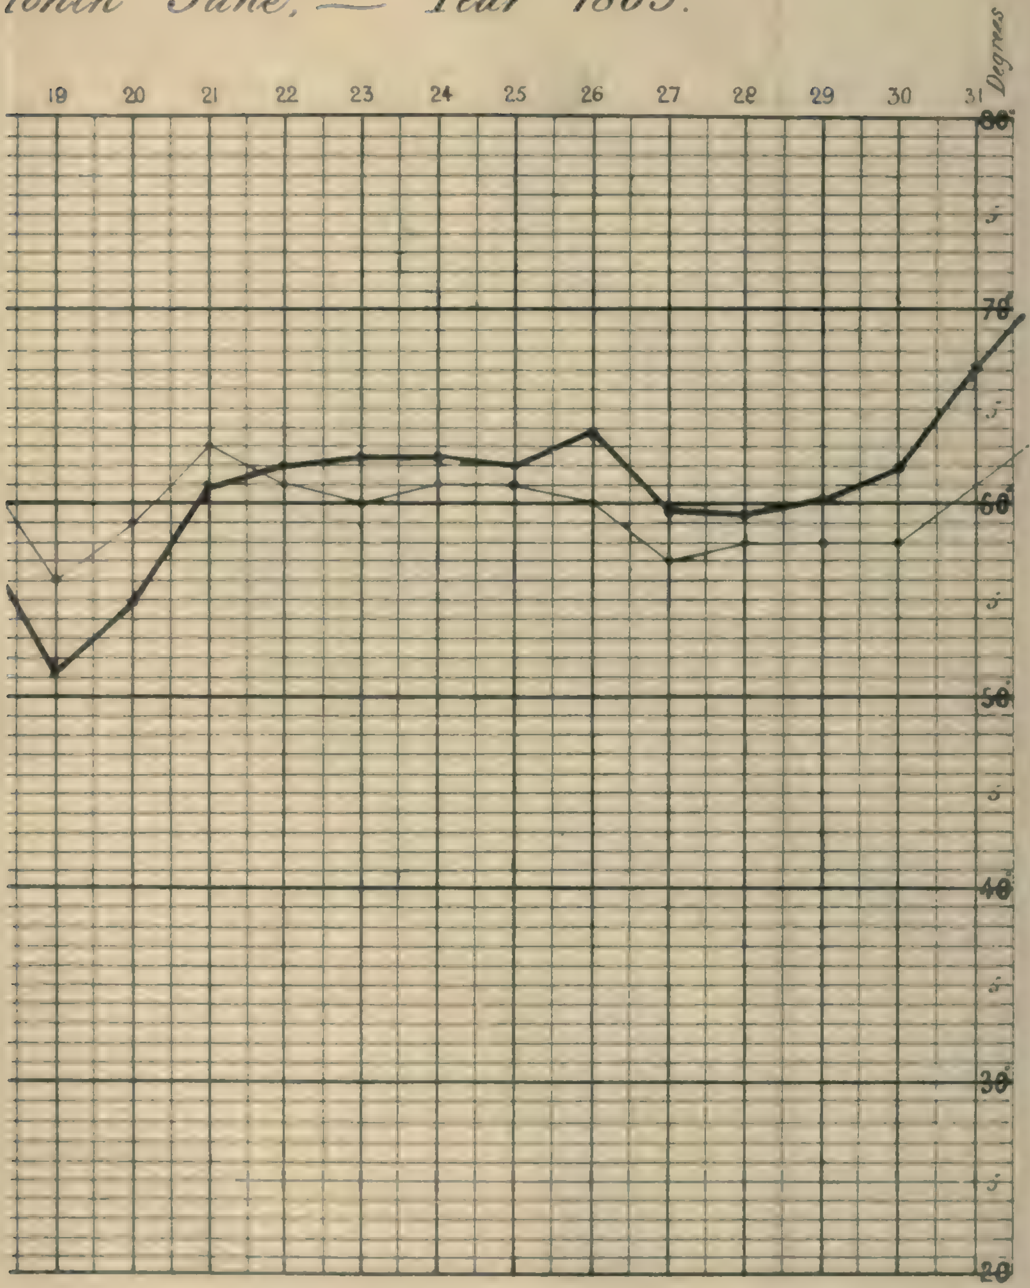
Month June, — Year 1863.



frequently, the highest point of a mountain range is so completely hidden by surrounding but lower peaks, that an observation for taking the requisite angles is not possible. It also often happens that the summit of a mountain is almost constantly covered with mist—or, at a portion of its height, such may be constant—which equally prevent the necessary trigonometrical observations. Independently of these considerations, the barometer affords a check on, and sometimes a verification of, results obtained by other methods. At the present time, our estimates of the height of many of the most extensive ranges of mountains, in various parts of the world, depend upon barometrical observations; and, perhaps, many of them require considerable modification before a correct altitude can be obtained. Much difficulty arises in the use of the ordinary mercurial instrument, owing to its want of portability, and the necessity of the corrections which have been pointed out: accordingly, some of our leading instrument-makers have turned their attention to the perfecting of the aneroid. One of these instruments, manufactured by Messrs. Negretti and Zambra, has been used by Mr. Glaisher in his balloon ascents; and he considered that it might be depended on at a pressure equal to one indicated by five inches of mercury. As our highest mountains have an elevation at which a much taller mercurial column is supported, it is probable that such instruments may be of great service for the purpose, as substitutes for the barometer.

The following table will be of great utility, both for the purpose of measuring heights by the barometer, and for adjusting the level between two places where barometrical observations are being carried on. The barometric column is supposed to stand at a height of 31 inches, at the sea-level. For any other barometric height at the sea-level, at the moment of observation, an allowance for the difference above or below 31 inches must be made; which is, of course, readily done by the rules of common proportion. The table is copied (but corrected) from the *Barometer Manual* of the Board of Trade.

DIFFERENCE TABLE FOR ELEVATIONS.

CHARTS FOR WEATHER REGISTRATION.—Instructions, of a very detailed character, have already been given in Chapter IV., as to the method of making observations by the barometer and thermometer; the precautions which must be taken; corrections to be made, &c. Many of our readers, however, may be disposed not only to register their observations in a book, for subsequent reference, but also feel desirous of adopting some plan by which they may possess a general and combined view of the barometric and thermometric changes that occur monthly; so that, by mere inspection, they may be able to trace the variations which have occurred. One of the best plans which we have yet seen, is that recommended and used by the Meteorological Department of the Board of Trade, and of which a specimen is given in the folio plate. By an ingenious contrivance, both the barometric and thermometric ranges are marked down on one diagram.

The sheet is divided by vertical and horizontal lines, between which the daily ranges are to be marked with dots and lines. On the left hand, a scale ascends, which is divided so as to indicate the height of the barometer from 28 to 31 inches. This is sub-divided into tenths; and these, again, may be easily reduced to halves, &c., in marking the height. On the right, the thermometric range is denoted, running from 20°, or 12° below freezing point of Fahrenheit's scale, to 80°. The horizontal lines are crossed by vertical dark lines, with an intermediate lighter one—each entire division being intended to denote a day. Thirty-one and a-half are provided; so that the first three half divisions may be used for the last day and a-half of the previous month—a method which is useful for "forecasting," for reasons mentioned at a previous page.* It will be seen that two observations, at least, both of the barometer and the thermometer, may thus be marked on the lines daily; and by dividing the intermediate spaces, even more may be mapped down.

The method of using the diagram is as follows:—Supposing that the barometer stands at 29·50, on the first day of the month. Look to the left hand scale, and trace, by the eye, the horizontal line from 29·5 to the vertical *dark* line running downwards from the figure 1, at the top of the scale. Make a dot at the point where they intersect—the height of the barometer will thus be indicated at the time the observation is made, which should be at 8 A.M., that affording the best daily average. If another observation be made at 8 P.M.—that is, at an interval of twelve hours—proceed in the same way, for any height, and mark a dot where the horizontal line intersects with the *light* vertical line, which will be half-way between 1 and 2, as marked on the top of the scale. Draw a straight line, connecting the dot of the morning and that of the evening observations—thus the dots will indicate the actual heights, whilst the line will show the course of variation in twelve hours. On the 2nd of the month, at 8 A.M., make a dot, corresponding to the barometric height, on the dark vertical line, as on the previous day, and then draw a line to it from the dot of the previous evening or morning observation, according as to whether a single or double one has been made. Proceeding in this manner, a line will daily appear to progress from the left to the right of the scale, indicating the changes which have occurred throughout the month. The *barometric* line should be made both *dark* and *thick*, to distinguish it from the *thermometric* line, which should be *fine*, for the same reason.

---

* See *ante*, p. 1176.

The indications of the thermometer are to be similarly marked. Supposing, for instance, that on the 1st of the month the thermometer stood at 62°—look on the right hand of the diagram for 60°, and, at two lines above it, will be found the division corresponding to 62°. By the eye, trace this line until it comes under figure 1 of the vertical scale, and there make a dot. Continue in the same manner as directed for the barometer, only making a *fine* line between the morning and evening, or morning and morning, divisions from day to day. Thus, the indications are to be traced by lines throughout the month, as is done with the barometer, and the two scales will be simultaneously marked for each day, or each twelve hours, as the observations are made and registered.

The first division and a-half, on the *left* hand of the diagram, are intended to indicate the respective heights of both instruments for the preceding 36 hours; that is, an entire division is given for the last day of the preceding month, and half a one for the day previous. The lines are to be connected with those of the current month, in the manner already described, and thus the observations of the two months will run on consecutively; and, from an inspection of the diagram, the probable weather for the commencement of the month may be predicted, without further reference to the plan of the past one. The place, month, and year of observation should be filled up at the top of the diagram; and space may be left at the bottom, to receive notes of any special meteorological occurrences.

To still further illustrate this method of registering, we may trace a portion of the folio plate. The indications have been brought from the previous month, and on the 1st of the current one, we notice that the height of the barometer (dark line) stands at 30·30; it then passes to 30·17, on the 2nd; the line then progresses to 30·05, and so on. Similarly, the thermometric fine line indicates 55° on the 1st of the month; on the 2nd, 59°, &c.; the heights of each instrument being simultaneously marked, and their variations clearly seen by the relative position of the dots and connecting lines on the diagram.

This plan is remarkable for its simplicity, and the ease with which any one may map out the observations made daily. For forecasting it has great advantages; for instead of appealing solely to the mind for the calculation of numerical differences, the eye is at once instructed, and, at a glance, the observer can see whether the barometer and thermometer are rising and falling together, or oppositely; whilst the rules for predicting weather, given at page 1176, may be immediately applied in connection with the observations on the direction of the wind blowing at the moment, or previously.

Although a full description has been given, in our previous pages, of the qualities which should characterise a good barometer, it may be useful here to mention some particulars in reference to the Standard Barometer, as supplied to the Navy by the Board of Trade; and the care which is shown in their construction, and subsequent verification, will be best understood by the following account of the mode of testing them, as described in the *Barometer Manual*. Our readers may thus learn some valuable lessons in respect to the purchase of instruments for their own use.

The barometers to be tested, are placed, together with a Standard,* in an air-tight chamber, to which an air-pump is applied, so that by partially exhausting the air, the Standard can be made to read much lower than the lowest pressure to which marine barometers are likely to be exposed; and by compressing the air, the mercury may also be read higher than it ever stands at the level of the sea. The tube of the Standard is contracted similarly to that of the marine barometer,† but a provision is made for adjusting the mercury in the cistern to the zero point. Glass windows are inserted in the upper part of the iron air-chamber, through which the scales of the barometers may be seen; but as the verniers cannot be moved, in the usual way, from the outside of the chamber, another method is adopted for reading the exact height of the mercury, independently of the verniers attached to the scales of the respective barometers. At the distance of some five or six feet from the air-tight chamber, a vertical scale is fixed; and the divisions on this scale correspond exactly with those on the tube of the Standard barometer. A vernier and telescope are made to slide on the scale, by means of a rack and pinion. The telescope has two horizontal wires—one fixed, and the other movable by a micrometer screw; so that the difference between the height of the column of mercury, and the nearest division on the scale of the Standard, and also of all the other barometers placed by the side of it for comparison, can be measured either with the vertical scale and vernier, or the micrometer wire. The means are thus possessed of testing barometers for index-error in any part of the scale, through the whole range of atmospheric pressure to which they are likely to be exposed; and the usual practice is to test them at every half-inch from 27·50 to 31 inches, which is about the extreme average range of the barometer in almost any latitude.

In this way various other descriptions of barometers have been tested; and some errors were found to be so large, that a few instruments read half an inch and upwards too high, while others read as much too low.‡ In some cases, those which were correct in one part of the scale, were found to be from half an inch to an inch wrong in other parts. In some the mercury would not descend lower than about 29 inches, owing to a fault very general in the construction of many common barometers—till lately, in frequent use—namely, *the cistern was not large enough* to hold the mercury which descended from the tube during a *low atmospheric pressure*.

In the Government Marine Barometers, the diameter of the *cistern* is about an inch and a quarter, and that of the *tube* about a quarter of an inch. The scale, instead of being divided into inches, in the usual way, is shortened, in the proportion of about 0·04 of an inch for every inch. The object of this is to avoid the necessity of applying a correction for the difference of capacity between the cistern and the tube. The perfection with which this is done may be judged of from the fact, that of the first twelve barometers tested at the Liverpool Observatory, with an apparatus exactly similar to that used at Kew (whence these instruments were sent by railway, after being tested and certified), the index corrections, in the pressures from 28 to 31 inches, of three of them, were the same; two differed 0·001 of an inch; and, for the remainder, the differences ranged from 0·002 to 0·006 of an inch. The corrections for capacity were therefore considered perfect, and, with one unimportant exception, agreed with those given at Kew.

From the above account, it will be seen how frequently common barometers may lead the observer astray—an occurrence which, whilst of comparatively slight importance on land, might cause the destruction of a vessel, and serious loss of life, if such indications of an imperfect instrument were relied on at sea. The peculiar nature and sudden advent of cyclonic storms,§ which are always accompanied by a barometric fall, render it of the utmost importance that the barometer on board of a vessel should be sensitive, and in good order; yet we have just seen that some instruments are sold, and doubtless "warranted," which would be incapable of showing a great mercurial depression, generally the only sign of the coming storm that could warn the mariner of impending danger. There is no difficulty whatever in having a good barometer properly tested; and as our knowledge of the science of storms is now so extensive, the commander of a vessel would be guilty of an equally great neglect of his duties and interests, if proceeding to sea without a good and certified instrument, as he would be were he to do so without either a compass or chronometer on board.

---

* One that has been already fully tested, in every respect, at the Kew Observatory.

† This contraction of the marine barometer-tube prevents what is called "pumping;" that is, the extreme oscillation caused by the motion of the ship in a rough sea.

‡ See *ante*, p. 1159.

§ See *ante*, p. 1175.

Whilst referring to methods of registering observations, we may observe that the Board of Trade lend barometers, &c., on certain conditions, to properly qualified commanders in the merchant service. They are expected to make continuous observations, and to report them at head-quarters as occasion will permit; honorary rewards being distributed when the instructions are fully carried out, or when special diligence has been shown. This plan will prove highly beneficial to the interests of science; for, by it, an immense amount of data will be gathered from all parts of the world, and thus our means of induction will be proportionately increased. Besides the registration of the heights of the barometer, &c., the observers are desired to notice all concomitant occurrences, so as to increase our knowledge of matters which, although apparently of minor importance, are really efficient aids to the more exact processes of scientific investigations.[*] It may not be unreasonable to hope, that, in the course of time, simultaneous observations will be undertaken throughout the world, on a plan similar to that adopted at our observatories in this and other countries. The labour of reducing them would, of course, be enormous; but the information obtained would be invaluable. Carried on during a number of years, we might, eventually, be able to form from them so complete a weather-chart for each ocean and coast, as would result in a general diminution of shipwrecks, which now cause, annually, some millions sterling of loss. To many, such a work would seem Utopian, and utterly beyond human power; but, after all, it would scarcely equal the labours of astronomers, who have mapped out the place of each star, and who, from data similarly acquired, can assign its place, even for years hence, within an error of but a few seconds of time. In this labour we are encouraged by knowing that no event in nature depends on chance, and that every phenomenon is the result of some law which has been impressed by the Creator. In its operation, it may be so intricate as to baffle, for years, and even ages, the deepest penetration on our part; but still it stands before the eye of the philosopher, presented as a great prize for his grasp—the only condition imposed on him for success being, an intelligent, persevering, and discreet use of each fact as it arises, and of correct induction as light bursts on his mental vision. For some thousands of years, ingenuity was puzzled to account for the motions of the solar system; the most intricate schemes were brought forth to explain them; but when human pride failed, nature's simplicity conquered; and one broad comprehensive law—that of gravitation—was at last understood and completely established; a result which adequately rewarded years of unremitting and patient toil.

GASEOUS RADIATION AND ABSORPTION OF HEAT, AND THEIR EFFECTS ON CLIMATE.—In the Section on Heat, we have called attention to a variety of phenomena resulting from the radiation and absorption of caloric; and in the Addenda to that section, some interesting experiments and results, obtained by Professor Tyndall, are briefly noticed. We shall here extend this subject, so as to point out its bearings on the science of meteorology, in connection with climatic differences, and may find that many phenomena, otherwise almost inexplicable, receive a happy solution through the inductions which may be properly made from the facts that will be brought forward.

Casting a glance at a map, from the poles to the equator, the intelligent student will not fail to remember how various is the climate of the different countries delineated on it; and, consequently, how greatly the natural productions vary. Whilst experience teaches us that certain forms of both animal and vegetable existence are confined within definite regions or zones; that, in some places, rain, snow, frost, and hail are unknown; whilst in others they are characteristic of the country; and, in some, that there is experienced, during the day, a tropical heat, followed by an almost Arctic severity of climate as soon as the night sets in—we naturally seek for some general law, which may embrace a broad and definite exposition of the causes operating in each instance; not being content with an approximative or probable solution of our inquiries.

What an almost infinite variety exists of the evidences of vitality in different portions of our globe. Commencing at the polar regions, we find vegetation—the immediate characteristic of climate—in its lowest forms; the lichens being predominant in all respects. Gradually approaching the equator, we first see hardy plants and trees, such as the willow, birch, alder, &c.; and grass also becomes common. Flowers of various kinds, with cereal crops, next appear as we arrive in countries such as our own; thus the luxuriance of vegetable nature, and its profusion, develop, until we arrive at tropical regions, where the heat and moisture combine to produce the richest and most gorgeous of floral beauties, and sugar, coffee, spices, fruits, &c., which can only flourish in such countries. Animal life equally sympathises with the peculiarities of climate, if we confine ourselves to those forms that are below the human species, to which alone is accorded the power of accommodating itself to every climate, no matter how severe or sudden the transition.

The general laws which influence this climatic variety have been already inquired into in the previous pages; and, in numerous instances, the particular or local disturbing causes have also been pointed out. There are, however, other influences of both kinds, to which we shall now direct attention, and which have been, till lately, almost unknown, or scarcely allowed for, to the extent which their importance demands.

We may first notice the effect of the obliquity of the sun's rays, as incident at various parts of the world, being well aware, that where the sun is vertical, those regions, as at the equator, are the hottest of any on the globe. At the outer limits of the atmosphere, it is considered that the area bounded north and south of the equator, by the parallels of latitude of 23° 45′, receives as much solar heat and light as does all the rest of the surface of the earth. Whilst an obliquity of 25°, in the incidence of a solar ray, causes a loss of one-half of its intensity at that angle before reaching the earth; an inclination of only 5° permits only $\frac{1}{20}$th of the maximum to be transmitted to us. It hence follows, that the remaining portion of our globe must, on areas equal to any given one at the equator, receive an exceedingly small proportion of the total calorific rays emanating from the sun.

From this we may plainly see, that the great breadth of land extending between the eastern and western limits of Africa, and the parallels of 23° 45′ north and south of the equator, must act as an enormous absorber of solar heat; which it afterwards radiates, and from which, by convection, the remaining portion of the earth receives a great accession beyond what would be its normal temperature. The upward current of hot air rising from this surface, spreads itself northward and southward, and its place is supplied by returning currents of cold air, which, by this compensating action, and influenced by the rotation of the earth, are productive of the trade winds, as already pointed out in our previous pages.[†]

But it is evident, that unless some special provision had been made for the retention of the heat thus absorbed about the equatorial regions, and subsequently carried, by convection, to the various parts of the globe, a large proportion would be again radiated into space, and be lost, so far as our earth is concerned. This provision is twofold: namely, that of the absorption effected by the solid crust of the earth, and that by the aqueous vapour which floats over its surface. It is particularly the latter provision that we wish here to investigate.

---

[*] See *ante*, p. 1177.

[†] See *ante*, Section on *Heat*, p. 30; and in this Section, p. 1184.

In our article on the Refraction of Heat, we pointed out that certain bodies have a property by virtue of which they either absorb or transmit that force; and that they vary much in the amount of this power: in fact, just as we noticed, that, with respect to light, some bodies are transparent, translucent, and opaque; so, similarly, some bodies have a precisely identical, or, at all events, analogous effect on radiant heat.* The general law of absorption was fully investigated in the article on that subject, a re-perusal of which will be useful to the student in connection with these remarks.†

It must be borne in mind, that considerable difference subsists between these two classes of absorbers. Those which refract heat have a general relation to certain similar properties in respect to light. Thus, rock-salt and alum will transmit and refract light; yet, whilst the former permits the passage of heat-rays with the greatest facility (exceeding that of plate-glass), a plate of alum, transparent to light, entirely obstructs the passage of non-luminous heat-rays. Similarly, we find that solid, good absorbers, such as lamp-black, &c., have a mutual relation to heat and light; but in this case they agree, for they absorb equally the luminous and calorific rays impinging on them.

Now, in nature, these two classes of absorbers and radiators are met with on the large scale. Every tract of land more or less absorbs the rays of heat, and also radiates them again into space. But above this solid matter is the atmosphere, which, by its heterogeneous nature, exercises a most important action on the heat reflected and radiated from the surface of the earth. Referring to the account of Dr. Tyndall's experiments (given at page 38, in the Section on Heat), we find that the mixture—not a chemical compound—forming our atmosphere, the carbonic acid generally found in it, and the aqueous vapour (also usually present), have each a definite and greatly varying relationship to, and action on, the rays of heat incident on, and transmitted by them. Here, again, we notice that certain qualities of bodies, such as transparency and translucency, are in connection alike with the forces of both light and heat; and the law of diathermancy seems to comprise a particular condition in regard to caloric, equivalent to transparency in relation to light.‡

Aqueous vapour possesses a wonderful power of absorbing the rays of heat, and thus preventing their passage from the earth into space. We have already noticed this when speaking of dew;§ as we then stated that a cloudy night entirely prevented its deposition; the clouds, of course, being composed of aqueous vapour in a partially condensed state, but still in minute divisions. But, in this case, the comparative opacity of the clouds would naturally suggest a certain amount of interference; and a supposition might be encouraged that they must act as a screen between the radiating surface of the earth and the open space beyond the limits of the atmosphere.

It is not, however, in the form of clouds alone, or even specially, that aqueous vapour becomes a retainer of terrestrial heat. Suspended invisibly, as in the clear air of a hot summer's day, it acts powerfully in absorbing the heat transmitted from the sun, and reflected or radiated from the earth, and that to an extent enormously beyond the similar power of our atmosphere when in a normal state; that is, considered as a mixture of oxygen and nitrogen gases simply. The moisture constantly present in the atmosphere has thus a most important influence on the temperature of most climates; indeed, all in which aqueous vapour is generally prevalent in the atmosphere.

This will be readily noticed if we compare the higher and lower latitudes of the earth, or even its mountain elevations. The nearer the poles, or the higher the elevation above the surface of the earth, the less the moisture that is constantly present in the superincumbent atmosphere;|| and on the other hand, the nearer we approach the equator, the greater becomes the constituent moisture: as a general and consequent law, therefore, the temperature is directly as the moisture in the air, under certain circumstances. In our own country, the contrast between the dry, cold, north-east wind, and that from the south-west, which is of a warm and genial temperature, and flowing from the Gulf-stream, is constantly recognised. For similar reasons, we shall find, in most countries, whilst ascending lofty mountains, which, at their base, have a climate of a high temperature, that we experience increasing cold until we arrive at a region where every particle of moisture is always congealed into the solid state, which will be at a point situated near what is called the snow-line. The folio plates give a general view of the chief elevations in the eastern and western hemispheres, and are accompanied with a scale, indicating the heights of mountain ranges, &c. There are also marked certain altitudes attained by Mr. Glaisher, Gay Lussac, and Humboldt, whose observations verify the remarks just made. A little above and below the snow-line, the annual variation of temperature either melts the congealed water in summer, or freezes it as winter comes on. The former process, together with the precipitation of moisture (as rain), gives rise to rivers, the chief of which are also noted, with a scale of their lengths, in the plates just referred to.

Thus we find, that when the atmosphere is destitute of suspended moisture, intense cold prevails, chiefly owing to the immediate radiation of the heat received with the luminous solar rays. On this principle may be further explained the fact noticed by Mr. Glaisher, that, as he ascended in the air, a blackened-bulb thermometer ceased to show an increased heat, when exposed to the full rays of the sun, beyond that indicated by those kept in the shade. We have already anticipated, in some respects, the solution of this at a previous page;¶ but may here add, that a blackened-bulb thermometer, similarly exposed at the sea-level, will occasionally rise even 40° to 60° above the temperature shown by a thermometer shaded from the rays of the sun at the same time and place. In the latter case, the absorbed heat will, according to the researches of Dr. Tyndall, be prevented from immediate radiation by the moisture resident in the surrounding hot atmosphere.

The average altitude of the snow-line does not depend entirely on latitude, but is greatly affected by the amount of moisture, &c., in the atmosphere. Thus, some portions of the Himalayas have the snow-line at 1,500 feet greater elevation than that common at the equator: and comparing, again, Sierra Nevada in Spain, in 35° north latitude, with some of the Himalayan mountains in Thibet, in the same latitude, we find that the snow-line of the Spanish mountain is at 9,500 feet, whilst that of the Himalayan ranges from 15,000 to 20,000 feet, above the sea-level—varying, in a distance of sixty miles, to the extent of 5,000 feet. This is chiefly due to the absence of moisture—a circumstance that prevents the formation of the snow, simply because there is literally nothing of watery matter to freeze. For similar reasons, the altitude of the snow-range on these mountains rises uniformly, in proceeding northward from India, and consequently from the equator, up to a north latitude of 35°. The rapid radiation of heat, and consequent equally rapid evaporation even of snow, in some parts of the Himalayan range, is the chief cause of this increased average altitude of the snow-line, which is frequently greater on the north than on the south side.

The following table gives its height above the sea-level, for many latitudes, both north and south of the equator, and will form a kind of supplement to the illustrations afforded in the folio plates. It will be noticed, that,

¶ See *ante*, p. 1184.

generally speaking, as the sea is approached, the snow-level falls; but still numerous other local interfering causes must also be taken into account; and such may easily be studied by reference to an ordinary map, in conjunction with the latitudes given in the table. Another instance of curious variation of the snow-level, in respect of the latitude, is furnished by the Carpathian range, the highest of which, exceeding 9,500 feet, and in north latitude 49°, is still below the snow-line, although the Alps, in 45°, have it at an elevation of about 8,500 feet. The increased altitude in respect to the Carpathian range, is due to the great convection of heat from the plains below, which, of course, are powerful radiators and absorbers.

ELEVATION OF THE SNOW-LINE ABOVE THE LEVEL OF THE SEA.

We have frequently remarked that extreme dryness is characteristic of certain regions; and Thibet furnishes an instance of it, and also of excessive temperature; for the climate is exceedingly cold and dry, owing to the great elevation of the plateau on which it is situated (10,000 to 15,000 feet); yet, although its latitude is from 30° to 38° north of the equator, the snow-line (20,000 feet) is higher by nearly 5,000 feet. So deficient is the moisture, that few vegetables of any kind can be cultivated; and in most parts, trees and herbage are entirely absent. The radiation from the earth is enormous; for whilst, during the day, the thermometer will frequently indicate a temperature of 150°, at night it falls below freezing point. This affords us another proof of the truth of Dr. Tyndall's deduction—that to the power possessed by suspended aqueous vapour of retaining heat by absorption, is due the warmth and genial temperature of such climates as our own.

The causes of excessive climates, and excessive changes occurring in comparatively uniform climates, may be readily traced, in many cases, to arise from rapid radiation of heat into space, uninterfered with by strata of superincumbent aqueous vapour suspended in the atmosphere. Amongst the excessive class, we have already instanced Thibet; but we may add another illustration in that of the Sahara, the great desert of northern Africa. It is comprised between latitudes 16° and 33° N., and longitudes 17° W. and 23° E., and chiefly consists of table-lands, varying in height from 1,000 to 2,000 feet above the sea-level, with occasional mountain groups attaining an elevation of from 3,000 to 6,000 feet. The temperature varies from 50° to 130°, during the day; whilst, at night, water freezes when exposed to the wind. In some parts no dew falls, and snow is unknown, owing to the entire absence of aqueous vapour. Rain falls only, in quantity, at intervals of some years; for during nine months, annually, easterly winds prevail, varied, for three months only, by those from the west, or the regions bordering on the Atlantic. Generally, no plant, except an occasional palm, is met with, which derives its nourishment from springs resting beneath the surface; the only variation from a perpetual death-like aspect being the oases so sparsely scattered, and situated in depressions below the ordinary level of the country. The simoom here spreads its destructive effects with the fullest energy, loaded, as it is, with fine sand, and possessing an intense and suffocating heat, which is destructive of both animal and vegetable life.

A great portion of the Russian empire, in Europe and Asia, has a climate of the excessive type. Situated remote from extensive ocean tracts, the entire area experiences only winds which have been robbed of their moisture before arriving in most parts of the country. Again, the cold, dry, Arctic winds freely course over the surface, from the Frozen Ocean to the southern limits of the empire, unchecked by any mountain ranges of sufficient height to afford due protection to the interior. Hence, so far north as St. Petersburg, the heat in summer is great;* whilst in the Crimea, which has the same latitude (45°) as the south of France and the north of Italy, snow lies often for five months on the ground; and the Sea of Azov, the northern parts of the Black Sea, and the adjacent rivers, are all frozen. The sufferings of our troops during the Russian war (1854—'56), in this region, afforded a painful illustration of the severity of the climate in that country. Located on the same parallel as Bordeaux, Milan, Venice, &c., where a genial warmth is rarely disturbed by great variations of temperature, our armies were decimated, near Sebastopol, by a winter scarcely inferior to an Arctic one in its rigour. At Odessa, one of the chief Crimean ports on the Black Sea, the thermometer frequently falls so low as — 24° Fah. in the winter; the heat in summer being exceedingly intense.

---

* The annual range of the thermometer, at St. Petersburg, is between 23° and 90° Fah.

In our own country we sometimes experience severe changes in the weather during the winter season; and, occasionally, the thermometer ranges very high in the height of summer. An extraordinary instance of the former kind occurred in 1860, when the mean *daily* average, for some days, fell surprisingly below the monthly average. In December of that year, the *mean* temperature of the 24th was 22°·4; on the 25th it fell so low as 20°·2. In many parts of the country the mercury fell far below zero; indeed, we noticed it, at about four miles north of London, at 2° below zero, or 34° below freezing point, early in the morning of the 25th; and at 4 A.M. of that day, on leaving a hot room and passing into the open air, the entire dress was *instantly* coated with fine particles like snow, arising from the congelation of the moisture which had permeated the clothing as perspiration. In some parts, a temperature so low as — 14°, or 46° below freezing point, was registered. Amongst other instances of the extreme severity of the weather, the breaking of the tires of railway carriage-wheels, owing to the contraction produced by the cold, was one of the most noticeable and common.

DISTRIBUTION OF HEAT.—The distribution of heat over the globe, in respect to latitudes and climates, is a subject of deep interest in many respects; and it has frequently, although perhaps incidentally, been noticed in the preceding pages. We shall devote a short space to its consideration, as being a question intimately connected with that which we have just been discussing.

It has been already remarked, that the regions near the equator may be considered as the chief heating surface on the globe. To the absorption of an immense amount of caloric by that portion of the continent of Africa, and its subsequent radiation, the genial temperature of Western Europe is due. On comparing the climate of temperate climes, in the latter continent, with those of others, we find fewer instances of excessive temperature; the heat and cold, at no season of the year, being intense, except under extraordinary and very rare occasions. Taking the area, including Britain, Denmark, Holland, France, Spain, and Portugal, we find climates in which every necessity of man, with respect to food, clothing, comfort, and luxury, can be produced; and to this cause, and also to the absence of positive noxious influences, Europe is chiefly indebted for its power as the centre of commerce, arts, manufactures, &c. This area is included between 35° and 60°, north of the equator; and if we refer to a map on Mercator's projection, bearing in mind the remarks already made on the climate of other countries, as Russia, Thibet, Tartary, &c., which are also included within the same parallels, we shall at once be impressed with a sense of the advantages that such portions of our continent possess.

One of the most accurate indications of the climate of any country is obtained from the monthly average of its temperature; and if this be noted, for each political or natural division, a series of lines may be drawn, which will intersect, on the map, places having an equal annual temperature. These have been called *isothermal lines*, and are generally drawn for each month of the year, besides that of the year itself. From the immense variety of local interfering causes, such lines are not coincident with the latitude of any two or more places. It is impossible, indeed, that they could be, unless the globe were entirely covered with water; for, as we have already seen, elevation, proximity to the sea, radiation, &c., all tend to produce an unceasing diversity of climatic characteristics, where land of even a moderate extent of area is found.

It was formerly considered that a mean between the average yearly temperatures, for a number of years, would indicate what we may term the climatic average. But that such would not be the true average will be plainly seen, if we consider the variety of temperatures which are observed in our own country, for example, monthly, in following years. Thus it is by no means a rare occurrence for us to experience, in succession, cold and damp springs and summers, which, for the years in which they occur, would seriously diminish the annual average. If, however, the same months are compared with each other, in successive years, and a mean struck between; and if the *monthly* average be taken, as indicative of the proper mean for our climate, we shall obtain a much more accurate idea of the mean which governs the year. This, therefore, is the method which is now universally adopted by meteorologists; and, at page 1172, the monthly means for Greenwich is given, which will illustrate these remarks.

To give some idea of the inflection of an isothermal line from any parallel of latitude, we may take that of the freezing point, or 32° Fahr. In January, commencing at Philadelphia in the United States, it crosses the banks of Newfoundland, touches the south of Iceland, and, descending to Holland, is extended by the Balkan to the Corea in Tartary, passing as far as the Aleutian Islands, in the North Pacific Ocean; the north latitudes being respectively, in round numbers, and commencing at Philadelphia—40°, 48°, 64°, 52°, 42°, 40°, 52°, for each of the positions we have named. Connecting this range of temperature with the north-easterly progress of the Gulf-stream,* we shall notice an immense wave of heat proceeding so far north as 64°, and producing a temperature as high as that found in a latitude of 40° (Philadelphia), which, although so much further south, has not the advantage of the heating effect arising from the Gulf-stream. The western shores of Europe, therefore, are situated under isothermal lines which have a great northerly inflection; and these contrast greatly, in direction, with those passing over extensive ranges of land. Thus we find, from the Balkan, where the Gulf-stream has no influence, to the Corea, that the isothermal line is nearly parallel with the latitude (42° to 40°) for a distance of several thousand miles; whilst between Philadelphia and Holland, a distance of 75° of longitude, there is a northerly inflection of 24°—a surprising instance of the influence which extensive surfaces of land and water possess in modifying climatic indications; the latter, in this instance, having an action in raising the temperature to an extent which has no parallel in any other portion of the globe. The warmer portion of this heat-ocean lies within 45° west of the meridian of Greenwich; whilst for 120° to the east, the monthly mean in the same latitude is much lower, and the isothermal inflection curves proportionally nearer to the equator.

Hitherto we have confined our remarks to latitudes north of the equator; but on the south of that line we find an entirely different condition to subsist. To 40° south, the average temperature is colder than up to the same parallel north of the equator; and South Shetland, Georgia, &c., although situated in a latitude as far south, as Scotland, in our island, is north of the equinoctial, have a climate in which the snow-line is level with the sea for the whole year, and they are destitute of all signs of vitality, except in the lowest forms of vegetable productions, as mosses, lichens, &c.

RAINFALL.—We need here only glance at another subject, which has already been repeatedly under review in this section—viz., the annual fall of rain in different regions. In our climate, where excessive ranges of temperature are rare, the amount of rain, although greater in some months than others, is pretty equally distributed throughout the year; whilst in tropical climates, in which the air is loaded with moisture at certain seasons, the fall of rain is chiefly confined to definite periods—a circumstance which has given rise to the terms "dry" and "rainy" season. In some such districts the amount of rainfall is prodigious. Thus, in French Guiana, about 130 inches fall annually; in Senegambia, 190; and at Paramaibo, 230 inches fall during the same period. At Cayenne, 21 inches have been measured in *one day*—an amount about equal to the *annual* rainfall at Paris, or of Essex in our own country.* At the equator, the entire fall for the year is produced during 80 days; whilst, in this country, from 150 to 200 wet days give the period during which the quantity for the year is afforded.

---

* See *ante*, p. 1156.

A great variety of circumstances must be taken into account in connection with the differences which various parts of the earth exhibit in respect to rainfall; and it will be exceedingly difficult to predicate, according to any known law, the amount which is due at any particular place. As in the case of the average annual temperature, and for similar reasons, the moisture, elevation, and isothermal characteristics are combined as influencing causes. In Europe, for instance, we may notice two extremes; one presented by the west coast, extending from Bergen, in Norway, to Gibraltar, in Spain, on the whole of which a mild temperature, considerable rainfall, and a large number of rainy days, are indicative of the yearly average of climate; whilst from the North Cape, through St. Petersburg, to Hungary and Turkey, the annual rainfall is only from one-third to a-half of that common to the range of country just referred to. The former region flanks the ocean and the Gulf-stream, whilst the interior of Russia is entirely protected from moist air. In Norway, again, we find that whilst, at the coast (Bergen, see following table), no less than 77 inches fall, yet, in the same latitude, but about 150 miles more inland, the annual average is not more than 21 inches—diminishing still more, until, at St. Petersburg, it arrives at a minimum.

The average annual direction of the wind has a great influence on the climate of all places. In the north of Africa, across the Sahara, easterly winds prevail for about nine months out of the year, and, together with the great heat, parch every object of either animal or vegetable life. Throughout the western part of the Old World, an easterly wind produces precisely such effects on a smaller scale; for it diminishes the rainfall, lessens the suspended moisture, and, in certain years, affects the climate most seriously, and interferes, harmfully, with many agricultural pursuits. In the West Indies, the north of South America, and Hindostan, we find an opposite extreme. Situated in the tropics, surrounded by the ocean, traversed by large rivers, and crossed by mountain-chains whose summits are crowned with perpetual snow, the air, in those regions, at the sea-level, is loaded with aqueous vapour, maintained at a high temperature by the excessive tropical heat. A sudden down-draught of cold air, caused by periodical disturbances in the upper regions, and the return of both polar currents, causes a heavy fall of rain within a short period; and thus the thirsty earth is suddenly compensated for the constant loss it had sustained by rapid evaporation. The transition from an arid desert into a luxuriant verdure of vegetation is almost as sudden; whilst the rivers, swollen by the enormous and sudden accession of water, overflow their banks, and, as with the Nile, which traverses an almost rainless district, spread fertility on all sides, even to a great extent beyond their natural boundaries.

Our antipodes, in Southern Australia, New Zealand, &c., have a greater fall of rain, on an average, annually, than we experience, north of the equator, in the same latitude. This is chiefly owing to their insular position, and their being situated in the midst of oceans extending for thousands of miles in all directions. Yet the interior of Australia, far removed from such ocean influences, is in a condition very similar to that of Africa, being generally a dry sandy desert; and many places, as Sydney, &c., are visited at certain seasons by the hot winds arising from the north-west. These, occasionally, indicate a temperature so high as 120° to 130° in the shade, and destroy every vestige of vegetable life: in a moment the wheat-fields and fruit trees are blasted, and the human subject suffers acutely from the suffocating atmosphere. These winds are the analogues of the sirocco of the Sahara and northern districts of Africa; and, like it, are loaded with fine sand or dust, which is deposited in prodigious quantities. In either case the causes are precisely the same—viz., the drying of a large body of air by its passing over extensive sandy regions; an increase of its temperature, owing to the radiation of the solar heat from the underlying ground; and the absence of mountain-ranges which usually protect the adjacent country, and cool the hot air passing over their snow-covered peaks.

Some portions of the earth are almost entirely unvisited by rain: amongst which may be named the greater part of Thibet and Tartary; many parts of Central India; Arabia; Egypt; Central Africa; part of Chili, &c.; and, in each case, absence of ocean influences is the cause. As might be expected, both animal and vegetable life suffer accordingly; but, in numerous instances, abundant dews compensate for this deficiency of rainfall; or the overflow of rivers fed from distant mountains, periodically supplies the place of rain—as in the case of the Nile, already named; the Amazon, Mississippi, Ganges, Indus, the Australian rivers, &c. Some parts of our colonies in South Australia and Victoria, suffer seriously in the absence of such periodical inundations, most of the rivers in that country becoming little better than pools in the dry season; the lakes even being almost desiccated in summer. Before the setting-in of the rainy season in many countries, the atmosphere, which had, perhaps for weeks or months, been clear and quite free from clouds, &c., gives an indication of the coming change. The wind attains a settled direction, which is invariable in each year for that season; hurricanes and fearful thunder-storms suddenly come on, and are followed by rains, during which as much as one inch per hour falls at some places. It is a most providential circumstance that the advent of the rainy season is thus forewarned, and its periodicity so regular; as the torrents of water, soon generated, would speedily wash away the products of a year's growth. In some parts of the West Indies the heavy rains fall in October, November, and December; but, during August, the islands are generally visited by fearful hurricanes, some of which have almost ruined the colonists, by the universal havoc which has been occasioned. These storms, occasionally, spread over the two following months, as at Jamaica, which has a wet season from May to August, and in October and November; August, September, and October being the hurricane season.

Although in several degrees of more southerly latitude, China participates in a climate resembling, respectively, those of England, France, and Northern Italy; and the productions of that interesting country are also in many cases similar. It is to some extent affected by the Pacific Ocean washing it on the east coast, as Europe is, on the west, by the Atlantic; the circumstances being similar in many respects—the direction of the wind, however, being varied. Shanghae, in 31° N. lat., possesses one of the finest climates in the world; and although extremes of temperature are met with throughout the country, still the air is generally salubrious, and extremely healthy even for Europeans. At Canton the heat of summer is very great, and the yearly average is high, being 70°; yet whilst in a latitude of 23° N., or nearly 30° further *south* than London, fires are required in the houses during winter, and snow and frost are occasionally seen in the streets.

North America presents some curious peculiarities of climate, which are rarely paralleled in any other part of the globe. Generally speaking, the annual average is about 10° or 15° lower, for the same latitudes, than in Europe, and the ranges of temperature are very excessive. In Canada the thermometer stands frequently at 20° below zero in winter, or 52° below freezing-point; whilst in summer, a heat of 100°, or 105°, is commonly experienced. Quebec, in lat. 47° N., has an *average mean*, in winter, of 14°, and in summer, of 68°—showing a very excessive type of climate; whilst so far south as Georgia (lat. 32° N.), the extreme ranges are from 13° to 100°. Compared with these, we may observe, that in lat. 32° S., at Perth, in Western Australia, the range is from 55° of winter, to 75° of summer *mean;* and in the same latitude, north, in Egypt, at the delta of the Nile, the *range* is from 50° to 60° in winter, and from 80° to 90° in summer.

---

* Excessive rainfalls are sometimes, and in certain places, noticed in England. Thus, on Spinkling-fell (height 948 feet), near Borrowdale, Cumberland, the mean of four years gave no less than 163 inches, and it has been nearly 200 in some years; whilst the total annual fall does not exceed, on an average, 31 inches for the whole country.

A great variety of circumstances combine to produce the low mean temperature of the northern portion of the American continent, a brief investigation of which may prove instructive. So far as is at present ascertained, one almost unbroken tract of frozen land or water extends between 60° N. lat. and the North Pole, a considerable portion being at a great elevation above the sea-level. The atmosphere over the whole of this region is, of course, cold, and free from aqueous vapour, and rarely, if ever, intermixes with warm currents of air from the south, to an extent sufficient to permanently modify its average temperature. Hence, whenever a N., N.W., or N.E. wind sets in, the greater portion of North America is exposed to a most inclement and chilling blast; and the immense quantities of icebergs floating southward from the Frozen Ocean, at certain seasons of the year, conduce most powerfully to increase this condition. The north-western portion of the continent is hedged in by a long range of hills—the "Rocky Mountains"—which extend from 70° to about 35° north latitude, with scarcely a break, and are continued to the extremity of the southern portion of the continent at Cape Horn, in latitude 55° S. The greater part of North America, comprised within the parallels of 35° and 70° N., is, therefore, completely shut out from the influence of the warm Pacific Ocean, the hill ranges being too high to permit of the passage of warm aërial currents over their generally frozen summits. On the east, the Gulf-stream, instead of impinging on its shores, passes over the Atlantic in a north-easterly direction, to Europe; and on the south, the high table-land of Mexico partly prevents the access of the hot tropical currents. About California, however, on the west coast, and beyond the Rocky Mountains, a more equable and mild climate subsists, because there the interfering causes, above described, are absent, and the genial air and moisture, arriving from the Pacific, exert their full influence in tempering the climate of that country.

Not only is the climate of North America of a very excessive type, but the range of temperature undergoes most remarkably sudden variations. In some parts of Canada, for instance, the thermometer will fall as much as 60° in 36 hours; and a variation of 30° or 40°, in the course of 24 hours, is by no means an uncommon occurrence during the winter season. The effect of such sudden changes—which, in a moist climate, would be positively injurious to animal life—is, to a great extent, moderated by the extreme dryness which prevails; the intense cold, of course, freeing the atmosphere from every vestige of suspended aqueous vapour. To such an extent does this occur, that, in the Arctic regions, the breath, as driven from the lungs, has its moisture instantly converted into minute particles of snow. The mechanical power of this extreme frost is often sufficient to rend trees and rocks, by the expansion of the ice, as if they had been blasted with gunpowder; metals, if touched by the hand, &c., blister the skin equally as when red-hot; and even hydrophobia is common amongst dogs, at Quebec, in December and January, just as would be, with more likelihood, expected during the hot months of summer.

The southern part of Mexico, between 15° and 20° north latitude, owing to the varying elevation of the land, presents some singular peculiarities of climate. On the low-lying coast the heat is very great, the mean annual temperature reaching an average of 76°. On the elevated table-land the mean is reduced to 64°. The climates range *hot*, beneath a height of 900 feet from the sea-level; *temperate*, at an elevation of from 4,000 to 5,000 feet; and become positively *cold*, at above 7,000 feet.

In a similar manner, and arising from like causes, the climate of Central America, extending between Mexico and the Isthmus of Panama, or between latitudes 18° and 8° N., varies considerably. On both sides the shores are washed by the ocean; the western by the Pacific, and the eastern by the Caribbean sea; and the temperature of the winter of each reaches nearly a mean of 80°. The temperature of the low-lying districts varies between 60° and 80°; but a range of mountains of considerable height (12,000 to 15,000 feet), being an intermediate link joining the Andes of South America, and the Rocky chain of the northern portion of the continent, must tend to modify considerably the heat, which would otherwise be very great. The rains that fall from May to October temper the climate on the Pacific coast; whilst those on the east side, falling between October and May, have there a similar effect, and render the country as healthy as any in the same latitude; fostering, at the same time, the greatest luxuriance and profusion amongst the vegetable productions of the country.

In South America every extreme of climate is found, this portion of the continent comprising all possible variety of elevation, &c. In the north, near the equator, and on the east coast, the level is low, the air moist and of a high temperature, and the rainfall, consequently, in some seasons, enormous, always exceeding in Guiana 100 inches annually, and occasionally reaching to more than double that quantity at places between 8° N. and 2° S. of the equator. On the west coast, the Andes, at an average distance of about 100 miles inland, rob the air of its moisture, as brought by the N.E. and S.E. trade-winds; and *northwards*, between the hills and the shore, from lat. 30° S. to 10° S., the chief parts of Peru and Chili present an almost rainless tract. To the *south* of 30° the air becomes more humid, the land being much narrower than in the northern part; and the prevalent winds are from the west, bringing with them moisture from the Pacific. The country, in fact, gradually assumes a condition, southward, resembling that of an island, so far as climate is concerned, extending thus as far as the south of Patagonia, in latitude 55° S. The Andes shut off the westerly breeze between 30° S. and 55° S., just as, above the parallel of 30° S. to 10° S., they exclude the easterly winds from the western coast; and thus another rainless tract is formed in the interior, occupying most of the southern portion of South America. The east and south-east coasts of that continent have the constant trade-winds from either the N.E. or S.E.; and the level plains of the interior, from 30° S. to the equator, are thus generally well watered: large rivers, including the mighty Amazon, flow through them, and a hot-moist climate tends to produce an unequalled profusion of most forms of animal and vegetable life. In these regions nature revels in her wildest and richest luxuriance; and on no other part of the globe are the mineral, vegetable, and animal kingdoms so fully developed: yet this tract is, at present, almost entirely unexplored, and its treasures jealously locked up by a narrow and selfish policy, that can only be paralleled in the darkest pages of the history of civilisation. It requires but little prophetic inspiration to foretel, that when the resources of the country become expanded, Brazil must hold a place in the world's history, which its extraordinary natural advantages will possibly make the most brilliant of any epoch. It may, perhaps, be now kept in reserve, to take, at some future time, the *status* of present flourishing kingdoms, when their power and riches have dwindled away, owing to the exhaustion of those natural capabilities they at this time possess—a result which is suggested by the present condition of many parts of Asia Minor and India.

We have thus passed in review the leading particulars which have reference to the rainfall, mean and excessive temperatures, &c., of the chief divisions of the earth; and it now only remains to notice a few facts in connection with the ocean-tracts, lakes, &c., which cover the rest of its surface. It has been explained, in previous pages, how much the climate of any place depends on a proximity to, or distance from, the sea. In the equatorial regions, the Pacific, Indian, and Atlantic oceans are the cause of the moist climates of tropical countries; whilst, on the other hand, the Arctic and Antarctic oceans tend to diminish the temperature of the land, not only in their immediate neighbourhood, but even for many degrees beyond their limits. Siberia, in North Asia; Lapland, Russia, and Norway in Europe; Greenland, and British and Russian America, are, to a great extent, frozen and inhospitable climes, owing to the extreme cold induced by the Frozen Ocean of the Arctic zone. From the Antarctic circle, northwards, to Patagonia, Tasmania, and New Zealand, the Southern Ocean reduces the mean temperature to an even greater extent than does the northern one in corresponding latitudes, owing, chiefly, to the greater area which is unoccupied by land, and hence not under the influence of the surface-absorption of the solar rays of heat. The difference of temperature between the two oceans is very remarkable; for we find, that whilst the Arctic has a heat of 40°, in lat. 70° N., the Antarctic, in lat. 68½° S., has one of but 30°·8; the difference for corresponding latitudes, within certain limits, being generally about 10°.

The area of inland seas and lakes is small, when compared with that of the oceans; but being mostly found in regions far removed from the sea, it must have a decided *local* effect on the country surrounding their shores. In Europe; the Baltic, Black, and Mediterranean seas; the Russian and Swiss lakes, &c.—in Asia; the Caspian, Aral, Baikal, and Black seas, &c.—in Africa; the Red Sea, Lakes Tchad, Nyassa, &c.—and, in America, the extensive system of lakes intersecting Canada, the United States, &c.—all have a direct influence on the adjacent country, either in reducing or raising its average temperature.* That areas of enclosed water should have these two opposite effects, in the same localities, at different seasons, may at first sight appear anomalous; but it can be easily explained. In the case of any lake or *nearly enclosed* sea—the Caspian being of the former, and the Black Sea of the latter type—it is plain that, during summer, the surrounding lands, owing to the absorption of solar heat, will be of a higher temperature than the waters of the lake, which reflect, but barely absorb, heat. On the contrary, during the winter, the water will be warmer than the land, because whilst the latter radiates, and therefore loses its heat acquired during summer, the lake radiates very slowly, and therefore as slowly loses its acquired temperature. Inland seas and lakes thus tend to equalise the amount of heat, and, like the fly-wheel in Mechanics, whilst they add no force, they regulate its distribution. As winter, however, passes away, the surface of such as are frozen will tend to maintain a low temperature in the surrounding atmosphere, just as we find in the great area of the North Atlantic, the icebergs, floating southwards, lower the temperature of the atmosphere; and coming into contact with the warmer air, in part produce fogs, so common about the banks of Newfoundland.†

The islands, spread throughout the oceans and seas, must have an effect analogous to that which we have described in respect to the lakes; and for the reasons already assigned, so far as the absorbing and radiating power of dry land is concerned. It is true that, individually, like the lakes, &c., they are extremely small, when compared with continents; but their great number, especially in the Pacific, compensates for their trifling area. They form so many surfaces from which currents of hot air are continually ascending, that are replaced by constant in-draughts of the cool sea-air. Hence islands generally possess those delightful land and sea-breezes, which, beneath the tropics, are often the only modifying agents that would permit many such places to be inhabited. In the Section on Heat this subject has been fully discussed, and some interesting observations, by Captain Maury, are also quoted, fully illustrating the nature of these land and water aërial currents.

In some islands the opposite coasts possess an entirely different climate—a circumstance which is generally attributable to extensive mountain ranges, having a considerable height above the sea-level; or to the setting-in of atmospheric currents from the ocean. Iceland presents a remarkable instance of this kind, owing to the different temperatures of the water by which it is surrounded. On the south side the Gulf-stream impinges, and has so great a heating effect, that the average annual temperature is 40°—an amount equal to that of Philadelphia, which is in a latitude of nearly 25° nearer the equator. But on the north side, where no such warming influences prevail, and at a distance of from 100 to 200 miles from the south coast, a region of perpetual snow and ice is found, which, when a north wind blows, often blasts, by its chilling influences, the remainder of the island, and even drives away the fish that otherwise abound in the surrounding ocean. England, Scotland, Denmark, and Norway, are similarly affected from the same cause; for on the west coast of each the climate is generally moist and mild; but the eastern side of each country, being exposed to the dry cold winds arriving from the interior of Russia, is generally bleak, and, in the northern districts, very cold and dry.‡ The Canaries afford a remarkable instance of this kind. Situated off the west coast of the African continent, and a little to the north of a line passing through the Sahara desert, they experience, at most times, a healthy climate; are refreshed by the sea-breezes, and possess a highly fertile and productive soil. When, however, an easterly or south-easterly wind prevails, the hot and dry winds from the desert reach the islands, accompanied at times with swarms of locusts; and from these causes, in conjoined operation, every vestige of vegetation is destroyed, the earth is parched up, and a desert, arid waste replaces the former luxuriant verdure. Ceylon presents instances of a similar kind; but in that island the variations are chiefly due to the differences of elevation of its various parts; and the mountain chain running through the island, has a remarkable effect on the climate of the east and west sides. When the S.W. monsoon sets in, the west side will receive copious rains, and be covered with a luxuriant tropical growth; whilst, on the east side, a great scarcity of water will be felt, and even an almost complete suspension of vegetable growth occurs, because the suspended aqueous moisture, arriving with the monsoon, is arrested in its course by the hills, and confined entirely to the opposite side of the island. We believe that similar circumstances affect the climate of Madagascar; but its interior is but little known, and, therefore, no accurate data have been obtained. Borneo has an almost south-European climate on its north side; whilst, on the south, that of a tropical character subsists. In the Mediterranean, Sicily presents another illustration; the mean annual temperature of Palermo, on the north, being 6° less than that of Catania on the south-east, the difference of latitude being only about one degree. In the West Indies, Guadeloupe has a low and hot west coast; whilst the east, which is elevated, is much more temperate; yet they are but a few miles apart. The same observations may also be applied to Jamaica, and many of the adjacent islands; and, generally speaking, each possesses a mountain range or tract, which, as we have already remarked, has so powerful an influence in tempering the excessive heat common to all tropical countries.

We have thus pointed out the chief causes, both of a general and special nature, which often affect the climate of continents, oceans, &c.; and our remarks will serve as an introduction to a table,§ in which we have included a variety of facts, carefully selected from various sources, and relating to subjects which have been discussed in the last few pages. The names of the chief countries, cities, &c., in each division of the world, are given in the first column; and, when important, several parts of the same country are named, so as to show the results of local disturbing causes. Wherever possible, and when the results could be relied on, the annual average fall of rain, running over several years, is marked down in the second column. In the succeeding one, the average mean temperature, taken from the *monthly mean* in most cases, is afforded;[*] but occasionally two "means" are given, because either an uncertainty existed, or the climate is subject to extraordinary variations in certain years—a by no means uncommon case with that of our own country. In the fourth column, either the extreme range of temperature, occurring in the year (*i. e.*, the greatest heat and cold), the mean of winter and summer, or the entire range is afforded. In attempting to give these particulars as accurately as possible, we can but remark, that the accounts of various observers differ so greatly, as to make it a matter of much difficulty to obtain information that can be relied on; and it is far more than likely, that the thermometers employed for this purpose have been often incorrect, for reasons already assigned at an earlier page.[†] Observations of this kind, if carelessly made, or with improper instruments, are worse than useless; we believe, however, that the figures in the following table will be found as nearly accurate as possible, because no one set of observations has been adopted, but rather independent data, so that they might act as a check on each other. If not otherwise stated, the temperatures are those of *nearly* the sea-level, or that distance above it on which the majority of towns are situated; which is generally not of any elevation worthy of notice, or likely to interfere, comparatively, with ordinary observations. For the sake of saving space, the letter E has been employed to indicate the *extreme* points between which the thermometer ranges; W shows the mean winter, and S the mean summer, average temperature; and R indicates the total range in degrees, which occurs between the highest and lowest readings in the course of the year.

---

* See, also, remarks on the temperature near the Lake of Geneva; *ante*, p. 1188.

† The folio plates, at page 1192, give the extent of the chief lakes in each hemisphere, and of the islands in the oceans; from which an idea of their influence, with respect to climate, may be gathered.

‡ See *ante*, pp. 1177 and 1193.

§ See end of this Section.

In the column devoted to "moisture," of course every remark is but comparative or suggestive. The use of the hygrometer has been but recently adopted beyond the precincts of our observatories, and hence, the character of a climate in this respect, must be, at present, often a matter of guess-work, or represented in somewhat ideal expressions. The reader, however, must bear in mind the remarks which have been frequently made respecting temperature and moisture; and wherever the annual mean of the former is high, with the rainfall large, and the thermometric range not *very* excessive, an atmosphere containing much suspended aqueous vapour may be expected. This is illustrated in the case of the Guianas, Senegambia, Ceylon, &c. On the other hand, an excessive range, little rainfall, and a comparatively high or low annual mean temperature, indicate a dry climate, as those of Canada, Thibet, the Sahara, Russia, &c. The last two columns give the latitudes and longitudes; in some cases, *nearly*—that is, within a few miles, for the purpose of including a small district surrounding the place of observation.

The table, as thus arranged, may be employed for the purpose of marking down, on a map, isothermal lines for any mean annual temperature which may be taken from column 3. The latitude corresponding to it will be found in column 6, and the longitudes in column 7. Thus, choosing from column 3, the average of 52°, and commencing in Ireland, we pass to the middle of England; through a part of France, to the north of Paris; Prussia; the north of Turkey, or south of Russia (possibly the N. of the Black Sea); the north of India, or perhaps some part of Thibet; the north of China; and thence to New Zealand and Tasmania. All these countries have, in some part, the mean annual average of 52°; and, accordingly, the isothermal *yearly* line will be included in them. If we next turn to column 4, it will be seen that the yearly average is struck from very varying *monthly* or *six-monthly* means, for the *ranges* of temperature are greatly different in each country. Thus, England has a *total annual* range of 85°; Prussia has an *average mean*, between winter and summer, of about 38°; whilst, in the north of China, the similar range of winter and summer means is 53°; and in New Zealand and Tasmania, it is only about 20°. By taking six winter and six summer months, respectively, according to the table of Greenwich average monthly temperatures (given at page 1172), we shall obtain a *mean range, between winter and summer*, of about 15° (which is, however, too small); so that each country named above, although having the same *mean annual* temperature, has a remarkably different *monthly* mean, from which that annual average has been deduced. The reader will therefore perceive why *two* sets of isothermal lines are needed—one for the year, and another for the month—as we have already pointed out at a previous page.[‡] By such a plan only, can a proper average climatic mean be obtained, which may be correctly compared with that of any other place.

The remarks which have been made about climates of the excessive type, will receive a complete illustration in the table; and the student will be able to trace the connection subsisting between rainfall, suspended moisture, and range of temperature, as affecting various places, but especially those of a tropical character. Amongst the extraordinary inflections produced by special disturbing causes, that of the Gulf-stream may be particularly noticed, both in respect to latitude and longitude, and from its origin, till it is lost in the North Polar seas. It will also be observed how much less remote the extremes of the annual range of temperature become as land-surfaces diminish in breadth, and tend towards an insular nature, except under extraordinary local circumstances (as in Iceland, &c.); and the influence of ocean currents, or ocean static conditions, may thus be completely and satisfactorily traced, in connection with latitudes on either side of the equator, and compared with the effect produced by extensive land-surfaces in other regions. The temperature of the ocean in different latitudes has been given, and will be found useful in many inquiries affecting climate, &c.

DISTRIBUTION OF PLANTS AND ANIMALS.—In connection with the science of Meteorology, we may make a few remarks on the distribution of plants and animals; and thus recommend to our readers, as a most interesting study, the comparison of the natural productions of each region, taken in relation to its climatic characteristics.

Whatever theories may be adopted, in ethnology, with respect to the races or varieties of men; in zoology, regarding animals; in botany, as to plants, &c.; and the inferences we may draw, geologically, from specimens of extinct species, respecting their former regions of existence;—it is patent to the most cursory observer, that, with the exception of man, all classes and families of animals and plants may be so arranged as to be considered indigenous to certain climates. The varieties of species are certainly very numerous; and normal characteristics are often modified by various circumstances. Thus the breed of cattle and horses, the quality of fruit, &c., are respectively the subjects of change when those are removed from the country in which they exist in a wild or uncultivated state. The art of training both plants and animals to undergo and bear this change, has, of late years, been carefully studied, and exceedingly interesting results have accrued; and the subject is one of great importance in a commercial point of view, as it is now being constantly attempted to introduce animals, &c., into our colonies, not only to improve the existing stock, but also to add other and useful forms to it. The alpaca, salmon, poultry, pheasants, &c., have thus been transported to our Australian settlements, and are likely to be extremely productive, and of great service; and the cinchona plant has similarly been carried to India, and promises soon to afford an abundant supply of quinine, so essential in cases of debility, ague, &c., in tropical climates. These afford striking instances of the value which is attached to the study of climatic meteorology: and to those so engaged, the following table will doubtless prove of great assistance. We may, however, give here some additional hints, by pointing out the productions which characterise the separate zones, both of latitude and elevation.

---

[*] See reasons for this, mentioned *ante*, p. 1194.

[†] See *ante*, remarks on the manufacture of thermometers, p. 1131.

[‡] See *ante*, p. 1194.

The varieties of climate may, as we have already seen, arise from either of two causes—latitude and elevation—or from their conjoint influence. Thus, at the equator, on the sea-level, we find an annual mean temperature of about 80°; but, ascending to a height of about 16,000 feet, we pass to a line of perpetual snow, equivalent to the condition of the polar regions. Now between these two extremes, it is found that, at every 2,000 feet, a zone is obtained as we ascend, nearly corresponding in productions with other zones, given by dividing the interval between the equator and the poles into eight parts, proceeding north or south from the equator. The *latitudinal* zones can only be limited approximately, because of the irregular inflections of the isothermal lines,[*] which rise towards the poles, or fall nearer the equator, according to various local affecting causes. The succeeding table, however, affords both the latitudes and longitudes of the various places, having the same yearly isothermal; and any map may thus be used in connection with the following observations, the line being temporarily traced by the pencil, from place to place, as required. To be explicit, we again remark, that elevation and latitude may be considered as convertible terms, in studying the distribution of living and extinct creatures of both kingdoms.

The following are the names of the zones, and their *approximate* range in latitude, north or south of the equator—subject to the modification of local causes.

1. Equatorial . .	extending	from	0° to 15°	lat.
2. Tropical . . .	„	„	15° to 24°	„
3. Sub-Tropical .	„	„	24° to 34°	„
4. Warm-Temperate	„	„	34° to 45°	„
5. Cool-Temperate	„	„	45° to 58°	„
6. Sub-Arctic . .	„	„	58° to 67°	„
7. Arctic . . .	„	„	67° to 75°	„
8. Polar	„	„	75° to 90°	„ (?)

1. Commencing with the equatorial regions, we find a climate exceedingly hot and moist, and just that in which vegetation has every circumstance favourable for its full development. There grow in perfection, palms, bananas, ginger, spices, gums, the beautiful water-lily called the Victoria Regia, rafflesia, the sugar-cane, coffee, dye-woods, cabinet woods, cotton, &c.

2. At about 15° north or south of the equator the tropical zone commences, and it extends to about 24° of latitude. Tree-ferns, convolvuli, pepper, tropical fruits of many kinds, the cocoa-nut, rice, coffee, sugar, dye-woods, cabinet woods, indigo, spices, gums, tobacco, and cotton, are extensively grown.

3. From 24° to 34°, which includes India, North Africa, the West Indies, &c., is the sub-tropical zone, the productions of which much resemble the former; but there may be added opium and tea, up to 31° N. This zone embraces the chief cotton-growing countries, both in India and the United States, and also of tobacco and sugar. The characteristic plants are the myrtle tribe, magnolias, large forest-trees, rich flowering plants, luscious fruits, date-palms, &c.

4 From 34° to 45° constitutes the warm-temperate zone, including Portugal, Spain, Greece, Italy, the south of France, &c. The vine, and the mulberry for the silk-worm, are characteristic. The trees are the cork-tree, oak, chesnut, beech, &c.; the myrtle, heaths, &c. The cereals flourish; rice is grown in some parts; amongst fruits are oranges, lemons, nuts of many kinds, grapes in great abundance for wine-making, or to be sold dried as raisins; currants for drying, grown in Greece; peaches, &c.;—such taking the place of sub-tropical fruits, which here disappear.

5. From 45° to 58° constitutes the cool-temperate zone; and the productions of our own country may, to some extent, be taken as the type. Amongst trees are the oak, elm, beech, ash, birch, &c.; cereals grow abundantly in the lower and middle latitudes; grasses also abound for pasture; flax and hemp are cultivated; apples, pears, plums, cherries, &c., are the fruits; the grape not ripening so as to be fit for producing wine, except in the lower division, where it is extensively produced. Great Britain, Ireland, Mid-France, Switzerland, Prussia, Austria, &c., are in this zone; and thus some of the most civilised portions of the world are comprised within its limits. In our country wheat will scarcely grow in the extreme north; hence oats and barley replace it to a large extent in Scotland, and also in Norway, Sweden, &c. The hop, ivy, honey-suckle, &c., are amongst the creeping plants, the two latter being common in the forests. Most of the colonised portions of Australia, Tasmania, and New Zealand are within this zone, in south latitude; and hence their vegetable products resemble those of the countries in Europe, similarly situated in north latitude; but are varied by the presence of trees peculiar to the Australian continent, such as the *Eucalyptus*, or gum-tree, a kind of acacia, numerous forest evergreens, tree-nettles, &c.

6. In the sub-Arctic zone, from 58° to 67°, the *Coniferæ* appear, and flourish well; hence the large pine-forests in Norway, and parts of North America which, however, from being so much cooler than in the same latitudes in Europe, have this kind of tree much nearer the equator. There are also the birch, willow, alder, grasses; rarely wheat; but oats, rye, and barley, lichens, and mosses.

7 & 8. The Arctic zone, extending from 67° to 75°, gradually loses all trace of trees, which are replaced by shrubs of rhododendra, bog-myrtle, lichens, and mosses; and, in the Polar zone, reaching hence to the poles, saxifrage, ranunculi, cochleariæ, and abundance of lichens, mark the extreme limits of vegetative power.

So far we have observed the distribution of plants, in respect to latitude, north or south of the equator—taken certainly on an extremely broad and general scale; for some portions of the earth's surface must be entirely omitted from any of the limits thus pointed out. Thibet, for example, whilst nominally in the sub-tropical zone, has really a climate almost, at times, resembling an Arctic one; but this is owing to its great elevation, of which we shall presently have to speak more fully. The Sahara desert, Arabia, much of Central Africa and South America, equally afford exceptions, the nature of which has been explained previously.[†]

With respect to zones of altitude, similar allowances have to be made, and for the same reasons. Commencing at the sea-level at the equator, we shall have, of course, a climate of the equatorial type, in which, up to a height of 2,000 feet, palms, bananas, ginger, &c., flourish. From 2,000 to 4,000 feet, the tree-ferns, &c., exist; from 4,000 to 6,000 feet, myrtles, laurels, magnolias, heaths, &c.; from 6,000 to 8,000 feet, evergreens, olives, &c.; from 8,000 to 10,000 feet, oaks, beeches, &c.; from 10,000 to 12,000 feet, firs, &c. (on Etna, so low as 7,000 feet, and in the Pyrenees, 5,500 feet); from 12,000 to 14,000 feet, rhododendra, and Alpine plants; and from 14,000 to 16,000 feet, Arctic plants of various kinds, mosses, and lichens in abundance—the latter, as in high latitudes, being the last form of vegetation that is met with.

It would be beyond the scope of our present object if we were to enquire minutely into the specific differences which subsist between the plants of the various zones, and the relation which they have with the climate in which any of them best flourish. This is a subject which would require considerable botanical knowledge on the part of our readers, and we should therefore have to presume on an acquaintance with that science, which has to be treated in detail in the succeeding volume. We may observe generally, however, that the existence of a plant depends more essentially on the *temperature* of any locality, than on the complete suitability of its food. This, of some kind, it can generally find anywhere, to an extent sufficient for bare existence, if not for luxuriant growth; but if the climate be too cold or hot, then many plants will not even grow; or, if they do, they never bear fruit which will ripen. This is a matter of constant experience, especially with the cereals, on which the food of man so greatly depends, and the growth of which is confined within the parallels of about 30° to 58° of latitude, or a corresponding elevation in respect to zones, above the equatorial sea-level. The same holds good with grapes, their limits, however, being somewhat more narrowed.

---

[*] See *ante*, p. 1194.

[†] See *ante*, p. 1193.

The distribution of plants is a matter of great importance, not only for the vegetable food of man, but as also affecting those animals on which he depends for sustenance, carriage, farm-labour, &c.; and hence every civilised country has certain features, both physical and social, which more or less distinguish it from others. It is true that the extensive application of steam in railways, vessels, machinery, &c., is fast obliterating these distinctive characteristics in many places; but the progress of such improvements is slow, compared with the extent over which they must spread, before the revolution they have to effect is completed. In our country such progress is rapid, as also in many others in Europe and North America; but most of the colonies still have to depend on brute force for the saving of human labour.

In the particular case of cattle, sheep, and horses, we have an illustration of this. These animals depend entirely for sustenance on the grasses or inferior cereals; and where such can be obtained of good quality, and in sufficient abundance, the breed of each is not only supported in quantity, but the quality is simultaneously improved. In England, particular attention has been paid to this; and the breeds have been so improved, that the horses, cattle, and wool of this country equal any other, and, in many cases, exceed in quality those of the very countries from which the original stock was first imported. This has arisen chiefly from our climate being peculiarly suitable for such purposes, aided by judicious training, and careful attention to the requirements of each animal.

Turning to Lapland, we find that cattle and horses are there replaced by an entirely different animal, the Reindeer. An almost total absence of grass is compensated for by an abundance of lichen, which is the favourite food of that useful creature; and thus the exigencies of the climate are completely met by a peculiar adaptation of the vegetable to the animal kingdom, brought about even by its extreme severity; whilst the human being has, in one animal, a source of food and clothing, and a beast of draught. The camel in Africa and Arabia, the elephant in India, the llama in Peru and Chili, &c., are instances of a similar kind—all tending to show how climatic variety is compensated for, in a manner as complete as the circumstances of the case require.

The subjects of food, temperature, and *clothing*, must be simultaneously considered in connection with the distribution of animals; for these three points are those on which their existence depends; the skin and its covering being an additional and most important matter in the economy of animal life. In the vegetable kingdom, the organs of respiration and digestion are of so simple a character as to be more easily adapted to varieties of change, and the food is usually present. On the other hand, the animal has nothing but its instincts to guide it in the search for food: and from this arise all the circumstances which affect its longevity, productive powers, &c.; the accidents of its life being induced by its cravings for sustenance, and, in fact, struggles for existence.

Commencing with one of the lower forms of animal life, as the *Mollusca*, we find them pretty equally distributed throughout the waters of the ocean; but always in respect to the peculiarities of each climate; for certain kinds are found only within well-defined limits of latitude, beyond which they rarely exist. Amongst the lowest class of creatures, the coral *Polypi* are almost exclusively confined to certain parts of the Pacific Ocean, where, for ages past, they have been slowly but surely rearing islands, now rapidly becoming the centres of civilisation. Amongst *Fish*, again, we find that some are confined to certain zones, beyond which they are rarely seen: instances of this are found in the salmon tribe, which is limited to the cool, temperate, or sub-arctic zones. But many of the tribes, apparently indigenous to our northern seas and rivers, have their representatives or substitutes in those of low latitudes, the species corresponding, except in some physiological adaptation required by altered circumstances of existence; the type being retained, whilst the exact identity is somewhat affected.

Amongst the *Reptilia*, as the lizards, or saurian tribe, the *Loricata*, &c.—of which our common field-lizard is typical, and the analogue of the crocodiles and alligators of the Nile, India, and America—the development proceeds rapidly as to size and strength, as lower latitudes are reached. The variety of these classes is very extensive about the equatorial and tropical regions, where they abound both on land and in water. Equally, amongst *Birds*, also, the same climatic law is influential: the eagle of Scotland and Norway has its family represented in the Himalayas, and by the condor in the Andes; and we may observe the same fact throughout the whole class. In some islands, however, exceptions exist, as in the apteryx and the dinornis of New Zealand, the emeu of Australia, the dodo of Madagascar, &c.; but still, comparative anatomists can find connecting links for this apparently broken chain.

With respect to *Mammalia*, the distinction of climate is very remarkable. The *Quadrumana* (monkeys, &c.) are invariably inhabitants of tropical countries; as are the *Carnivora* (the lion, tiger, &c.), with comparatively few exceptions. The *Pachydermata* (elephant, rhinoceros, hippopotamus, &c.) are nearly limited to these regions. The *Rodentia* (beavers, rats, hares, &c.) are more extensively distributed, for their food is more generally diffused in its growth. A similar remark applies to the *Insectivora*. The *Edentata* are almost exclusively confined to tropical countries, especially on the south of the equator: they include the ant-eater, pangolin, sloth, &c. The *Ruminantia*, in which our domestic animals (of which we have already spoken) are comprised, embrace a vast variety, as the camel, llama, deer, giraffe, goat, bison, buffalo, &c. Amongst the horse tribe, or *Solidungula*, we may notice how much the ass is degenerated in our climate, compared with his appearance, temper, &c., in regions more southerly, as in Arabia, Asia Minor, &c., where he appears to great advantage; and, indeed, there some species are of great beauty, and even swiftness, as is seen in the djiggetai of Central Asia. Possibly the zebra may also be allied to it, for it partakes of many of its characteristics. The *Sirenia*, as the manatees and dugongs, resemble, in many respects, our *Cetacea* (whales) and *Pinnipedia* (seals); whilst the *Marsupiala* (kangaroos) are allied to the opossum of America.

We have specially remarked on the clothing of animals, as being peculiarly related to the climate in which any species is indigenous. Several remarkable instances of this may be cited. The Arctic bear, *Thalassarctos maritimus* of naturalists, exclusively a native of the polar regions, is clothed with a profusion of hair, the texture and colour of which prevents the rapid conduction and radiation of heat from its body.* Even the feet are covered with hair, which is supposed to give it a firm hold when walking over the snow and ice. The Arctic fox, *Vulpes lagopus*, is similarly clothed with abundant fur; but what is remarkable, the hair, which is of a dark-brown colour in summer, becomes quite white in winter, increasing rapidly in length and thickness, just as the exigency of the severe climate necessitates such a protection. Some species of the hare, as the *Lepus variabilis*, and of the weasels, as the ermine (*Mustela erminea*), which are confined to the colder climates, have the colour of the fur changed similarly, as winter approaches: this may frequently be noticed in both animals in the northern parts of our own country. Amongst the dog tribe, or *Canidæ*, as the Newfoundland and St. Bernard breed, we find a similar provision against the extreme cold, contrasting strongly with the clothing of the greyhound, &c., which are indigenous to milder climates. Numerous instances of this kind might be adduced; but the above will be sufficient to show how much the natural clothing, &c., of the animal becomes self-adaptable to climatic extremes, and excessive ranges in the temperature of the seasons.

---

* See *ante*, Section on Heat, pp. 22 and 26.

Considerable analogy subsists, in general, between the external and protecting coat of trees and animals. The *exogenous* kind of plants, such as all the trees of this and other cool countries, are furnished with a thick bark, which affords a most essential protection to the tree during its growth, and the removal of which would cause its destruction. In *endogenous** plants, as the palms, bamboo, sugar-cane, &c., which are confined to tropical countries, this cuticle, or bark, if any exist (which has been disputed), is of the most elementary kind; and, after a certain period, not only does it not increase, but seems to prevent the stem also from increasing in width; hence the endogens are almost invariably tall and tapering plants, bearing flowers and fruits only at their upper extremities. It has been considered, indeed, that the "bark" of the endogens is nothing more than the hardened external cells of the stem; whilst that of the exogens is a true and complete sheath, regularly produced during the growth of the tree, and essentially connected with its vitality.

With respect to the growth of food specially adapted to certain species of animals, and which we have already noticed in respect to cattle, horses, sheep, &c., we may add a few more instances that are well worthy of notice, as indicative of the climate of many regions. The deer tribe are very fond of certain kinds of lichens, and both the plants and animals begin to be simultaneously developed as the climate becomes suitable for each. In the north of Scotland, for example, wild deer are scattered sparsely, and so is their lichen-food; but as we proceed further north, as in Lapland, Iceland, and Greenland, both the animal and vegetable—which are, comparatively speaking, a curiosity in our country—become essential to the existence of the inhabitants; the *lichen islandicus*, or Iceland moss, for example, being an abundant and characteristic production of that country.

Taking an extreme case of a similar nature, let us transfer our observations to a climate of an entirely opposite character—namely, that of the parched deserts of Northern Africa and Arabia. The herbage produced is at once scanty and coarse, and utterly unfit to support horses; but the camel feeds well on it, and is also enabled, by its peculiar constitution, even to accumulate a kind of stock of food, in the shape of the fat which forms its humps, and which are gradually assimilated into the system whenever its ordinary food cannot be obtained. Its stomach is so arranged in deep cells, as to enable it to retain a store of water when necessary, the cells being expanded or contracted by the voluntary or instinctive action of the quadruped. If taken far northward, it is removed from its natural sphere, and will die, in places where the horse tribe are produced in the greatest numbers, and in the best condition; yet the llama, which is the camel of South America, is impatient of heat, and, being a native of the Andes, frequently retreats, in warm weather, to the snow-line—generally living in flocks, at a great altitude above the sea-level. In Peru and Chili, the llama is employed as a beast of draught; as is the camel in Arabia and Africa; and, like it, affords food and clothing to the natives of those rocky and mountainous countries. Singularly enough, it varies from the camel (whose feet are adapted for walking on sand) in having completely divided toes, which are thus so suitable for climbing the rocks; and also in the absence of humps, which its more abundant, or perhaps extensively diffused, food renders unnecessary. Its clothing is a woolly hair, remarkable for its warmth, and it effectually protects the animal from the sudden changes of climate that occur in travelling from the plains to the mountains, so universal near the western coasts of South America.†

It will have been gathered from the preceding remarks, that certain species of animals are only found in definite tracts or zones. Such localities have been termed *specific centres*; and it is from these that animals of certain species have been spread, accidentally or otherwise, in countries to which they do not naturally belong—in a like manner, indeed, to the transplantation of objects of vegetable growth into climates similar to those in which they grow naturally. In judging of the original place of any species, it must be borne in mind, that influences besides those of climate are constantly active in effecting changes; and none, perhaps, more so than the progress of civilisation. Man has driven before him many animals from their ancient haunts; as, in our own country, the wolf, bear, hyæna, beaver, &c., have long been extinct. In geology, we are often able to judge of the climate which must have existed ages ago, in many places, by finding fossils of certain animals, comparing them with existing species, and inferring, from the habits of such, what must have been those of their ancient families. An instance of this kind is presented by the fossil elk of Ireland, which has undoubtedly existed since the creation of man. It is, therefore, highly essential that the exact specific centre of any recent and existing species should be carefully ascertained, as otherwise, in the comparison of them with fossil remains, serious errors may arise. Occasionally we meet with animals whose specific centres are so exactly shown, as to leave no reasonable doubt of their being confined to one region. Of this kind are the *Ornithorhyncidæ* and *Echidnidæ*, natives exclusively of Australia and Tasmania. These two families resemble each other in some respects: the ornithorhynchus, however, is distinguished by having the jaws precisely like the bill of the duck, with a body resembling that of the ordinary quadruped; many of the organs, &c., presenting analogies to that of the birds. In the echidna, the snout is produced into a long cylindrical organ, the body being thick and short, and covered with hairs. These two families are certainly paradoxes in natural history, and afford remarkable instances of the restriction of animals within certain specific centres.‡

Perhaps we may be indebted for the discovery of these singular creatures (and entertain the hope of many more in the Australian continent), to the fact, that man has, as yet, done little there in "improving" its immense extent of uncultivated, and, indeed, unexplored territory. Not only does civilisation wage war with the brute creation—but even our own species, when found as aborigines in any country, soon undergo a similar fate, as may be witnessed in nearly the whole of the northern portion of the American continent, but especially in that called the United States. In many parts, wholesale extermination, or extradition, has been resorted to, especially in the southern districts; and the destruction of the aborigines by the Spaniards, in other parts of the continent, are too fresh in the minds of our readers to require recital here. In most instances, the original inhabitants, where undisturbed and completely acclimatised, live happily and healthily in regions which are almost surely the grave of the intruding white man. The coasts of South America, Western Africa, &c., afford illustrations of this fact, and astonishingly declare, even in the case of the almost ever-accommodating constitution of our species, that we are subject to the law of specific centres, the removal from which may be productive of danger, or extinction in some cases—only, under any circumstances, to be provided against by an intelligence of which the lower kinds of animals are entirely destitute.

But although quadrupeds seem unable to exist in other than climates similar to that in which they are native, except under special circumstances—as when under the care of man—and, further, cannot shift from place to place, in cases of sudden changes of temperature, for any great distance; we find amongst the birds a powerful instinct, by which they remove themselves from one country to another at certain seasons, and so escape the inconveniences or death which they would otherwise have to suffer. In some birds, as the swallow, this migratory instinct is most strongly manifested, even so far as to cause them to forget their progeny, if it have been hatched late in the summer season, and but just previously to the usual time of their autumnal flight for other regions. This instinct is not confined solely to one order of birds, nor to any particular climate, at least within the limits of the temperate and arctic zones, but is almost universal. Amongst the *Natatores*, some of the auks, which are arctic birds, leave their native regions, and visit our coasts—going, as winter advances, even so far south as Italy and Sicily: so do the puffins, terns, teals, widgeons, pochards, wild swans and geese, flamingoes, &c. Of the *Grallatores*, the crakes, snipes, tatlers, spoonbills, storks, herons, cranes, &c., similarly migrate; some of this order spending the winter in Africa and South Asia, returning to the far north to breed in spring. The *Cursores*, ostriches, &c., possessing wings of but a rudimentary nature, are, like the quadrupeds, confined to one region throughout their lives; and their physical characters accord with this law of their existence. Amongst the *Rasores*, some are migratory, as the quails, &c.; but, generally speaking, they remain in their native country, having but little powers of flight. It is from this order that man has selected, out of the class of birds, those which are now domesticated; amongst them being the fowl tribe, pheasants, partridges, the peacock, &c. The *Columbæ*, or doves, in this, as in most respects, resemble the *Rasores*: some, however, as the turtle-dove, *Columba turtur*, are migratory. In this order is included the extinct dodo. The *Scansores*, comprising the cuckoos, woodpeckers, parrots, and toucans, have at least the first-named bird migratory, as is well known by its welcome visit to this country in early spring. Amongst the *Passeres*—one of the largest orders of birds, including our chief songsters—the nightingale is another welcome visitor to England, extending its passage to Sweden, Denmark, and Russia, but rarely going so far north with us as even the south of Scotland: the migration of the swallow tribe is familiar to all. The *Raptores*, or birds of prey, comprising the owls, eagles, falcons, &c., like the *Carnivora* amongst the mammalia, confine themselves to their own specific centres, having a ready supply of food generally at their command, and their clothing being abundantly provided in the thick covering of feathers which protect them in all seasons.

---

* The terms "exogenous" and "exogens" are applied to such trees as the oak, elm, apple, &c., which increase in bulk by a growth *outwardly*; whilst "endogenous" and "endogens" are referred to such as grow *inwardly*, as the palm-tree, common wheat, grass, &c. The former increase constantly *both* in width and height; but the latter, after a certain period, grow in height alone.

† See *ante*, p. 1196.

‡ See pp. 412, 413—Vol. II.

We thus find, throughout each department of the vegetable and animal creations, from the lowest lichen to man himself, that the nature of climate is an essential element of existence, being at all times either permissive or exclusive in its operation. This arises, primarily, from the fact, that on the atmosphere depends the existence of all animate creation. Its chemical constitution is such, that plants and animals must equally breathe it, availing themselves of one (oxygen), or perhaps the other also (nitrogen), of its essential constituents. Its apparently accidental addition (carbonic acid), however, whilst deleterious to the animal, is of the utmost importance to the vegetable; for as that breathes, it assimilates to its organisation the carbon, and thus increases gradually in bulk and height. The purely physical qualities of the atmosphere are of equal importance, and have as complete an influence on vitality; for a certain density, temperature, moisture, &c., must be maintained, to carry on vegetable and animal growth; and the extent of this, with respect to the maturity of each individual, depends conjointly on a proper adaptation of both the chemical and physical qualities of the air to that purpose. Even descending from animated existence to the mineral kingdom, we notice that meteorological phenomena act precisely as essential a part; and this is really prevenient to, and therefore preparatory for, the subsequent processes of vegetation and animalisation. The bare and unfruitful rock is exposed, year after year, to the disintegrating power of air and moisture; its surface slowly crumbles into dust, and its chemical constituents are gradually eliminated; a spore of moss falls on to that surface, vegetates, and decays, and a small amount of "mould" is thus formed; a stray seed, dropped perhaps by a bird in its flight, alights thereon, germinates, and produces seeds, which falling on the rock, bring forth more, and, gradually, the naked surface becomes coated with verdure; birds and animals feed on this produce; and, lastly, man claims the ground as his heritage. Such a sketch is no flight of scientific romance—it is simply a history of every part of the globe that now bears a vital appearance. Indeed, by such means alone, have nearly the whole of the islands of the Pacific been converted from coral beds to abodes of civilised humanity; their surface, now teeming with every necessity and comfort of life, having once been a bare rock, changed, in the lapse of ages, by operations which have just been so incompletely described. In many parts of our own country this process may be watched from year to year; and in the experience of most of us, there may be remembered spots which, once hard and unfruitful, now reward the labours of the husbandman with abundant, and frequently overflowing harvests.

METEOROLOGY, AND ITS ETHNOLOGIC RELATIONS.—In the preceding article we have incidentally referred to the influence of climate on mankind, in respect to the varieties of our species; and without entering deeply into Ethnology (which will form the subject of a separate section in the second volume), we shall here draw attention to a few circumstances well worthy of notice; and that may, in part, serve as an introduction to the section referred to.

A little reflection reminds us that our world is peopled with a vast variety of human beings, whose differences are at once physical, mental, and moral. These three qualities of our race almost always vary simultaneously; in fact, there is evidently an established law which governs moral and mental development, in connection with that of the body. In the same tribes of any nation, the difference of the sexes is due, not so much to an original mental and moral cast, as to the difference of physical organisation. It hence follows, that whatever influence acts on the body, reacts on the sentient principle; and, by a repetition of action, a permanent habit is created, which at last becomes a distinctive feature of the individual of the tribe, and, consequently, of that variety of the human species to which it belongs. With the broad causes, and their specific effects, we cannot here deal, but must confine ourselves entirely to such as arise from the action of climate, as of heat, moisture, &c., and the ordinary food that the climate in which the individual resides, affords for his sustenance.

Commencing with the northern regions, we find the Esquimaux and Laplanders, inhabitants of the arctic zones, generally speaking, to be of exceedingly small stature, and ordinarily deficient of mental and moral culture. They mostly lead a travelling life, obtaining their food by the chase; some of it, as the seal, &c., being of the coarsest kind: the habitations, with the Esquimaux, are generally snow-burrows. For a lengthened period of the year they live in darkness, owing to the long night which the absence of the sun occasions during winter; and hence their climate cuts them off from most associations of the beautiful in nature, which, to more favoured people in the south, are sources of education, and refinement of mind and taste. The entire duties of their existence seem, in fact, to be comprised in two branches—one, of seeking their food; and the other, of eating it. Frequently, owing to the depth of snow, supply fails them, and thus another misfortune is added to the peculiarities of their condition, by the nature of the climate in which they constantly live.

To those dwelling in the temperate zones, it may seem impossible to picture a more forlorn state than that possessed by such people. Yet they seem to find an existence not only tolerable, but even have enjoyments, which are certainly peculiar to themselves. Habit and nature have so far acclimatised them, that they rarely, if ever, stray into more southerly climes; the reindeer, dogs, fish, seals, &c., which are, like them, indigenous to the country, provide them in food, with clothing, and the means of moving from place to place; and the oil of the whale, with such drift-wood as is cast on the shores of the lakes and seas, affords fuel and artificial light. In fact, they are as much adapted to what we must call the "specific centre" of their existence, as are any of the lower forms of creation to which we have previously devoted our enquiries. In person, both Esquimaux and Laplander, although of short stature, are strong, active, and hardy: they are dirty in their habits, addicted to the use of ardent spirits when they can obtain them, and the Esquimaux are extravagantly fond of oil as an essential article of food.

The latter particulars are, however, explicable on chemical and physiological principles. The intense cold of the climate requires a constant supply of carbonaceous matter in the food, which, by slow combustion, during the process of respiration, may educe animal heat. That the craving for fatty matter is not confined to them, under such circumstances, has been proved by the experience of all arctic navigators; and we were informed, as an instance of the kind, by an eminent commander of one of the expeditions in those regions, that tallow candles were often eaten by our own seamen whilst they were journeying with sledges over the snow—so powerful does our instinct lead us to its gratification, even in objects which, under other circumstances, would be turned from with extreme disgust. With respect to the use of ardent spirits in cold climates, we may notice that, in Sweden, eight gallons are consumed by each individual, on an average for the whole population, annually; and in the northern parts of Great Britain, it is well known that stimulants may be drunk, with impunity, to an extent which would be exceedingly injurious, if not fatal, in warmer climates.

Although anticipating subsequent observations, we must here contrast the necessities of the inhabitants, their tastes, and the natural productions of the country, with those of regions of a different climate, for the purpose of impressing on the minds of our readers the fact, that each zone is, in every respect, peculiarly adapted for the wants of the individuals whose "specific centre" of existence is found within it. Turning, for this purpose, to Spain, Portugal, South-France, Italy, and Greece, we notice that the characteristic vegetable productions (the only sure indications of climate) are just such as the exigencies of those climates demand. The fruits, &c.—as the grape, melon, orange—the salads, leguminous products, &c., are all chiefly composed of water, which has an exactly opposite alimentary effect on the animal system to that of the carbonaceous food, so abundantly provided in the northern regions. In the former countries, the external temperature leaves little to be required in the way of heat-giving food; whereas in the arctic climes such is absolutely essential. Even the natural starch-food of hot countries has but little heating power, as is seen in the rice of Egypt, India, America, &c.

The remarks which we have made respecting the Esquimaux, may be, within certain limitations, applied to all tribes living northward of the parallel of 68° to 70° north latitude, in both hemispheres. They have, so far as is yet known, no analogues in the southern or Antarctic circle, as the inhabited land in those regions does not extend northward beyond about 60° S.; or, perhaps, Tierra del Fuego, in lat. 55° S., is the extreme inhabitable limit.

We must now take a broad zone—say from 65° to 40° of north latitude, between which are comprised what are called the temperate regions. With but comparatively trifling exceptions, in respect to number, the whole of the civilised world may be considered to be comprised within these limits, excluding, of course, the Chinese empire. Nearly the whole of inhabited Europe, and North America, containing together about 350 millions of people, is embraced between these parallels; and here art, science, literature, commerce, &c., have their origin and home. Without being too minute in our enquiries, it is impossible not to notice the peculiarities impressed on each variety of the human species living within these limits, by the circumstances of climate, which, in many cases, corresponds in its boundary to the political and social divisions. Moisture and dryness as distinctly mark their traces, both physically and mentally, on each people, as they do on the productions of the earth, amongst the vegetable kingdom. Contrast, for instance, the phlegmatic Dutchman with the volatile and vivacious Frenchman; or the plodding and steady-going Briton, even with himself, when transplanted into the drier climate of the Canadas and the United States. The latter country, although peopled by immigrants from every civilised nation in Europe, has, during the last seventy years, produced a variety of humanity, as distinctly marked in physical, mental, and social peculiarities, and, as contrasted with the original stock, as are the changes which have ever been produced by the acclimatisation of any plant. Indeed, it will come within the experience of any thoughtful person, that removal from a moist to a dry climate, produces, in the course of years, a great effect on any individual, which is typical of the change of species-characteristics, to which we have just called attention. Generally speaking, the perception becomes keener; the interval between volition and action shorter; and hence, boldness of enterprise, whether political or commercial, arises as a natural result; the adage, "*Cœlum, non animan mutant,*" &c., of the Latin poet, might have held good when only the narrowest sea had to be crossed, but loses its force in our time, when oceans are less thought of than were lakes in former days.

The Chinese empire presents as marked a peculiarity in human history, as the paradoxical Australian animal[*]—to which reference has already been made—does in natural history; the specific centre, in either case, being as decidedly marked. Secluded, until within recent years, almost completely from the rest of the world by a national policy, the Chinese have preserved for ages the individual peculiarities which denote their physical, mental, and moral condition. Their language—oral and written—habits, customs, dress, religion, &c., all seem *sui-generis*, and afford a most interesting study to the ethnologist. The greater portion of their country is comprised between the parallels of 20° and 40° of north latitude, and hence they are nearer the equator by several degrees than is any portion of Europe. But, as we have pointed out at a previous page,[†] the climate does not greatly differ from that of the south of France, Spain, Portugal, &c., owing to causes already explained; and, coincident with that fact, we notice that, in many respects, the productions of the earth resemble such as are found in the countries just named. The Chinese territories, therefore, although situated, geographically, in the subtropical zone, really belong, climatically, to that of the warm and cool-temperate; and it is remarkable how many of the mental characteristics and acquirements of the people correspond to those possessed by nations similarly situated in Europe. Their ingenuity is surprising; the arts and sciences have made great progress; and, in many respects, they excel Europeans. All the appliances of agriculture and commerce are of a very advanced character; and in works both of utility and ornament, they are frequently copied or imitated by western rivals. The Japanese, whom we include with the Chinese, have shown astonishing skill in imitating articles of European manufacture; and some optical instruments, as telescopes, &c., which they have produced, have astonished us by their excellency of construction. Although but a few years have elapsed since a steam-vessel was first seen by them, they have been able to produce engines, boilers, &c., so complete, as to run vessels of their own construction on their waters. They contrast wonderfully with the nomadic tribes in Central Asia, who, within the same parallels of latitude, but living at a great elevation, and in a severe climate,[*] are still in a semi-savage state, devoid of all the arts, and chiefly exist to gratify the instincts of animal nature.

---

[*] See remarks on the ornithorhynchus, &c., at page 1201.

[†] See *ante*, p. 1195.

With certain modifications, these remarks might be extended to Hindostan, Persia, Mexico, Brazil, &c.; but we shall refrain from further illustrations of the kind, referring our readers to the Section on Ethnology for fuller details.

Africa, owing to the intense heat, and the unhealthiness of its climate, has been, with but trifling exceptions, little explored. Around its coasts various settlements have been established by many nations, since the fall of the Egyptian and Carthaginian empires, up to the present day; but every glimpse into its interior has revealed human nature in its darkest forms, both literally and metaphorically. The Africans of the interior are completely isolated, both by the climate and difficulties of access; and seem to be split up into so many varieties, that scarcely anything but the physical characteristic has been arrived at, respecting them, with any degree of certainty. The negroes are distinguished from every other variety of the human race by the darkness of the skin, the woolliness or cotton-like character of the hair, protruding and thick lips, a yellow sclerotica of the eye,[†] &c. They contrast greatly with the more intelligent tribes inhabiting Nubia and Abyssinia, of which we shall presently speak. Dr. Latham remarks—"*A negro is an intertropical African, in a humid, alluvian locality.* . . . . In respect to descent, the negro of Sennaar has his closest relations, in the way of language, manners, and blood, with the African of Nubia, Abyssinia, and the parts about his own country. Not so, however, his physical conformation. This is with the Africans of Senegambia and Guinea—a fact brought about by the common conditions of *heat, moisture, and a low sea-level.*" This quotation of the opinion of one of our most intelligent ethnologists, gives a strong confirmation to the statements we have already advanced respecting the influence of climate on the characteristics of the varieties of our race. The same author observes, respecting the Hottentot—"The Hottentot stock has a better claim to be considered as forming a second species of the *genus homo* than any other section of mankind. . . . . Stature low, with slight limbs; colour, more brown or yellow than black (that of new-born children said to be nearly white); cheek-bones prominent; nasal profile depressed; hair in tuft, rather than equally distributed over the head." In contrast with these we may describe the Nubians, who, although dwelling between latitudes 13° and 24° north, are yet situated in a climate strikingly different from that of the negro and Hottentot country—that of the Nubians being from 3,000 *to* 4,000 *feet of elevation above the sea-level.* Rüppell thus speaks of them:—"A long oval countenance; beautifully curved nose, somewhat rounded towards the top; proportionally thick lips, but not protruding excessively; a retreating chin; scanty beard; lively eyes; strongly frizzled, *but never woolly*, hair; remarkably beautiful figures, generally of middle size; and a bronze colour." Of the inhabitants in the neighbourhood of Lake Tshad, it may be remarked, that they are perhaps the lowest specimens of humanity, and the most complete savages, in every respect, that the world can afford.

We have described three varieties of Africans, sufficiently to show how much human characteristics may vary with the circumstances of latitude, elevation, temperature, moisture, &c.; and, therefore, how much physical, mental, and moral development are dependent on the same. It is no part of our business to enter into the delicate question, of how far the degraded portion of our race may be elevated by removal into more genial climes, and by association with ameliorated conditions? But the successful instances of the kind are too numerous to require specifying. The recently established colony of Liberia has given wonderful testimony to the power of such influences in Africa itself; and our own and other countries will afford thousands of examples in which the neglected sons of Africa have shown a mental and moral aptitude, which places them in no way inferior to the rest of mankind.

In North and South America, situated between 70° of north and 55° of south latitude, great variety subsists. The Esquimaux we have already described;[‡] and, between their country and Mexico, numerous tribes of Indians roam, which are now rapidly becoming extinct. In Mexico, between 15° and 30° of north latitude—yet, generally speaking, at about 6,000 *or* 8,000 *feet of elevation above the sea-level*, and therefore, although situated, geographically, in the tropics, climatically nearly in the temperate zone—civilisation formerly existed to an astonishing extent. The pyramids, temples, grottoes, aqueducts, bridges, and other ruins, attest the skill of the former inhabitants, not only in architecture, but also in sculpture, picture-writing, &c. Passing to the Carib islands, we meet with the analogues of the African; whilst in Patagonia, between 39° and 55° of south latitude, we notice a fine, tall, robust, active, and warlike race, terminating, in a cool climate, the last vestige of humanity to the south of the equator.

In this rapid, and, therefore, exceedingly incomplete notice of some of the leading varieties of the human species, we have been desirous of directing attention to the *general influence* which latitude or elevation,[§] temperature, moisture, &c., exercise on physical, mental, and moral development: and that the student may more distinctly understand the tendency of our observations, we recommend a re-perusal of the description of the climatic characteristics, given, for each country, at page 1195, and the pages succeeding it. By reading the two articles, in their mutual connection, he will be able to comprehend the relationship and importance of the subjects. We must, however, guard our readers against accounting, *solely* on climatic grounds, for the great differences which subsist between the physical, intellectual, and moral condition of varieties of the human race. Such would be pushing the argument too far, and would prove in itself its own refutation. The object we have held in view, has been to show the important and ever active *accessory influence* of climate, and not to place it beyond other and far more powerful causes—to which we cannot here even allude, as being beyond the scope of our present enquiry. It would be ridiculous to argue, because any tribe is placed in a climate either excessively hot or cold, tropic or arctic, high or low in respect to the sea-level, moist or dry, &c., that it must necessarily be distinguished by depressed or elevated qualities in body and mind. The influencing tendency is alone to be regarded, and allowed for; and comparison is only to be made between two tribes similar in every respect, with the exception of climate, if we would gain an absolute knowledge of its effects. No condition of this kind can be found existing on the face of our globe: our enquiries and conclusions are, therefore, solely of a generally relative character, and afford an aid for arriving at a correct judgment, rather than being pronunciatory of the judgment itself. If possible, extensive tracts of land should be chosen, because islands frequently, if not invariably, are subject to many causes producing great uncertainty of climate. A bold contrast is afforded, for instance, by the great Sahara in Africa, and the plains of North America; some portions of Thibet, in Asia, and the north-eastern parts of South America; the interior of Africa and Australia generally, and their coasts, &c.; in each of which distinctions of all kinds are so decidedly marked.

METEOROLOGY IN ITS CONNECTION WITH ENDEMIC AND EPIDEMIC DISEASES.—That certain peculiarities or changes of climate are connected with endemic and epidemic diseases, is a matter of no doubt whatever; instances of which, in the yellow fever of the West Indies, the direful cholera of India, the plague of the East, &c., are familiar to all; but the chain of causation is by no means satisfactorily understood. If, in each case, a series of identical and progressive changes in the atmosphere of an infected place could be determined as invariably preceding the outbreak of the disease, the difficulties of this interesting subject would be lessened, if not entirely removed. But no such direct connection has yet been established; which may be partly owing to the deficient method of observation adopted until within late years, and also to the great obscurity of the causes which always precede, but often escape our notice, despite of every endeavour to discover them. These difficulties have already been named by Dr. Scoffern at a previous page;* and we only re-enter on the subject for the purpose of pointing out, more definitely, the facts of the case, which have hitherto been but incidentally mentioned, and to supplement, in some particulars, the remarks which have been offered.

---

[*] See remarks on Thibet, &c., at page 1198, *ante*.

[†] See *ante*, p. 48, Section on *Light*.

[‡] See *ante*, p. 1202.

[§] See remarks respecting these being convertible terms, at page 1199.

Wherever an endemic or epidemic prevails, it will be generally found that the temperature and moisture of the district have much to do with it, and that they are either in excess or deficiency, according to the nature of the complaint. Such diseases are generally of two kinds; namely, those attacking either the organs of respiration or digestion. Amongst the former may be instanced influenza, bronchitis, and diseases of the lungs in general; and, of the latter kind, are diarrhœa, cholera, &c.: another class, that of the purely febrile type, has specific characters of its own.

In a hot and moist atmosphere, the entire human system generally suffers from debility; but a dry air, if either very hot or cold, and not long continued in, produces, comparatively speaking, but little inconvenience. Thus it is no uncommon occurrence for the temperature in Canada to fall to 20° or 30°, and, in the Arctic regions, to 60° or 70° *below zero*, where, so long as the air is still, no harm ensues; on the other hand, a temperature of 200° and 300°, with *dry* air, is quite harmless to the human body exposed to it. In India, Africa, and the West Indies, where, however, *great moisture* generally, but not always, accompanies a high temperature, the utmost danger exists to Europeans; the liver, organs of digestion, &c., becoming affected; and hence a predisposition to diseases of all kinds is generated; the body, in fact, enters, in respect to nearly all its organs and functions, into abnormal conditions, and disease is, generally speaking, the universal consequent.

In our own country, the sudden changes of temperature, with a comparatively moist atmosphere, are frequently productive of serious consequences, although those changes are slight in comparison with such as constantly take place, even within a few hours, in the Canadas. But with us, as in some parts of India and other countries, the conducting power of the moisture is the cause of injury; hence a hot summer in England is more intolerable to a West Indian, and a cold winter to a Russian, than such seasons are in their own countries; because there, on the average, the air is much drier, and therefore conducts heat, both to and from the body, much more slowly. The most healthy climates are, generally speaking—*all other things being equal*—those that are the driest: hence, in some parts of Chili, on the plains in the Andes, where the air is very dry and bracing, an age of about 100 years is by no means uncommon in individuals; and even that is very often greatly exceeded.

In numerous cases, therefore, we may partly account for the prevalence of disease in districts, or at certain seasons, by a rapid change in the conditions of temperature and moisture. In some parts of the tropical and sub-tropical zones, the duration of the rainy and hot seasons, and their changes, afford just such circumstances as are likely to produce disease in the human subject; for the skin, ever casting off, by its millions of pores, the watery humours and effete matter from the system, is often suddenly checked, or unduly stimulated in its action; and hence febrile symptoms, and inflammation of the organs of respiration and digestion, are immediately induced, and dysentery, in its worst forms, becomes prevalent and fatal.

In the remarks which we have already made on the meteorological influence of drainage, at page 1186, we have pointed out some of the evils arising from a moist climate, either when hot or cold, and also from local conditions of the same kind: several countries are also named in which these conditions are always present. In such places, the increase or check of perspiration so commonly occurring, is quite sufficient to account for the various diseases endemic in them. But, in many places, there can be no doubt that the outbreak of either an endemic or epidemic, may be due, directly, to the presence in the air of poisonous exhalations, which have an immediate action of their own on the human system, or may act conjointly with changes of temperature and moisture. The visitations of cholera in this country, during the last thirty years, have been highly instructive to the scientific observer, in respect to such causes; and perhaps, incidentally, have done more to improve the *general health* of the nation, than would have resulted had not their fatal effect stimulated us to adopt universal sanitary measures.

A careful observation of meteorological conditions which prevail preceding to, and during an outbreak of cholera, generally records a comparatively high temperature, and a moist and stagnant atmosphere. Diseases of the diarrhœa kind are rarely, if ever, prevalent during periods of high wind; and, on the other hand, they are *always* most virulent and fatal in places where a constant change of the atmosphere of the locality does not take place. During the last visitation of cholera in London, Lambeth and Southwark—a great portion of which districts is below the level of the Thames at high water, and constantly very damp—suffered most seriously and fatally from the disease; and, generally speaking, those districts which, like the above, were badly drained, and not exposed to the natural ventilation produced by free access of natural aërial currents, were plainly marked as infected and dangerous localities.

Another and important quality of moist air, to which but little attention has been directed, is the power of aqueous vapour, in a suspended state, of holding in solution gases, &c., and of thus carrying with it exhalations of all kinds, in a form ready for assimilation with the human system. Dry air may be mixed with other gases, which, in most cases, will readily diffuse themselves through it; but moist air, by reason of the water it contains, becomes a much more effective poison-carrier. Hence arises the peculiar smell of marsh lands in autumn; of water in which "greens" have been boiled, &c.: and, in each of these instances, the gases evolved during the chemical decomposition of the vegetable substances, are carried off in a volatile form, and are thus frequently detected by the sense of smell. With respect to the nature of these volatile poisons thus evolved, little or nothing is known.—We have already referred to this subject in the Section on Chemistry;† stating that it has hitherto been impossible to detect the active poison thus floating in the air, with the exception of the sulphuretted hydrogen, to which some have attributed, together with a carburetted hydrogen, the chief influence of miasmatic effluvia. The great attention which has lately been paid to detecting the presence of free ozone in the air,‡ may eventually be rewarded by a further insight into this interesting but obscure subject; at least, it is in that direction alone that any hope for a solution of our difficulties can be at present cherished.

In tropical countries, where a hot-moist air always prevails, the climate at the mouths of rivers, which generally enter the sea by a "delta" consisting of low-lying marsh lands, is almost invariably unhealthy, and sometimes uninhabitable. The periodical overflow of the rivers during the rainy season, inundates the land, often over a very extensive area. Vegetation progresses rapidly when the stream subsides; and, eventually, the decomposition of the plants produces malaria of an exceedingly fatal character. The atmosphere is sometimes poisoned even far into the interior, by the sea-breeze carrying the miasmatic air; and thus the baleful influence is largely spread over the adjacent country.* The mouths of the Mississippi, Amazon, Ganges, &c., afford instances of this kind.

* See *ante*, p. 1154.

† See *ante*, pp. 428, 429.

‡ See *ante*, pp. 1187, 1188.

So far, we have suggested some of the causes which induce certain endemic and epidemic diseases, that chiefly attack the liver, stomach, &c.; but in our own country we have a constant and fearful source of disease and death, arising from affections of the lungs, including consumption, and complaints of a phthisical character in general. A very considerable proportion of the mortality (about one-sixth) arises from this cause; and after making due allowance for unhealthy manufactures, sedentary occupations, &c., still much is left, as the cause of that class of disease, to our variable, cold, and damp climate. There is, no doubt, much to be said for the prevalence of phthisis amongst us on the ground of hereditary tendency; but this frequently disappears in the course of successive descendants; whilst the mortality, in general, is not lessened, but rather has an annual increase.

We shall learn much respecting the influence of meteorological conditions on this disease, by comparing the indications afforded by different localities and seasons. In Holland, for example—which, of all other European countries, is the most damp; where a continual exhalation of moisture rises from the land, on which an almost constant fog settles at many periods of the year; a country, in fact, which is nothing better than an immense reclaimed sea-marsh—we find that phthisis is alarmingly common. Not only does a moist climate thus predispose to the disease, but a low elevation is equally as dangerous—perhaps on account of want of drainage, and consequent dampness. All these conditions meet in Holland, and their results are accordingly fatal to an extraordinary extent.

But, turning to drier climes, we find the opposite conditions to obtain. In Northern Russia, where the range of temperature is excessive, but the air exceedingly dry, consumptive diseases are very rare. Even within the tropics, where the influence of excessive heat induces debility—a constant source of the disease—yet the dryness of the air in some places prevents its occurrence. But we find, that if the inhabitants of those countries, or even the animals common in them, are removed to our climate, the diseases most commonly fatal to both are those of the phthisical type. Elevation above the sea-level, and, consequently, above a stagnant and moist atmosphere, is equally preventive of the disease; and to patients in the early, or even late stages, the removal to a dry and equable climate is the only chance left for possible restoration to health.

Having noticed the localities which most favour phthisis, we may remark on the influence of the seasons of the year. Winter and spring are generally the most predisposing and fatal; and in this fact we introduce another element, besides that of moisture—namely, the falling temperature of the atmosphere. As autumn approaches, the suspended moisture of the air, held invisible during the heat of summer, becomes condensed by the loss of caloric which the earth sustains, or rather, perhaps, by the failing supply, owing to the gradually increasing obliquity of the rays of the sun.† The atmosphere then holds the water in the form of minute vesicles, which, as we have seen, may have gases in solution, and prove a source of irritation to the organs of respiration. The increased sensible moisture rapidly conducts away the normal heat of the body; often checks perspiration; produces catarrhal affections, or constant irritation of the mucous membrane; debilitates the system; and thus gradually induces those conditions in which tuberculous or scrofulous affections are sure to make rapid progress. Sudden changes of temperature, together with the dampness of the air, ensue; and thus the disease, already planted, is fostered and matured. Possibly, as we have already hinted, the prevalence of free ozone, with a northerly or easterly wind, also accelerates the irritation of the bronchial tubes.‡ The effects of the advancing winter season are similarly developed, and constantly-recurring atmospheric changes prevail, until the cold winds of early spring complete the work of destruction. Such is an outline of the various causes which produce and accelerate a disease that carries off about one person in every five or six of our population; and of which, perhaps, scarcely a household in our land has not had painful experience.

Our remarks have hitherto been directed to general climatic causes, as inducive of phthisical complaints; and we can here only mention, that impure air, formed in close apartments, factories, workshops, &c., especially amongst millinery and such trades, is another and fatal cause, for reasons similar to those already assigned. The organs of respiration are kept, under such circumstances, for hours breathing air of a high temperature, and loaded with moisture, and various impurities. The individual, on passing into the open air, instantly encounters a lower temperature, varying with the changes of the season, &c.; and, gradually, this chain of influences acts precisely in the manner already described, and similar dangerous and fatal results follow.

Our space, and the limits of our subject, forbid us discussing the effects of climate in producing diseases of a scrofulous character, which are nearly allied to, if not identical with those we have been mentioning. Such are often the direct consequences of exposure to cold, moisture, &c.: and, in every case, a predisposition to those affections is almost certain to become developed in climates of a moist and variable nature; hence their prevalence in this country.

Having glanced at those diseases of the organs of respiration and digestion which result from climatic influences, we may, lastly, make a few observations on some of the most fatal of all endemics or epidemics—namely, fevers of the typhoid class. It is familiarly known of these, that they are most common in places where impure air and want of cleanliness are found; poverty, filth, intemperance, and vice, being their hotbeds. Yet climate has a most marked influence on these diseases, both with regard to the countries and seasons of their appearance. Typhus is completely unknown in the tropical regions, where a profuse and continued perspiration quickly carries off the effete matters of the body; and it is invariably prevalent in countries which have a cold and moist climate—becoming, in fact, an endemic in them. This may arise in a twofold manner; namely, in part, from the nature of the climate, by its sudden changes checking the perspiration, and inducing internal inflammatory symptoms, with deterioration of the blood; and also because the moisture of the atmosphere always assists in the spread of a disease, for reasons already given. But another and universal cause is found in the depressing influences on the animal system that such climates exercise; and typhus, of all others, is that which is most attendant on a debilitated state of the functions. Again, in moist weather, the skin often has a greater absorbing power; and hence a re-entry of excreted humours into the blood, or of infective and contagious matter, is more likely to take place. It is also noticed, that diseases of the typhoid class are always more prevalent during cold and rainy weather, than in that of a dry and bracing nature, in any locality, whether it be endemically or epidemically affected.

The report on the health of the navy, for 1860, contains some valuable statistics, showing the influence which climate has on the outbreak and prevalence of disease: and the following summary of the accounts from the East Indian, China, and Australian stations, affords ample verification of the statements we have advanced in the preceding pages.

The average ratio of sickness differed very considerably in the different vessels of the squadron: but the variety of employment to which they were subjected, prevents a fair comparison between them. The crews of those vessels most at sea, were much healthier than those employed in the rivers or harbours, or on the coast, for the obvious reason that they were not exposed, in the same degree, to the various diseases which are always produced by free communication with the shore. The total force was 8,540 men, of whom 615 were invalided; and the number of deaths was 244; making, together, a total loss to the service of about 10 per cent. Of the 244 deaths, no less than 116 were caused by dysentery*—the intractable disease of the Chinese coast. Experience has shown, that fever and dysentery follow the seasons in the order of their origin and decline; that they almost entirely disappear during the winter months; reappear in spring; and increase rapidly, in virulence and fatality, throughout the warm months of summer and autumn, until the cold of the approaching winter again puts them out of existence.

---

* See *ante*, p. 1186. † See *ante*, p. 1191. ‡ See *ante*, p. 1187.

The returns show, that *dysenteric attacks were twice as numerous during the warm, as they were during the cold season;* and it appears that the greater portion of them were consequent upon exposure, in boats and on the shore, during August and September, when the force was employed in the Gulf of Pechili, but more especially when off the estuary of the Pehtang and Peiho rivers, or in about latitude 39° N. The experience of the last few years has shown, that the causes which give rise to fever and dysentery on the main-land of China, south of 32° latitude, are either altogether inoperative on the coast of Japan, or exist in a far less potent form. This suggests the obvious necessity of running northward, out of the dysenteric latitudes, immediately on the appearance of this fatal disease amongst the men. This, however, could not be done, owing to the military and naval operations which, in 1860, confined the squadron to the above-named waters.

The health of the Australian squadron contrasts most favourably with the above. The total number of the force was about 940 men; and of these, 22 were invalided, and 13 died; making a total loss of less than 4 per cent., or under one-half of that occurring on the East India and China station. The loss to the service, by invaliding, was greatest on the last-named station, where their ratio rose to 72 per 1,000 men; and least on the Australian, where it amounted to 24 per 1,000 men. The deaths by diseases were greatest on the North American and West India station, where their ratio was 38·7 per 1,000 men; and least on the Pacific station, where it amounted only to 3·7 per 1,000 men. The high number of deaths on the first-named station is attributable to the outbreak of yellow fever.

Yellow fever and dysentery were the chief instruments of death, and dysentery and pulmonary complaints, of invaliding. They are all preventible, and essentially climatic; but, generally speaking, pulmonary complaints were found to increase directly as attention to proper ventilation was neglected; for, in the *St. Jean d'Acre*, where there was no ventilation, there were 285 of such cases, out of a crew of 815; whilst in the *Marlborough*, under circumstances otherwise identical, out of an average complement of 1,145 men, and where particular attention was paid to the ventilation of the decks where the crew slept, there were only seven cases.

The general result gathered from the report is, that even in the case of yellow fever, dysentery, and other fatal diseases, proper attention and care, if exercised duly, will, on the most unhealthy stations—as on the west coast of Africa—secure a comparative immunity from disease; whilst on a healthy station, like the Mediterranean, their neglect is sure to be followed by invaliding, and numerous fatal cases. We thus see, that despite the malevolent influences of climate, still we have left in our hands a means of prevention in nearly every case.

It is no part of our province to point out the different characteristics of the diseases already referred to, or to descend into particulars respecting the symptoms attending the various forms or stages of them. It has been solely our object to give a general view of the connection which subsists between them and the meteorological conditions of our atmosphere; and in doing so, we have confined ourselves to matters familiarly known to most of our readers. We might have instanced a vast variety of affections to which the human subject is liable, arising from sudden changes of temperature, or its excessive range; but we should have trenched considerably on the domains of medical science, and perhaps lessened the force of the arguments and proofs already adduced. We may add generally, however, that almost every disease of the organs of respiration and digestion may be identified with climatic considerations, directly or remotely; and, therefore, the study of meteorology, in its pathological aspects, is one of the highest importance, and deserving of the deepest attention from the general and professional observer.

Whilst science points out, and explains, the causes, progress, &c., of such diseases, it is also its office to suggest such remedies as may tend to prevent them; but, as we have remarked in reference to our knowledge of the causes, so we must own, in respect to its application, that both are limited, owing to the paucity and obscurity of the facts which we possess. It is only of late years that the science of meteorology has been brought to bear on sanitary questions, and hence a proper estimate of the extent of their connection has yet to be made. In previous pages† we have mentioned the influence which a thorough system of drainage has in improving the climatic and sanitary conditions of low-lying and marshy places. In most of our large cities and towns, great attention is now paid to local sanitary matters; surface-water, which is so fertile a source of disease, is now quickly removed; drains are applied to each house; sewage-matter is carried to a distance from its places of production; and various other details, which we need not enumerate, are effected—all tending to render more pure, dry, and therefore healthy, the atmosphere of even the worst localities. By such means an immense amount of good has been effected, the mortality has been decreased, and the public health greatly benefited; although we have not yet attained, by a great length, to the maximum of improvement placed within our power by engineering and chemical science.

Despite every advance, however, there must still be certain localities which, on account of the peculiarities of their position, will always remain far below the standard at which others have arrived. We need but instance Hull, Liverpool, Bristol, &c., which, from their low elevation above, and proximity to, the sea, must necessarily have a moist and variable climate. In each case the drainage mixes with the sea-water running close to them; and as the sewage-matter comes in contact with the saline particles of the ocean, decomposition takes place, and the evolution of poisonous gases is the result. It is to be hoped, however, that the great drainage scheme, inaugurated by the metropolis, will gradually spread in the provinces, and that the refuse from private houses, factories, &c., will in time be everywhere removed far from its sources—a result than which nothing can be more essential for the health of the inhabitants. Then the moist superincumbent atmosphere will at least have less addition to its harmful qualities, arising from the suspension and solution of gases—to which we have frequently alluded, and which constant experience has proved to be so active a cause of disease; and the average moisture will also be itself diminished in many cases.

Our possessions in India have ever been a source of enormous expense, in connection with the civil and military departments, owing to the excessive mortality which constantly occurs. Of late years, the extraordinary fatality which has happened there, even to the highest in power—whose intelligence, means, and position would lead them to the use of every art to prolong life—shows, that however much other causes may operate prejudicially to the health of Europeans, still to the climatic peculiarities its existence must be chiefly due. The subject has received the earnest attention of many scientific men; and experience has shown, that the only remedy, or rather relief, which can be obtained at present, is that of frequent removal up to the elevated plains in the interior—

---

† See *ante*, pp. 1183 and 1186.

as at Simla. This station is about 8,000 feet above the sea-level—a height that, according to the laws we explained at a previous page,* should afford a climate of the temperate character. It has now become a place of general resort for most Europeans resident in India; and its cool bracing air soon restores the sufferer, if he be not already too far debilitated. Referring to the following table of mean temperatures, &c., we find that the annual mean of Calcutta, Bombay, and Madras, is nearly 83°; whilst, at an elevation of 7,000 feet, it does not exceed 57°; hence, by simply ascending to a comparatively moderate elevation, the cool climate is readily reached. There are numerous other stations of this kind, in various parts of the peninsula, equally adapted for the alleviation of the effects of a climate almost intolerable, at times, to all but the natives.

A very ingenious method of purifying the air of any place—especially calculated for India, for the hospitals of which it was first proposed by Dr. Forbes Watson—has been already described in the Section on Chemistry.† Charcoal broken into pieces of the size of a pea, or a little larger, is distributed on trays enclosed in an air-tight case. The whole supply of air required in the establishment, is driven or drawn through the charcoal by suitable mechanical power. The moisture of the air is removed by caustic lime, which is substituted for this purpose, in another case, for charcoal; but the two arrangements can be employed, side by side, in combined operation. This method we have repeatedly and continuedly tested, and have found it exceedingly effective, the air being both purified and dried to any extent that may be desired. Arrangements of this kind would doubtless be of essential service in every tropical climate, where excessive moisture and miasmatic exhalations are usually so prevalent. We refer our readers to the extracts, from the descriptive pamphlet published by the inventors (given at the page just named) for a description of the *modus operandi*, and the benefits derived from this method. Of course such plans are limited in their operation, and can only be used in buildings, &c.: but in a city like Calcutta—which, from its situation amongst lagunes and pools of standing water, can scarcely be made more unhealthy than it is—a contrivance of this kind, or a similar adaptation of charcoal and lime, so applied, cannot but prove of great benefit as a preventive of disease generally.

Although the connection of meteorology with questions of health and sanitary measures, is one of great interest and importance, we cannot, for want of space, pursue it further. The various matters urged already for the consideration of our readers, have been selected with a view of calling attention to palpable instances; and others, of less evident character, but of almost equal consequence, we are compelled to leave untouched. It would be almost impossible, in fact, to state the limits of the subject, seeing, as we have, that so much of the physical, intellectual, and even moral character of a community, is so intimately connected with the condition of the atmosphere, and meteorological phenomena in general. It must be a matter of astonishment to many reflecting persons, that so common and well-known objects as air and moisture, should have such an astounding influence on our individual and social welfare; but to one thoroughly acquainted with the ordinary laws of nature, that cause of surprise at once loses its singularity; for it is but one out of thousands of instances in which a comparatively simple agent is productive of numerous and all-important results.

CONCLUDING REMARKS.—Perhaps it may not be out of place to make a few remarks in reference to the desirability of extending meteorological observations. Our readers will have gathered from the earlier part of the section, by Dr. Scoffern, a general knowledge of the science, immediately followed by practical instructions from Mr. Lowe, so well known by his ability as a scientific observer. In this chapter, it has been our endeavour to supplement the teachings of those gentlemen, by an account of all the new discoveries in the science, together with results, which a somewhat lengthened personal experience has enabled us to gather; so that, taken together, the reader will obtain full instructions, and an adequate knowledge of the science as it exists at the present day. We have enlarged on the popular branch of the subject, in the hope of inducing many of our readers to commence making observations; and have shown how much each individual has a personal interest in it, both in respect to his own health and comfort, and of the welfare of the community at large. Towards the close of the year 1863, perhaps the most terrific storm which has visited these islands during this century, spread its ravages both on land and water, and many valuable lives were sacrificed. It was one of the peculiar cyclone class,‡ in which no skill of our seamen seemed to be of avail: but, disastrous as have been its effects, they are trifling to what would have occurred, had not an almost universal deference been paid at our ports to the warnings given by Admiral Fitzroy, some time preceding its commencement; and by which many fleets of vessels were consequently detained in our harbours. Now, so valuable a result is simply the consequence of careful deductions, from an extended series of *individual* observations of meteorological phenomena, carried on, as yet, for a few years only. The more numerous these become, and the more widely-spread the observers, the nearer shall we arrive at a proper estimate of the changes in the weather, so incessant in our variable climate; because all correct deductions must be drawn, not from any one set of observations, but must depend, rather, on the check against error, which a multiplicity of them alone can ensure.

It hence follows, that all who possess a degree of intelligence and education beyond many of their fellows, have morally imposed on them a duty, which, from its nature, they can share, but never justly resign exclusively to others, provided they have the means and knowledge sufficient for its performance. The amount of knowledge required has been pointed out in the various parts of this section; and, from the other portions of this volume, it is believed that such may be easily acquired. In the Section on Heat, for example, the laws of conduction, radiation, absorption, temperature, &c., are fully explained: in that of Light, refraction, &c., may be studied: the nature and causes of natural electric phenomena may be examined in the Section on Electricity: of magnetic disturbances, in that on Magnetism: and the conduction, &c., of sound, in the Section on Acoustics. In the Section on Chemistry, the chemical properties of air and water, ozone, the various gases found in the atmosphere, derived from all sources, &c., are discussed: and the chapter on the sanitary applications of the science, will be found to have a connection with many of the subjects treated of in the present section. In the Mathematical Section, decimal notation, &c., may be studied, as required in setting down meteorological facts. In the Mechanical Sections, Statics and Pneumatics will be found to have an intimate connection with the science of meteorology: and in the Section on Astronomy, some facts as to the places of the constellations will be highly useful, in watching and noting the direction of meteoric bodies, the Aurora Borealis, &c.

Thus the intelligent reader may readily gain sufficient information from this volume, to enable him to become fully competent to undertake a series of meteorological observations, in all their different branches. The instruments he will at first require, are the barometer, thermometer, and hygrometer; others of minor importance can be afterwards added. Instructions for the purchase and management of, and for making observations by them, are plentifully supplied in this section, together with hints as to gathering various collateral indications, afforded constantly around us. The best form of registration for the barometer and thermometer, is that described and illustrated at page 1189; but a ruled book should also be kept, in which the figures obtained at each observation are to be duly entered, with any other particulars which may deserve remembrance. Various minutiæ are fully explained by Mr. Lowe, in the fourth chapter of the section, which will serve as a guide in all departments of practical meteorology; so that, altogether, even the most inexperienced need no further help than is thus afforded.

---

After such observations have been taken with due care, and properly registered, copies should be sent either to the Meteorological Society of London, or to the Meteorological Department of the Board of Trade.

The following pages afford tables of average rainfall, mean temperature, &c., to which reference has been made in this chapter. We have also appended, at foot, an account of a winter ascent, made by Mr. Glaisher on January 12, 1864; the results of which our readers may compare with others already described at page 1180, *et seq.*

[To Mr. Glaisher, for whose labours science is indebted for the reduction and generalisation of the observations, recorded and published by the Meteorological Society (of which he is the esteemed Honorary Secretary) since its foundation in 1850; and to Admiral Fitzroy, at the head of the Meteorological Department of the Board of Trade, we are under a debt of the greatest obligation, on account of the kind assistance they have afforded us by supplying the fullest particulars in their possession. Of these we have made great use in the preceding pages of this chapter; and have much pleasure in thus acknowledging the sources of our information. —EDITOR.]

MR. GLAISHER'S WINTER ASCENT, ON JANUARY 12, 1864.—The balloon left the Royal Arsenal, Woolwich, at seven minutes after two, with nearly a south wind, and passed over the river Thames; but, when at the height of 400 feet, the wind changed to a point with a great deal of west in it, and we found ourselves passing down the centre of the river. At 2h. 9m., at the height of 550 feet, we fell into a strong S.W. current; we crossed Tilbury Railway at 2h. 14m.; Hainault Forest was west at 2h. 21m., and our course was N.E., or almost directly towards the Blackwater River. Under these circumstances, we did not dare to rise as we intended. At 2h. 28m. we were 3,700 feet high; the direction of the wind changing to S. nearly. At 2h. 43m. we saw a large town east of us, which we thought was Chelmsford, and inferred our course to be nearly N. At 2h. 54m. we saw Maldon, the Blackwater River, and the sea-coast, which we estimated at a distance of fifteen to twenty miles east; we were then about 7,500 feet high. The wind continuing S. nearly, we determined to go above the clouds. At 3h. 8m. we were 8,500 feet high, and the wind veered to S.S.W. At 3h. 16m. we were 9,500 feet high, and the wind changed to S.S.E., and continued in this direction, we believed, to our highest point, which was 13,000 feet at 3h. 31m. There the earth was quite obscured, and we had nothing whatever to guide us as to our rate of motion, or of our locality. As the sun would set in little more than half-an-hour, we gave up the hope of reaching five miles, resolving to pass downwards through the clouds, and ascertain our position. At 3h. 37m. we were 10,500 feet high; in five minutes we descended to 8,500 feet, and beneath the clouds, being still 6,500 feet from the earth, which looked barren; and, as there was no place that any of us knew, we could not determine our locality at all. At four o'clock we saw a forest of pines. We still descended slowly to 1,250 feet, by 4h. 7m. We saw a village; and after passing this the earth looked barren—there were no villages, and scarcely any habitations. The mist was so thick we could not see two miles ahead, but we came to the ground at 4h. 15m., near Brandon.

On the ground the temperature was 42°; decreased to 38½° by 2h. 10m.; but it increased to 45° by 2h. 25m., and the sensation was then one of great warmth: at 2h. 28m. it decreased to 41½°; was 38° at 2h. 30m., and 31° at 2h. 35m. at 6,200 feet high; it was then nearly constant about 30° till 3h., when our height was 7,500 feet; it then decreased to 20° by 3h. 16m. at the height of 9,500 feet, and continued to decrease, and was 11° at 3h. 31m., at the height of 13,000 feet; it increased to 16° in six minutes on descending to 10,000 feet, and constantly increased with decrease of elevation to 40° at the height of 1,000 feet, and to 42° on the ground. Although it was probable that warm currents of air might be met with, it was quite unexpected to encounter such within 1,000 feet of the earth, and extending to nearly 4,000 feet high; the thickness of this warm S.W. wind being fully 3,000 feet. At the height of half a mile the temperature was nearly 4° warmer than on the ground; at this height, hitherto, we have always found the temperature from 12° to 16° colder.

Dew was deposited at the temperature of 35° before starting; at 36° between the heights of 1,500 and 3,000 feet; at 26° at 4,000 feet, decreasing to zero at 9,500 feet; and the dew-point was 4°, 5°, and 6° below zero at heights exceeding 10,000 feet: on passing below 10,000 feet the dew-point was the same as the temperature of the air, and therefore the air was saturated with moisture, and continued so till we very nearly reached the earth.

On leaving, the earth was dull, and the air very misty. When afterwards viewed, its appearance was very different from that in summer: all looked barren, bleak, and ice-bound; every sheet of water was covered with ice; and Mr. Coxwell, notwithstanding his 502 ascents, said he never before had seen sheets of water in their frozen aspect with those peculiar white-fringed edges which attracted our special attention. At 2h. 45m., at the height of 7,000 feet, we heard a railway train, and then the tick-tick of a threshing machine; and afterwards, at the height of 7,200 feet, we heard people's voices; and these were the only sounds we caught. At 3h. 29m., on looking down, we saw snow falling upon a fine cloud, the surface of which was unbroken and even, being free from irregularities, and with boundary lines very sharply defined. At this time dense clouds were far above us, and the air seemed to be full of snow. At 3h. 31m. we were about 13,000 feet high; and as we are quite ignorant of all meteorological conditions in the higher atmosphere at this time of the year, it was with great regret that I heard Mr. Coxwell's decision to descend; we were in fine but thick snow; we had lost sight of the earth, with, we believed, no great length of land before us, and even that being towards the sea. Had we ascended another mile, our descent must have been very close to the coast; and considering that the sun was setting, with large sheets of vapour obscuring the view, I felt that Mr. Coxwell's judgment was again wisely exercised, and I abstained from influencing him in any way whatever.

From 3h. 32m. fine granular snow covered my note-book, and continued till 3h. 47m., when we were about entering a cloud in descending, having a thickness of about 600 feet, through which space we passed in two minutes. The balloon must have been laden with snow. The cloud was saturated with moisture, as was the air below the cloud till within 1,000 feet of the earth. At 3h. 39m. Mr Coxwell was darker than usual; Mr. Norris was reddish-bluish; and I was redder than usual, with both eyes much suffused. At 4h. 9m. it became so dark that it was with difficulty I could read the instruments. The sun had set, a dense mist was in all directions, and we could not see far ahead. Mr. Coxwell then began the descent. The place was quite barren, and, to all appearances, uninhabited; the grapnel passed through light sand for some little time, but the descent was managed so admirably that we came down without causing injury to a single instrument.

Ozone papers were somewhat coloured, but those exposed at the Royal Observatory, Greenwich, remained colourless. The anemometer at the Royal Observatory, Greenwich, registered six miles as the horizontal movement of the air during the time the balloon passed more than 100 miles. The sun was never seen, and there was no opportunity of using the actinometer, the spectroscope, or the polariscope.

It will be seen that the above results widely differ from those afforded during ascents in the summer season.

July 17.—The differences between the readings are shown in the last column, and exhibit an increasing difference, increasing in amount with decreasing readings, till at the highest point the discordance between the readings amounted to half an inch. It is presumed that the aneroid barometer was in error to these amounts; but both instruments were broken in the descent, and no more information can be given.

August 18.—The differences between the readings of the mercurial and aneroid barometers in this ascent were as constant as could be expected, as the readings could seldom be strictly simultaneous. Upon the whole, the readings of the aneroid are as good as those of the siphon.

THE MEAN DECREASE OF TEMPERATURE OF THE AIR WITH A CLOUDY SKY.

Up to 1,000 feet was . . . . 4°·5 from 7 experiments, or 1° in 222 feet.
From 1,000 to 2,000 ,, ... 4°·2 ,, 7 ,, ,, 239 feet.
From 2,000 to 3,000 ,, ... 4°·1 ,, 10 ,, ,, 244 feet.
From 3,000 to 4,000 ,, ... 3°·7 ,, 10 ,, ,, 271 feet.
From 4,000 to 5,000 ,, ... 3°·1 ,, 6 ,, 323 feet.

THE MEAN DECREASE OF TEMPERATURE OF THE AIR WITH A PARTIALLY CLEAR SKY.

Up to 1,000 feet was . . . . 7°·2 from 5 experiments, or 1° in 139 feet.
From 1,000 to 2,000 ,, ... 5°·3 ,, 5 ,, ,, 189 feet.
From 2,000 to 3,000 ,, ... 4°·6 ,, 5 ,, ,, 254 feet.
From 3,000 to 4,000 ,, ... 3°·4 ,, 7 ,, ,, 295 feet.
From 4,000 to 5,000 ,, ... 2°·9 ,, 6 ,, ,, 345 feet.

TABLE, *showing the adopted Reading of the Barometer, reduced to 32° Fah.; calculated Height above the Sea; Temperature of the Air; and Dew-point, during Mr. Glaisher's Ascent on August 18th, 1862.* (See, also, p. 1182.)

Time—P.M.	Barometer.	Height.	Temp. of Air.	Temp. of Dew-point.	Time—P.M.	Barometer.	Height.	Temp. of Air.	Temp of Dew-point.

END OF VOL. I.

INDEX TO VOL. I.

SECTION I.—HEAT.

ABSORBERS and radiators of heat, 26.
Absorbing power of bodies, 26.
Absorption of heat, 26.
Air-currents produced by heat, 27.
Air, latent heat of, 24.
Alum, effects of, on heat, 29.
Analogies between light and heat, 40.
Animal processes, products of, 33.
Arctic regions, cold of the, 30.
Arsenic in gas, 32.
Atmosphere, constitution of the, 33.
Atmosphere, impurities of the, 33.
Atmospheric pressure affects the boiling-point, 20.
Atomic weights and specific heat, 26.
Atoms, 13.

BATTERY, thermo-electric, 29.
Boiling fountains of Iceland, 30.
Boiling-point, depends on atmospheric pressure, 20.
Boiling-points, table of, 20.
Boutigny's experiments on heat, 23.
Breguet's thermometer, 19.
Brick-lining for grates, 32.

CALORIC, 13.
Carbonic acid, fatal effects of, as produced from stoves, 32.
Carbonic acid, freezing of, 25.
Carbonic acid produced by combustion, 32.
Central forces, heat, &c., intensity of, 26.
Chauffer, danger of the, 32.
Chemical action produces heat, 15.
Churches, ventilation of, 34.
Climate and heat, 27.
Cloth, radiating and absorbing power of, 28.
Clothing, conducting power of, 22.
Coal as fuel, 31.
Coal-gas, tallow, &c., products of the combustion of, 33.
Cohesion opposed by heat, 15.
Combustion, 31.
Condensation of steam, 25.
Condensation of vapour, 21.
Conducting power, tables of, 37.
Conduction by metals, 21.
Conduction by solid bodies, 21.
Conduction of heat, 21.
Conductors, bad, 21.
Conductors, good, 21.
Conductors, table of, 22.
Congelation, continual on mountain-ranges, 31.
Convection of heat, 22.
Cooking and heating, 31.
Corpuscular theory of heat, 13.
Cryophorus, the, 24.
Currents, air, and water, 30.

DENMARK, temperature of, 30.
Densities of hot and cold air, 32.
Dew, owing to radiation of heat by the earth, 28.
Dew prevented by the presence of cloud, 28.
Dew, production of, 26.
Diathermancy, 28.
Diathermanous bodies, 28.
Distillation, process of, 25.
Double refraction, 28.
Draughts, cause of, 34.
Drying by steam, 25.

EARTH, absorptive power of, 28.
Earth, cause of the heat of the, 30.
Earth, internal heat of the, 30.
Earth, radiation of the, 26, 27.
Earths, radiating power of, 28.
Effects of heat, tables of, 37.
Effects of expansion by heat, 16.
Elasticity of vapour, tables of, 37.
Electricity produces heat, 15.
Ericsson's air-engine, 18.
Esquimaux snow-hut, 31.
Ether, 13.
Evaporation, 20.
Expansion of gases, 18.
Expansion of liquids, 16.
Expansion of solid bodies, 15.
Expansion of water forming steam, 35.
Expansion produced by heat, 15.
Expansion, tables of, 37.

FERTILITY of soils, caused by heat, 31.
Fevers, causes of, 33.
Fire-grates, badly constructed and wasteful, 31.
Fire-proof safes, 22.
Force of heat, intensity of the, 26.
Freezing-mixtures, 24.
Freezing-mixtures, tables of, 37.
Freezing water in a red-hot crucible, 23.
Freezing water by the air-pump, 24.
Friction produces heat, 14.
Fuel, combustion of, 31.
Fur, feathers, &c., conducting power of, 22.
Fusion by electricity, 19.
Fusion of solid bodies, 18.

GALVANOMETER, the, 29.
Gas, products of the combustion of, 32.
Gas stoves, 32.
Gases, condensation of, 25.
Gases, expansion of, 18.
Gases, solidification of, 25.
Gases, specific heat of, 26.
Geysers, 30.
Glass, conducting power of, 22.
Grates, brick lining economical for, 32.
Grates, polished reflectors for, 32.
Gulf stream, 17.
Gulf stream, cause of, 30.

HANDLING red-hot lead, 23.
Heat, absorption of, 26.
Heat and electro-magnetism, 29.
Heat, cause of, 13.
Heat, conduction of, 21.
Heat, convection of, 22.
Heat, effects of, 15.
Heat, focalisation of, 27.
Heat, introduction to, 13.
Heat, latent, 24.
Heat, polarisation of, 29.
Heat produced by chemical action, 15.
Heat produced by friction, 14.
Heat produced by percussion, 15.
Heat, production of, 14.
Heat, quantities of, 26.
Heat, radiant, addenda on, 38.
Heat, radiation of, 26.
Heat, reflection of, 26.
Heat, refraction of, 28.
Heat, sensible, measured by electricity, 29.
Heat, specific, 25.
Heat-spectrum, 29.
Heat, terrestrial, 30.
Heat, transmission of, 29.
Heating by hot air, 34.
Heating by steam and hot water, 34.
Heating-surface, proportion of, for warming purposes, 36.
Heights measured by the boiling-point of water, 20.
High-pressure steam, 21.
Hot and cold air, their densities, 32.
Hot-water apparatus, ordinary, 35.
Hot-water apparatus, Perkins', 35.
House ventilation, 33.
Houses of Parliament, ventilation of, 34.

ICE, latent heat of, 24.
Iceland spar, refractive powers of, 28.
Internal heat of the earth, 30.
Inter-polar currents, 30.

KITE's ventilator, 34.

LAMP-BLACK, radiating power of, 26.
Land-breezes, cause of, 27.
Latent heat, 24.
Latent heat in ice, 24.
Latent heat, loss of, 25.
Latent heat of air, 24.
Latent heat of steam, 24.
Latent heat of vapours, 24.
Latent heat, tables of, 37.
Light, polarised, 29.
Light, refraction of, 28.
Liquefaction by heat, 18.
Liquids, specific heat of, 26.

McKINNELL's ventilator, 34.
Melloni's experiments, 29.
Melting-points of bodies, 18.
Metals, conducting power of, 22.
Mexico, heat of the Gulf of, 30.
Monsoons, typhoons, &c., cause of, 30.

NATURE of heat, 13.

OVEN, American, 28.
Over-crowding of houses, 33.

PERCUSSION produces heat, 15.
Physical geography, 27.
Polarisation of heat, 29.
Pressure, atmospheric, 35.
Pressure of steam, 35.
Production of cold by the air-pump, 24.
Production of heat, 14.
Pure air essential to life, 33.
Pyrometers, Daniell's and Wedgwood's, 19.

Quantity of heat, 26.

Radiancy of gases, 39.
Radiant heat, addenda on, 38.
Radiant heat, Dr. Tyndall on, 38.
Radiating power of bodies, 26.
Radiating power, table of, 37.
Radiation and reflection, as affecting climate, 31.
Radiation of heat, 26.
Radiation, terrestrial, produces dew, 26.
Radiators and absorbers of heat, 26.
Radiators, good, 28.
Reflecting power, table of, 37.
Reflection of heat, 26.
Reflectors, metallic, 27.
Reflectors, parabolic, 27.
Refraction, double, 28.
Refraction of heat, 28.
Refraction of light, 28.
Refraction produced by water, 28.
Repulsion, 15.
Rock-salt, effect of, on heat, 29.

Scotland, temperature of, 30.
Sea-breezes, cause of, 26.
Sensible heat, 24.
Snow, bad conducting power of, 31.
Soil, absorption by, 31.
Soil, reflecting power of, 31.
Spheroidal state of water, 23.
Specific heat, 25.
Specific heat and atomic weights, 26.
Specific heat, estimation of, 25.
Specific heat of bodies, 25.
Specific heat of gases and vapours, 26.
Specific heat of liquids, 26.
Specific heat of metals, 25.
Specific heat of water, 25.
Specific heat, skeleton table of, 25.
Specific heat, table of, 37.
Spectrum, heat, 29.
Spontaneous combustion, 15.
States of matter caused by heat, 15.
Steam and its applications, 35.
Steam-boilers, covered with felt, 22.
Steam-boiler explosions, 23.
Steam, boiling by, 36.
Steam, cause of, 21.
Steam, drying by, 36.
Steam employed for heating purposes, 36.
Steam-engines, combined, 36.
Steam-engine, condenser of the, 36.
Steam-engine, condensing, 25, 36.
Steam-engine, low-pressure, 36.
Steam-engine, the, 36.
Steam-engine, the locomotive, 36.
Steam, high-pressure, 35.
Steam, latent heat of, 24.
Steam-pipes, coated with felt, 22.
Steam-pipes, radiation of, 36.
Steam, pressure of, 35.
Steam, temperature of, 35.
Steam, uses of, in manufactures, 36.
Stoves, 32.
Stoves, gas, 32.
Stoves injurious to health, 32.
Stream, Gulf, cause of the, 30.
Sulphur, &c., in gas, 32.

Table of boiling-points, 38.
Table of conducting power, 37.
Table of elasticity of vapour of water, 37.
Table of expansion of solids, 37.
Table of freezing-mixtures, 37.
Table of latent heat, 37.
Table of melting-points, 38.
Table of radiating power, 37.
Table of reflecting power, 37.
Table of specific heat, 37.
Tables of the effects of heat, 37, *et seq.*
Temperature of the earth, internal, 30.
Temperature, range of, 31.
Temperature—(See Thermometers).
Terrestrial heat, 30.
Theories of heat, 13.
Thermal changes measured by electricity, 29.
Thermo-electric battery, 29.
Thermo-electricity, 29.
Thermometers, 17.
Thermometer, air, 27.
Thermometer, differential, 27.
Thermo-multiplier, 29.
Thermoscopes, 27.
Thermotics, 13.
Trade-winds, cause of, 30.
Transmission of heat through bodies, 29.
Tropics, heat of the, 30.

Undulation of ether, 14.
Undulatory forces, 13.
Unequal expansion of bodies, 16.

Vaporisation, 20.
Vapours, cause of, 20.
Vapours, latent heat of, 24.
Vapour, pressure of, 35.
Ventilation and warming, 31.
Ventilation of apartments, 32.
Ventilation of the Houses of Parliament, 34.
Ventilation, principles of, 23, 32.
Ventilators, various, 33, 34.
Vital heat, 15.
Vitiation of air by animal products, 33.
Vitiation of air by combustion, 33.
Vitiation of air, causes of the, 32.
Volcanoes, 30.

Walking on red-hot iron, 23.
Walls, cooling effect of, 34.
Warming and ventilation, 31.
Warming by steam, 25, 35.
Waves of ether, 13.
Welding, 19.
Wind and storms produced by heat, 27.
Windows, cooling effect of, 34.
Wine-coolers, 24.
Wood, conducting power of, 22.

SECTION II.—LIGHT.*

Aberration, chromatic, 53.
Aberration, spherical, 44.
Absorption of light, 42.
Achromatic lenses, 53, 54.
Achromatic microscopes, 65.
Achromatic telescopes, 72.
Achromatism, 53.
Actinic rays, 57.
Actinism, 57.
Air-plates, colours of thin, 51.
Analyser, the, 81.
Analysis, spectrum, 55, 166, *et seq.*
Animals, eyes of, 49.
Artificial and solar light, 54.
Artificial illumination (see separate Index), 86.
Astronomical telescopes, 73.
Atmospheric refraction, 45.
Axes, negative, 79.
Axes, optic, of double refracting bodies, 79.
Axes, positive, 79.
Axis of lenses, 47.

Bags for gas, 62.
Bestall's polariscope, 81.
Biaxial crystals, 79.
Biot's polarising apparatus, 82.
Birds, eyes of, 49.
Blowpipe, oxy-hydrogen, 62.
Bunsen's and Kirchkoff's discoveries, 55, 166.
Burning-glasses, 76.
Calorific rays, 49, 57.
Camera-lucida, the, 60.
Camera-obscura, the, 59.
Camera, the, 59.
Cassegranian telescope, the, 74.
Catoptrics, 42.
Chemical decomposition produced by light, 58.
Chemical rays, 49, 50, 57.
Choroid of the eye, 48.
Chromatic aberration, 53.
Chromatropes, 64.
Circular polarisation, 84.
Clouds, cause of the colour of, 50.
Coddington lens, the, 65.
Colour, cause of, 50.
Colour, phenomena of, 49.
Colour produced by polarisation, 81, 83.
Coloured light produced by the prism, 41, 49.
Coloured light, waves of, 41.
Colours, complementary, 51, 52.
Colours, contrast of, 52.
Colours, occular defects respecting, 59.
Colours of thin plates of air, &c., 51.
Colours, primary, 41.
Complementary colours, 51, 52.
Compound microscopes, 65.
Concave lenses—(See Lenses).
Concave mirrors, 43, *et seq.*, 74.
Construction of lenses, 46, *et seq.*
Contrast of colours, 52.
Convergence, 43.
Convex lenses—(See Lenses).
Convex mirrors, 74.
Cornea, the, 48.
Crystalline lens of the eye, 48.
Curved reflectors, 43, 74.

Daltonism, 59.
Debusscope, the, 77.
Decomposition of light, 41.
Diamagnetism, relation of, to light, 85.
Diffraction of light, 52.
Dioptrics, 45.
Dispersion, epipolic, 54.
Dispersion of light, 49, 53.
Dissolving views, 63, *et seq.*
Divergence, 43.
Double refraction, 79.

Effects of light on organised bodies, 56, *et seq.*
Electric light—(See Index to "Artificial Illumination").
Electric light, photographic spectra of the, 166, *et seq.*
Electricity and light, 85.
Elliptic reflectors, 45.
Epipolic dispersion, 54.
Extraordinary ray, 79.
Eye, lenses of the, 48.
Eye, the structure of the, 47.
Eye-glasses, 65, 72.
Eyes of animals, 49.
Eyes of birds, 49.

---

* See, also, following Indexes to "Artificial Illumination" and "Photography.

Eyes of fishes, 49.

FISHES, eyes of, 49.
Fluorescence, 78.
Focal point, 43.
Focus, 43.
Fraunhoffer's lines, 55, *et seq*.

GALILEAN telescope, the, 72.
Gas-bags, 62.
Gas-holders, 63.
Gases, preparation of, for the lime-light, 61, 62, 63.
Glass, multiplying, the, 60.
Glasses, burning, 76,
Glasses, magnifying, 76.
Gregorian telescope, the, 74.

HEALTH, influence of light on, 58.
Herschel's telescope, 74.
Hydrogen gas, to prepare, 62.

ICELAND spar, refractive power of, 79.
Incidence, angle of, 42, *et seq*.
Index of refraction, 46.
Instruments, optical, 59.
Interference of light, 52.
Interference of sound, 52.
Iris, the, of the eye, 48.

KALEIDOSCOPE, the, 77.
Kalotrope, the, 77.

LANTERNS for dissolving views, &c., 61, *et seq*.
Length of waves of light, 41.
Lens, the Coddington, 65.
Lens, the Stanhope, 65.
Lenses, 46.
Lenses, achromatic, 53, 54.
Lenses, focus of, 47.
Lenses, magnifying power of, 47.
Lenses, to cleanse, 63,
Light, 41.
Light a radial force, 42.
Light, absorption of, 42.
Light, apparatus for the lime, and oxy-calcium, 61, 62.
Light, artificial (see "Artificial Illumination"), 86.
Light, colours of white, 41, 49.
Light, decomposition of, 41.
Light, diffraction of, 52.
Light, dispersion of, 53.
Light, double refraction of, 79.
Light, effects of, on organised bodies, 56, *et seq*.
Light, intensity of, 42.
Light, interference of, 52.
Light, length of the waves of, 41.
Light, lime, 62.
Light, mono-chromatic, 54.
Light of the sun, 43, 168.
Light, oxy-calcium, 62.
Light, oxy-hydrogen, 62.
Light, polarisation of, 80
Light, polarised, 80.
Light, reflection of, 42.
Light, refraction of, 45.
Light, speed of, 42, 51, 168.
Light, vital action of, 58.
Lime-light, 62.
Lime-light—(See, also, Index to "Artificial Illumination").
Lines, Fraunhoffer's, 55, *et seq*.
Luminous rays, 49—57.

MAGIC-LANTERN, the, 61.
Magnetism, relation of, to light, 85.
Magnifying-glasses, 76.
Management of magic-lanterns, &c., 63.
Meniscus, the—(See Lenses).
Mica, colour of, by polarised light, 81.
Mica, optic axis of, 84.
Microscope, lenses for, 65.
Microscope, the oxy-hydrogen, 67.
Microscope, the Coddington, 65.
Microscope, the single, 65.
Microscope, the solar, 69.
Microscope, the Stanhope, 65.
Microscopes, 64.
Microscopes, achromatic, 65.
Microscopes, compound, 65.
Microscopes, management of compound, 66.
Microscopic photographs, 68.
Milk and polarised light, 85.
Mirrors, 42, 43, *et seq*.
Mirrors, concave, 74.
Mirrors, convex, 74.
Mirrors, curved, 43, *et seq*., 74.
Mirrors, plane, 42.
Mono-chromatic light, 54.
Multiplying-glass, the, 60.

NEGATIVE axes, 79.
Newtonian telescope, the, 74.
Newton's rings, 51.
Nicol's prism, 83, 84.
Nitre, optic axis of, 79, 84.

OBJECT-GLASS, 65, 72.
Objects for the microscope, 66, 68, 69.
Objects, to mount, 66, 68, 69.
Occular defects with respect to colour, 59.
Oil of turpentine, and polarised light, 85.
Opacity, 42.
Optic axes of double refracting bodies, 79.
Optic axis of mica, 84.
Optic axis of nitre, 84.
Optical instruments, 59, *et seq*.—(See name of each also).
Optical instruments, miscellaneous, 74.
Optic nerve, 48.
Optics, 41.
Ordinary ray, 79.
Organised bodies, effects of light on, 56, *et seq*.
Oxy-calcium light, 62.
Oxygen gas, to prepare, 61.
Oxy-hydrogen blow-pipe, 62.
Oxy-hydrogen light, 62—(See, also, Index to "Artificial Illumination").
Oxy-hydrogen microscope, 67.

PARABOLIC reflector, 45.
Phantasmascope, 77.
Phosphorescence, 78.
Photographs for the microscope, 68.
Photography (see separate Index), 140.
Physioscope, the, 64.
Plane polarisation, 80.
Plane reflection, 42.
Plano-concave lenses—(See Lenses).
Plano-convex lenses—(See Lenses).
Plants, influence of light on the growth of, 56.
Plate, polarising, 80.
Plates of air, colours of thin, 51.
Polarisation, angle of, 80.
Polarisation, circular, 84.
Polarisation, left-handed, 85.
Polarisation, plane, 80.
Polarisation, right-handed, 85.
Polariscope, Bestall's, 81.
Polariscopes, 81.
Polarised light, phenomena of, 82, *et seq*.
Positive axes, 79.
Power of telescopes, 72.
Primary colours, 41, 49.
Prism, the, 41, 49.
Prism, made of various materials, 49.
Prismatic spectrum, 41.
Prussiate of potass, colours of, 81.
Pupil, the, of the eye, 48.

RADIAL forces, 42.
Rainbow, cause of the, 50.
Rainbow, colours of, 50.
Ray, extraordinary, 79.
Ray, ordinary, 79.
Ray, polarised, 80.
Rays, actinic, 57.
Rays, calorific, 49, 57.
Rays, chemical, 49, 50, 57.
Rays, luminous, 49—57.
Reflecting telescopes, 73.
Reflection, angle of, 42, *et seq*.
Reflection, curved, 43.
Reflection, laws of, 42.
Reflection of light, 42.
Reflection, plane, 42.
Reflector, elliptic, 45.
Reflector, parabolic, 45.
Reflector, spherical, 44.
Refraction, atmospheric, 45.
Refraction, double, 79.
Refraction, double, cause of, 79.
Refraction, index of, 46.
Refraction of light, 45.
Refraction, table of indices of, 46.
Refractive power of bodies varies, 46.
Rock-crystal and polarised light, 84.
Rose's kalotrope, 77.
Rosse's, Lord, telescope, 74.

SCLEROTICA, the, 48.
Screens for magic-lanterns, &c., 63.
Selenite, colour of, under polarised light, 83.
Short-sightedness, 49.
Sight, defective, 49.
Sight, organ of, 48.
Single refraction, 45.
Skin, effects of light on the human, 58.
Soap-bubble, colours of the, 51.
Solar and artificial light, 54, 168.
Solar light, 43, 168.
Solar microscope, the, 69.
Spectacles, 75.
Spectrum analysis, 55, 166, *et seq*.
Spectrum, prismatic, 41, 49.
Speculum for telescopes, 73.
Speed of light, 41, 51, 168.
Spherical aberration, 44.
Spherical reflectors, 44.
Squinting, 49.
Stanhope lens, the, 65.
Sugar and polarised light, 85.

TELESCOPE, astronomical, 73.
Telescope, Galilean, 72.
Telescope, Gregorian, 74.
Telescope, Herschel's, 74.
Telescope, Lord Rosse's, 74.
Telescope, simple, 72.
Telescope, the Cassegranian, 74.
Telescope, the Newtonian, 74.
Telescopes, 71.
Telescopes, achromatic, 72, 73.
Telescopes, lenses of, 72.
Telescopes, ordinary, 73.
Telescopes, power of, 72.
Telescopes, reflecting, 73.
Telescopes, refracting, 72.
Telescopes, speculum of, 73.
Thaumatrope, the, 77.
Thin plates of air, colours of, 51.
Tourmaline, polarising properties of the, 83.
Translucency, 42.
Transparency, 42.

UNANNEALED glass, effects of polarised light on, 84.
Undulations, length of, 41, 51.
Undulations, number of, 41, 51.
Uniaxial bodies, 79.

VELOCITY of light, 42, 51, 168.
Views, dissolving, 63, *et seq*.
Vital action of light, 58.

WAVES of light, length, &c., of, 41, 51.
White light, decomposition of, 41, 51.

ARTIFICIAL ILLUMINATION.

ACIDS, fatty, 95, *et seq.*
Acids, stearic, &c., 95, *et seq.*
Action of heat on organic matter, 116.
Air of rooms, vitiation of by gas, &c., 134.
Almond oil, 104.
Ammonia, 116.
Analysis of gas, 120.
Ancient lamps, 87, 108.
Aniline, 118.
Animal oils, 103.
Aquafortis, action of, on fats, 102.
Argand's invention, 87, 110, 129.
Artificial illumination, 86.
Atmospheric air, and light, 88.

BENZOLE, 107.
Billow's burner, 90.
Bisulphide of carbon in gas, 116, 119.
Bleaching of wax, 98.
Bowditch's apparatus for supplying air to lamps, 92.
Bude light, 112,
Bunsen's photometer, 93.
Burners—(See Gas-burners).

CAMELINE oil, 105.
Camphine lamps, 112.
Camphine, or oil of turpentine, 106.
Candles, composite, 97.
Candles, dip, 94.
Candles, materials employed in the making of, 93.
Candles, palm and cocoa-nut oil, 95.
Candles, stearine, 97.
Candles, varieties and manufacture of, 93.
Candles, wax, 98.
Candles, wicks of, 93.
Carbonic acid gas from combustion, 91.
Carbonic oxide, 116.
Caropa or crab-oil, 95.
Castor oil, 101.
Cetine, 97.
Cetylic acid, 97.
Chévreul's discovery, and its application, 95.
Coal-gas, its composition, 91, 117.
Coal naphtha, 107.
Coals, relative value of, 117.
Cocoa-nut oil, 95, 105.
Cocum oil, 95.
Cod-liver oil, 104.
Colouring effects of nitric and sulphuric acids, 101.
Colour of flame, 90.
Combustibles, relative value of, 91.
Combustion, laws of, 88.
Combustion, manner of, 89.
Combustion, products of, 91.
Combustion, spontaneous, causes of, 100.
Combustion, theories of, 88.
Commercial value of gas as tested by the photometer, 120.
Composite candles, 97.
Cotton-seed oil, 105.

DAVY'S (Sir Humphry) investigations, 91.
Davy's safety-lamp, 92.
Dip candles, 94.
Dodder or cameline oil, 105.
Drummond light, 90, 134, 139.

ECLAIRAGE AU GAZ for lamps, 106.
Effects of cold on flame, 91.
Electric light, 134, *et seq.*
Electric light, batteries used for the, 135.
Electric light, cost of producing the, 139.
Electric light, Holmes', 139.
Electric light, intensity of the, 138.
Electric light, lamps for the, 136.
Electric light, Lemolt's method, 137.
Electric light, mode of obtaining the, 135.
Electric light, optical effects of the, in water, 139.
Electric light, Pearce's method, 137.
Electric light, Staite's method, 137.
Epie oil, 95.
Eremacausis, or slow-burning, 89.
Explosions of gas, 132.

FALOTS of Paris, 87.
Fatty acids, 95.
Fatty acids, by hot and cold pressure, 97.
Fatty acids, decomposition of, by sulphuric acid, 96.
Fatty acids, distillation of by steam, 96.
Fatty acids, Frémy's process, 96.
Fatty acids, how obtained, 95.
Fatty acids, Milly's process, 97.
Fatty acids, saponification process, 96.
Fatty acids, sulphuric acid process, 96.
Fish oils, 104.
Fitzmaurice light, the, 139.
Flame, burning at high temperatures, 90.
Flame, cause of light in, 89.
Flame, colour and heat of, 90, 91.
Flame, effects of cold on, 91.
Flame, nature and causes of, 89.
Flame, quantity and intensity of, 90.
Fusel oil, 107.

GALAM butter, 95.
Gas, ammoniacal, 116.
Gas, analysis of, 120.
Gas, application of governors to, 131.
Gas-burners, 128.
Gas-burners, bat's-wing and simple jet, 128.
Gas-burners, cockspur, 128.
Gas-burners, fish-tail, 128.
Gas-burners, Gardner's, 128.
Gas-burners, Gaumont's, 129.
Gas-burners, Leslie's Argand, 130.
Gas-burners, outside, 133.
Gas-burners, relative economy of, 130.
Gas-burners, self-regulating, 131.
Gas-burners, sun, 129.
Gas-burners, the Boccius, 129.
Gas-burners, the pinnacle, 130.
Gas-burners, various Argand, 129.
Gas, carbonic acid, from combustion, 91.
Gas, carbonic oxide, 116.
Gas-coal, materials used for, 117.
Gas, chlorine and bromine tests, 120.
Gas, commercial value of, 120.
Gas, early history of, 114.
Gas, explosive force of, 132.
Gas, first employed in public streets, 115.
Gas from coal-tar, 126.
Gas from wine-lees and grape-skins, 126.
Gas, general remarks on, 114.
Gas, generation of water, 124.
Gas-governors, 131.
Gas, hydrocarbon, 123.
Gas, hydrogen, 116.
Gas, illuminating power of water, 124.
Gas, impurities of, 116, 118.
Gas, innocuous illuminating agents, 134.
Gas, introduction of, 88.
Gas, light-giving, 116.
Gas, light-giving, relative value of, 122.
Gas, management of, 132.
Gas, manufacture of, 116.
Gas-meter, 126.
Gas-meter, dry, 127.
Gas-meters, general management of, 132.
Gas-meter, principle of the, 126.
Gas-meter, wet, 126.
Gas, oil, 122.
Gas, olefiant, 116.
Gas, peat, 125.
Gas, poisonous properties of coal, 133.
Gas, portable, 123.
Gas, pressure of, 130.
Gas, Prussian blue from, 119.
Gas, purifying of, 117.
Gas, rate of burning of, 130.
Gas-regulators, 131.
Gas, resin, 123.
Gas, specific gravity of, 121.
Gas, statistics of, 115.
Gas, sulphuric acid and explosive tests, 121.
Gas-tar, products of, 118.
Gas, tests of impurities in, 119.
Gas, value of refuse matter of, 118.
Gas, value of water, 125.
Gas-ventilation, 133.
Gas, vitiating effects of different lights, 119, 133.
Gas, wood, 125.
Ghea or Shea butter, 95.
Glover's self-regulating burner, 131.
Governors, gas, 131.

HEAT, action of, on organic matter, 116.
Heat of flame, 91.
Hemp-seed oil, 105.
History of artificial light, 86.
Holmes' electric light, 139.
Hydrocarbon gas, 123.
Hydrocarbon gas, illuminating power of, 124.
Hydrocarbon gas, its generation, 124.
Hydrocarbon gas, value of, 125.
Hydrogen gas, 116.

ILLUMINATING agents, vitiating effects of, 133.
Illuminating power of different oils, 102.
Illuminating power of solid bodies, 89, 90.
Illumination, artificial, 86.
Illumination, history of artificial, 86.
Illuminations, street, 88.
Ilpa oil, 95.
Impurities of gas, 116, 118.
Instruments for measuring light, 92.
Intensity of flame, 92.

KHATZUM-BUTTER, 95.

LAMP oils, 99.
Lamps, ancient, 87.
Lamps, Argand, 110.
Lamps, Argand, discovery of, 109.
Lamps, camphine, 113.
Lamps, fountain and carcel, 112.
Lamps, management of, 109.
Lamps, naphtha, 113.
Lamps of the ancients, 108.
Lamps, oil, 109.
Lamps, sinumbra, 111.
Lamps, solar, 112.
Lamps, solar, principle of, 112.
Lamps, spirits for, 106.
Lamps, vapour, 113.
Lamps, varieties of, 109.
Lamps with glass, first used, 88.
Lamps with oxydator, 110.
Lanterns of horn, 88.
Lard oil, 104.
Lavoisier's theory of combustion, 88.
Laws of light, 92.
Laws of combustion and flame, 88.
Leslie's photometer, 92.
Light, depression of, 92.
Light, electric, 134, *et seq.*
Light, Fitzmaurice, the, 139.
Light in flame, cause of, 90.
Light, instruments for measuring, 92.
Light, intensity of, 92.
Light, oxy-hydrogen, 90, 134, 139.
Light (radiant) and heat, laws of, 92.
Linseed oil, 105.
Luminous burning, 89.

MANAGEMENT of gas, 132.
Management of oil-lamps, 109.

Margarine, 95.
Meters, gas, wet and dry, 126.
Mould candles, 93, 94.
Mustard-seed oil, 105.

Naphtha, 107.
Naphtha lamps, 113.
Nature of flame, 89.
Neat's-foot oil, 102.
Neem oil, 95.
Nitric acid, action of, on oils, 102.
Nitrous acid test of oils, 102.
Nut oil, 105.

Oil, caropa or crab, 95.
Oil, coal-naphtha, 107.
Oil, cocum, 95.
Oil, dodder or cameline, 105.
Oil, epie, 95.
Oil, fusel, 107.
Oil gas, 122.
Oil gas, specific gravity of, 122.
Oil, ilpa, 95.
Oil-lamps, 109.
Oil, neem, 95.
Oil of fermented liquor, 107.
Oil, olive, 104.
Oil, sessamum, 105.
Oil, spa, 95.
Oils, extracting and refining of, 99.
Oils, fish and seal, 104.
Oils, heat as a test of purity in, 101.
Oils, illuminating power of, 102.
Oils, lamp, 99.
Oils, properties and specific gravity of, 100.
Oils, sources of, 99.
Oils, varieties of, 103.
Oils, vegetable, 104.
Oils, volatile, 106.
Oils, whale and train, 103.
Olefiant gas, 116.
Oleic acid in oil, 104.
Olive oil, 104.
Orange-seed oil, 104.
Oxy-hydrogen light, 90, 134, 139.

Palm oil, 94.
Palmer's candles, 95.
Palmitine, 95.
Paraffine, 98.
Paraffine, Brown's process, 98.
Paraffine, manufacture, &c., of, 98.
Paraffine, Reece's process, 98.
Peat gas, 125.
Petroleum, 107.
Petroline, 98.
Phlogistic theory, 88.
Photometry, or measuring light, 92, 120.
Piney tallow, 95.
Poisonous properties of coal-gas, 133.
Poppy oils, 105.
Portable gas, 123.
Poutet's test for pure oils, 102.
Pressure of gas, most economical, 130.
Price's candles, 97.
Principles of lamps, 109, *et seq.*
Products of combustion, 91.
Purification of gas, 118.

Radiant light, laws of, 92.
Rape-seed oil, 105.
Rarefaction reduces flame, 92.
Regulators, gas, 131.
Relative gas-giving value of coals, 117.
Relative gas-making power of coals, 122.
Resin gas, 123.
Ritchie's apparatus for measuring light, 92.
Rumford's method of measuring light, 92.

Safety lamp, 92.
Seal oil, 104.
Sesamum oil, 105.
Spa oil, 95.
Spermaceti, 97.
Spermaceti candles, 97.
Spermaceti, characteristics of, 97.
Spermaceti, manufacture of, 97.
Spirits for lamps, 106.
Spontaneous combustion, 100.
Stearine, 95.
Stearine candles, 97.
Stearine, processes for obtaining, &c., 96, *et seq.*
Steel mill of the miner, 139.
Street illumination, 88.
Sulphuretted hydrogen in gas, 116, 119.
Sulphuric acid, action of, on oils, 101.
Sulphuric acid, injurious to books, &c., 119.
Sulphuric acid produced during combustion of gas, 119.

Tallow, 94.
Tallow candles, 94.
Tallow, piney, 95.
Tar, gas from, 126.
Tar, products of, 118.
Test for impurities in gas, 119.
Test of gas by bromine, 120.
Test of gas by chlorine, 120.
Test of gas by durability, 121.
Test of gas by explosion, 121.
Test of gas by specific gravity, 121.
Test of gas by sulphuric acid, 121.
Test of pure oils, 101.
Theories of combustion, 88.
Turpentine, 106.

Value of the refuse of gas-works, 118.
Vegetable fats, 95.
Vegetable oils, 99, 104.
Vegetable wax, 97.
Ventilation and gas explosions, 133.
Vitiating effects of different illuminating agents, 119, 133.
Vitiation of air in rooms by gas, &c., 133, 134.
Volatile oils, 106.

Walrus oil, 104.
Water-gas, 125.
Wax, bleaching of, 98.
Wax, its varieties and characteristics, 97.
Wax of commerce, the melting-point of, 98.
Whale oil, 103.
Wheatstone's photometer, 92.
Wicks of candles, 93.
Wood gas, 125.

Young's paraffine oil lamp, 139.
Young's paraffine process, 98.

PHOTOGRAPHY.

Acetic acid, 145.
Acetic acid, glacial, 146.
Acids—(See their names).
Adjustment of the camera, 147.
Albumen process, the, 159.
Albumenisation of paper, 153.
Apparatus, photographic, 142.
Apparatus required, 144.
Artificial light, photographs produced by, 163.

Baths, silver, 148, 149, 151.
Bromide of silver, 145.
Bromine, 144.

Calotype process, 158.
Camera, adjustment of the, 147.
Camera, choice of a, 143.
Camera, construction of the, 143.
Camera, different kinds of, 143.
Camera, focussing the, 143.
Camera, lenses of the, 143.
Camera, supports for the, 143.
Camera, the, 142.
Celestial photography, 164, 165.
Chemicals required in photography, 144.
Chemistry, photographic, 144.
Chlorine, 144.
Chromotype process, 158.
Collodio-albumen process, 160.
Collodion, 145.
Collodion, coating the plate with, 148.
Collodion, dry process, 160.
Collodion, for negatives, 151.
Collodion negatives, 151.
Collodion positives, general remarks, 150, 151.
Collodion, positive pictures, 146, *et seq.*
Collodion, precautions in coating a plate with, 148.
Collodion process, the, 146.
Collodion, to make, 145.
Colouring photographs, 163.
Copying-frame, the, 144, 154.
Copying from negatives, 154.
Cyanide of potassium, 146.

Daguerreotype plates, preparation of, iodising, mercurialising, and fixing, 156, *et seq.*
Daguerreotype process, the, 156.
Daguerreotypes, toning process for, 158.
Dark room, light to be used in the, 148.
Dark room, requisites for the, 148.
Dark room, the, 148.
Developing, precautions required in, 150.
Developing process, 149.
Developing solutions for negatives, 152.
Developing solutions for positives, 150.
Dipping-bath, the, 144, 149.
Distilled water, 141.
Dry collodion process, 160.

Elementary photography, directions for pursuing, 140, *et seq.*
Engraving, photographic, 161.
Exposing the sensitive plate, 149.
Exposure, time of, in the camera, 149.

Fixing collodion pictures, 150.
Fixing Daguerreotypes, 157.
Fixing process, 141.
Fixing solutions for positives, 150.
Focussing the lenses, 147.
Fothergill process, the, 160.

Gallic acid, 146.
Gelatine paper, 153.
Glass plate easily abraded, 147.
Glass plate, to clean the, 146.
Glass plate, to coat with collodion, 147.
Gun-cotton, 145.

Hair-dyeing materials, 142.
Hyposulphite of sodium, 141.

Iodide of silver, 145.
Iodides used in photography, 145.
Iodine, 144.
Iodising Daguerreotypes, 156.

Iron, proto-nitrate, 146,
Iron, proto-sulphate of, 146.

JAMES', Sir Henry, engraving process, 161.
Juices of flowers, photogenic nature of the, 140.

LIGHT, its effects on animals, 140.

MARKING-INK, 142.
Mercurialising Daguerreotypes, 157.
Microscopic photography, 163.

NEGATIVE and positive pictures, distinction between, 151.
Negative collodion pictures, 151.
Negative developing solutions, 152.
Negative fixing solutions, 152.
Negative pictures, 141.
Negatives, printing from, 152.
Negative, silver bath for, 151.
Negatives, varnishes for, 152.
Nitrate of silver, 145.
Nitric acid, 146.

ORGANIC matter and salts of silver, 140.

PAPER positives (see Printing from Negatives), 153, *et seq.*
Paper (see Printing also), 153.
Photographers, early, 140.
Photographic apparatus, 143.
Photographic chemistry, 144.
Photographic engraving, 161.
Photographic registration, 163.
Photographs, to colour, 163.
Photography, 140.
Photography by artificial light, 163.
Photography, celestial, 164, 165.
Photography, cleanliness required in the pursuit of, 140.
Photography, concluding remarks on, 165.
Photography, early history of, 140.
Photography, introductory experiments in, 140.
Photography, microscopic, 163.
Photography, stereoscopic, 162.
Portrait, taking a, 147, *et seq.*
Positive collodion pictures, 146, *et seq.*
Positive pictures, 141.
Potassium, cyanide of, 146.
Pretcsh's engraving process, 162.
Printing, albumenisation of paper for, 153.
Printing, choice of paper for, 153.
Printing, fixing the paper for positive, 154.
Printing from negatives, 152.
Printing of paper positives, finishing the, 155.
Printing, preparation of paper for, 153.
Printing, salting and sensitising the paper for, 141, 153, 154.
Printing, the copying process from negatives, 154.
Printing, the toning process, 154.
Process, Pretcsh's engraving, 162.
Process, Sir Henry James' engraving, 161.
Process, the albumen, 159.
Process, the calotype, 158.
Process, the chromotype, 158.
Process, the collodion, 146.
Process, the collodio-albumen, 160.
Process, the Daguerreotype, 156.
Process, the dry collodion, 160.
Process, the Fothergill, 160.
Process, the wax paper, 159.
Processes, photographic, 146, *et seq.*
Proto-nitrate of iron, 146.
Proto-sulphate of iron, 146.
Pyrogallic acid, 146.

REGISTRATION, photographic, 163.

SALTING process, 141.
Salts of silver, 145.
Sensitising the collodion plate, 148.
Sensitive paper, 141, 154.
Silver baths, 148.
Silver baths, preparation of, 148, 149, 151.
Silver, chloride of, 141.
Silver, nitrate of, 145.
Silver salts, 145.
Silver salts, changeable by light, 140.
"Sitting for a portrait," 147.
Sodium, hyposulphite, 141, 146.
Stereoscopic photography, 162.
Still, useful form of, 141.
Supports for sitters, 147.

TAKING a portrait, directions for, 147.
Toning baths, 155.
Toning Daguerreotypes, 158.
Toning processes, 155.

VARNISHES for negatives, 152.
Varnishes for positives, 150.

WAX-PAPER process, the, 159.

SECTION III.—ELECTRICITY.

ALKALIES, decomposition of, 195.
Animal electric currents, 197.
Animal electricity, 185.
Anode, the, 194.
Atmospheric electricity, 183.
Attraction and repulsion, 175.
Aurora Borealis, 174.

BATTERIES, voltaic, 186—(See also names of each).
Battery, Leyden, 179.
Blasting by the voltaic battery, 192, 193.
Boiling water by voltaic electricity, 192.
Breaking glass plates, 182.
Brush, the electric, 174.
Bunsen's battery, 189.
Bunsen's battery, experiment with a series of, 190.
Bursting glass tube, 182.

CALLAN'S battery, 190,
Calorific effects of electricity, 181, 192.
Carbon batteries, 189.
Cathode, the, 194.
Charging a jar and battery, 179.
Chemical action in voltaic batteries, 186.
Chemical effects of a voltaic battery, 193.
Chemical theory, 186, 187.
Combustion of metals, 191.
Conducting power of liquids, 187.
Conducting power of moisture, 177.
Conducting-wires, &c., 187.
Conduction, electric, 176
Conductors, 177, 184.
Contact theory, 186, 187.
Crosse's electrical experiments, 195.
Crosse's electro-chemical experiments, 195.
Cylinder electrical machine, 170.

DANIELL'S battery, 188.
Daniell's battery, experiment with a series of, 190.
Davy, Sir Humphry, experiments, 195.
Death by lightning, 184.
Decomposition of alkalies, 195.
Decomposition of water, 194.
Discharging a jar, 179.
Disruption discharge, experiments on, 191, 192.
Double electrical theory, 178.

ELECTRIC brush, the, 174.
Electric conduction, 176.
Electric light, the, 191.
Electric spark, the, 173.
Electric windmill, 175.
Electrical bells, 176.
Electrical induction, 178.
Electrical kite, 183.
Electrical machines, 170, *et seq.*
Electrical repulsion, 170.
Electrical shock, the, 184.
Electrical theories, 177.
Electricity a radiating force, 176.
Electricity, atmospheric, 183.
Electricity, calorific effects of, 181, 192.
Electricity, chemical effects of frictional, 185.
Electricity, frictional, 169.
Electricity from fur, 170.
Electricity from glass, 169.
Electricity from paper, 170.
Electricity from sealing-wax, 169.
Electricity, intensity of, 176.
Electricity, luminous effects of, 181, 191.
Electricity, mechanical effects of, 181.
Electricity of fishes, 185.
Electricity, production of, 169.
Electricity, voltaic, 186.
Electro-chemical decomposition, 194.
Electro-chemistry, 193, *et seq.*
Electro-decomposition—(See Electro-Metallurgy).
Electrodes, 194.
Electro-gilding—(See Electro-Metallurgy)
Electro-metallurgy, 197—(See separate Index).
Electrometers, 176.
Electrophorus, 172.
Electro-plating—(See Electro-Metallurgy).
Electroscopes, 176.
Electrotyping—(See Electro-Metallurgy).
Experiments with Leyden battery, various, 181, 182.

FISHES, electrical, 185.
Forces of nature, 197.
Franklin's kite experiment, 183.
Frictional electricity, 169.

GALVANI'S experiments, 186.
Galvanometer, the, 195.
Gas battery, Grove's, 191.
Grove's battery, 189.
Grove's battery, experiments with a series of, 190.
Grove's gas battery, 191.
Gutta-percha machine, 172.
Gymnotus, the, 185.

HART'S gas-igniting apparatus, 193.
Hydro-electric machine, 172.

IGNITION by the electric spark, 175, 182
Ignition of gas, 182, 193.
Ignition of gunpowder, 181, 193.
Ignition of wire, 192.
Induction, 178.
Induction, theories of, 180.
Infernal machines, Russian voltaic, 193.
Insects, production of, 196.
Intensity of electricity, 176.

Intensity of the voltaic current, 187.
Iron and other conductors, 177.
Iron batteries, 190.
Iron, cast, batteries, 190.

Jar, Leyden, 178.

Kite, electrical, 183.

Leyden jar, a simple, 180.
Leyden jar and battery, 178.
Leyden jar, to charge a, by the electrophorus, 180.
Lightning, accidents from, 184.
Lightning, cause of, 183.
Lightning-conductors, 184.
Lime-light, 194.
Luminous effects of electricity, 181, 191.

Machines, electrical, 170.
Management of electrical machines, 171.
Management of voltaic batteries, 187.
Mechanical effects of electricity, 181, *et seq.*
Melting of steel wire, 182.
Mesmerism, 197.
Minerals, production of, 196.

Negative and positive electricity, 177.
Negative and positive plates, 186.
Nerves and muscles, electric currents in, 185.
Nobili's rings, 196.

Pasley's experiments, 193.
Physiological effects of electricity, 184.
Physiological effects of voltaic electricity, 196.
Pile, the voltaic, 188.
Plate-machine, 170.
Plates of voltaic batteries, 186.
Pointed bodies, electrical effects of, 175.
Poles of a battery, 194.
Positive and negative electricity, 177.
Positive and negative plates, 186.
Power of voltaic batteries, 187, 190.

Quantity of the voltaic current, 187.

Repulsion, electrical, 170, 175.
Resinous electricity, 178.
Russian voltaic infernal machines, 193.

Salts, neutral decomposition of, 195.
Shock, the electrical, 184, 196.
Silurus electricus, the, 185.
Simmonds' electrical machine, 171.
Single electrical theory, 178.
Smee's battery, 190.
Spark, electric, various experiments with, 174.
Spark in gases, 174.
Spark in vacuo, 173.
Spark, the electric, 173.
Steam, electricity from, 172.

Theories, electrical, 177.
Thermo-electricity, 241.
Thermo-electric batteries, 241, 242.
Thermo-electric currents, 241, 242.
Thunder, cause of, 184.
Torpedo, the, 185.
Trees, general electrical conducting power of, 184.

Universal discharger, 180.

Vacuo, spark in, 173.
Vitreous electricity, 178.
Voltaic batteries, 186.
Voltaic batteries, negative and positive plates of, 186.
Voltaic batteries, theories of, 186.
Voltaic battery, Bunsen's, 189.
Voltaic battery, Callan's, 190.
Voltaic battery, calorific effects of the, 192.
Voltaic battery, carbon, 189.
Voltaic battery, cast-iron, 190.
Voltaic battery, chemical effects of the, 193.
Voltaic battery, Daniell's, 188.
Voltaic battery, gas, 191.
Voltaic battery, Grove's, 189.
Voltaic battery, luminous effects of the, 191.
Voltaic battery, simple, 186.
Voltaic battery, Smee's, 190.
Voltaic battery, Wollaston's, 188.
Voltaic current, direction of the, 186.
Voltaic electricity, 186.
Voltaic electricity, medical uses of, 196.
Voltaic electricity, physiological effects of, 196.
Voltaic pile, the, 188.

Water, decomposition of, 194.
Water, electricity from, 172.
Winter's electrical machine, 171.
Wollaston's battery, 188.
Wylde's modification of Grove's battery, 189.

ELECTRO-METALLURGY.

Acetate of zinc, how obtained, 201.
Acid and basic affinities, 205.
Acierage process of Joubert, 239.
Adhesive depositions, 229.
Adhesive deposits, 216, 229.
Adhesive liquids, 216.
Affinities, chemical, of metals, 204.
Alloy solutions, 217.
Alternation of chemical affinities, 206.
Alternations of the electric circuit, 208.
Amalgamation of zinc, 215.
Anions defined, 209.
Anodes defined, 209.
Antimony easily deposited, 219.
Antimony solutions, 218.
Applications of copper deposition, 233.
Arrangement of the depositing vat, 215.
Atomic weights of elements, 211.

Basic affinities of acids and metals, 205.
Batteries, management of, 232.
Batteries, various voltaic, 186, 214.
Battery cells, 214.
Battery liquids, 216.
Battery power, to regulate, 230.
Becquerel's gilding liquid, 228.
Bichloride of platinum in solution coats platinum in contact with zinc, 201.
Binary theory of electrolysis, 212.
Bismuth salts, 219.
Bismuth solutions, 219.
Blacklead as a conductor, 216.
Blackleading the mould, 230.
Boilers and furnaces, 213.
Brandeley's silvering process, 223.
Brassing processes and solutions, 222.
Briant's solution for gilding, 228.
Bright silvering solution, 225.
Bright solution of silver, management of, 235.
Brunel's formula for brassing solutions, 222.

Cadmium solutions, 220.
Cast-iron and zinc articles, to prepare, 229.
Cathodes defined, 209.
Cations defined, 209.
Cells, battery, 215.
Cells, porous, 215.
Chemical affinities of metals, 204.
Chemical affinity of metals and liquids, 204.
Chemical affinity, difference of, 204.
Chemical character of cyanide of silver, 226.
Chemical conditions of deposition, 203.
Chloride of antimony coats a piece of antimony in contact with zinc, 200.
Chloride of antimony coats a piece of platinum in contact with tin, 200.
Chloride of bismuth coats antimony, 201.
Chloride of bismuth coats brass in contact with zinc, copper in contact with tin, and German silver in contact with iron, 200.
Chloride of gold, 226.
Chloride of bismuth in a solution of hydrochlorate of bismuth, bismuth is deposited on several metals, 200.
Chloride of nickel and ammonia coats copper, in contact with zinc, with nickel, 221.
Chloride of zinc, 201.
Circulation of chemical affinities, 206.
Cloth, to copper, 234.
Cobalt solutions, 221.
Compound deposition, 203.
Conditions of deposition, 203, 210.
Conducting, to render moulds, 230.
Conductivity, electrical, 209.
Connecting surfaces must be clean, 233.
Connecting wires, 212, 216.
Copper, and platinised silver for batteries, 215.
Copper, immersed in dilute sulphuric acid, and silver in sulphate solution, placed in contact, the copper dissolves, and the silver is coated with copper, 199.
Copper immersed in sulphate solution and dilute sulphuric acid, that part immersed in the sulphate solution will be coated with copper, 198.
Copper-plates, to etch, 235.
Copper salts, 221.
Copper solutions, 222.
Copper solutions, management of, 233.
Copper strongly acted on by nitric acid, 204.
Coppering cloth, 234.
Copying models, flowers, &c., 234.
Copying type, &c., 234.
Copying woodcuts, &c., 233.
Current affinity, 206.
Cyanide of gold, 227.
Cyanide of gold by chemical process, 227.
Cyanide of potassium, 225, 226.
Cyanide of silver solution, 224, 226.

Daguerreotypes copied by deposition, 234.
Daniell's battery, 214.
Decomposition, electrical, 209.
Definite electro-chemical action, 211.
Deposit, quality, quantity, spread of, &c., 231.
Depositing liquids, effect of light on, 233.
Depositing liquids, 217, 218.
Depositing liquid, to test and select, 217.
Depositing solutions, 217.
Depositing vessels and vats, 215.
Deposition by magnet and coil, 202.
Deposition by one metal and one liquid, 199.
Deposition by one metal and two liquids, 201.
Deposition by two metals and one liquid, 200.

Deposition by two metals and two liquids, 202.
Deposition, to prevent, 229.
Dipping liquids, 216.
Direction of electric currents, 209.
Dissolving plates, position of, 232.
Dynamic conditions, 210.

Elastic moulding, 216, 229, 230.
Elastic moulding composition, 216, 230.
Electric currents, direction of, 209.
Electric decomposition of liquids, 209.
Electrical conditions required for deposition, 203, 207.
Electrical conducting circuit, 208.
Electrical polarity of dissolving metals, 207.
Electrical relations between tin and iron, 221.
Electrical terms of decomposition, 207, 209.
Electricity, sources of, 213.
Electro-chemical scale of elements, 209.
Electro-deposition, practice of, 213.
Electro-deposition substituted for stereotyping, 234.
Electro-deposition, theory of, 197.
Electro-gilding liquid, 227.
Electro-plating liquids, 224.
Electrodes defined, 211, 239.
Electrodes, position and form of, 210.
Electrodes, size, &c., of, 212.
Electrolysis, binary theory of, 212.
Elements, atomic weight of, 211.
Elements, electro-chemical scale of, 209.
Engraved plates, Joubert's process of acieraging, 239.
Etching copper, 235.
Explosive power of antimony freshly deposited, 219.

Facts of electro-deposition, 198.
Finishing plated articles, 236.
Fizeau's gilding liquid, 228.
Flowers, to copy in copper, 234.
Fluidity essential to deposition, 205.
Form of electrodes, 211.
Formula for gilding copper, 228.
Free acids required in metallic solutions for deposition, 207, 217.
Furnaces, boilers, &c., 213.

General rules, 232.
German silver, deposition of, 223.
Gilding by immersion and solutions, 227, 228.
Gilding liquids, various, 228.
Gilding solutions, management of, 236.
Glass surfaces for deposition, preparing, 230.
Glyphography, 235.
Gold, chloride of, 226.
Gold, cyanide of, 227.
Gold deposition by battery process, 227.
Gold immersed in acids is not affected, 204.
Gold, recovery of from solutions, 236, 238.
Gold solution for battery process, 226, 227.

Heat and deposition, 209.
Hydrochlorate of terchloride of antimony coats many metals with antimony, 199.
Hypo-nitrite of lead coats copper, tin, and brass with lead, if in contact with zinc, 200.

Immersion of articles in the vat, 230.
Influence of light on deposition, 210.
Influence of temperature, 210.
Intensity of electrical current, 231.
Iron immersed in solution of sulphate of copper, effects on, 199.
Iron, Joubert's process of depositing, 239.
Iron solutions and salts, 221.

Joubert's acierage process, 239.

Lead salts and solutions, 221.
Length of connecting wires, 212.
Levol's solution for gilding silver, 228.
Light, effect of, on depositing liquids, 233.
Liquids prevented from mixing by a porous partition, 199.
List of patents connected with electro-deposition, 239.
Logical conditions of deposition, 212.
Lyons and Millward's patent silvering process, 225.

Magnet and coil depositions, 202.
Magneto-electric machine, 213.
Making depositing solutions, 217.
Management of batteries, 232.
Management of copper solutions, 233.
Management of silver solutions, 235.
Managing gilding solutions, 236.
Materials for moulding, 216.
Mathematical conditions of deposition, 198, 203, 211.
Mechanical conditions of deposition, 203, 210.
Mercury solutions, 223.
Metals, to prepare, for deposits, 229.
Methods of studying electro-deposition, 198.
Morris and Johnson's brassing process, 222.
Motion of articles in the vat, 232.
Moulding, materials for, 216.
Moulding, method of, 229.
Moulding by phosphorous composition, 230.
Moulds, to render conducting, 230.

Necessity of proper proportions of water, 207.
Negative substances necessary to deposition, 207.
Nickel solutions, 221.
Nitrate of lead coats copper, brass, or silver with lead, if in contact with zinc, 200.
Nitrate of mercury coats silver in contact with zinc or iron, or platinum in contact with copper, 201.
Non-adhesive deposits, 229.

Objects of practical deposition, 212.
One metal in one liquid, 198.
Ontological conditions of deposition, 212.
Order of affinities of metals for acids, 204.
Oxide of copper in ammonia coats platinum in contact with zinc, 201.

Palladium solutions, 228.
Parkes' patent silvering liquid, 224.
Parkes' phosphorous moulding composition, 216.
Patents, list of, 239.
Peculiarities of silver solutions, 235.
Phosphorous moulding composition, 216, 230.
Phosphorus, liquid, as a conductor, 216.
Pickling liquids, 216.
Plates, names of, 209.
Plating liquids, 225.
Platinised silver, 215.
Platinum not affected by most acids, 204.
Platinum salts and solutions, 228.
Polarity of plates in solutions, 208.
Poles, names of, 209.
Porous cells, 215.
Position of articles and dissolving-plate, 232.
Position of electrodes, 210.
Positive substances necessary to deposition, 207.
Potassium, cyanide of, to make, test, &c., 225.
Potassium immersed in most liquids produces chemical action, 204.
Preparing metals for non-adhesive deposits, 229.
Preparing metals for receiving deposits, 229.
Preparing surfaces of elastic moulds, 230.
Proportion of free acid in depositing liquid, 207.
Proto-chloride of tin coats antimony, tin, and copper, when in contact with zinc or lead, 200.
Proto-sulphate of iron coats platinum if in contact with zinc, 200.

Quality of a deposit, 231.
Quantity of a current, 231.
Quantity of a deposit, 231.

Rapidity of deposition, 212, 233.
Recovering gold by the dry method, 238.
Recovering gold solutions from liquids, 236.
Recovering silver by the dry method, 238.
Recovering silver by the wet method, 237.
Recovering silver from exhausted solutions, 237.
Regulating battery power, 230.
Regulating quantity, &c., of metal deposited, 231.
Rendering moulds conductible, 230.
Re-silvering old articles, 236.
Ruolz's gilding solution, 228.
Russell and Woolrich's patent brassing process, 222.

Salts of iron, 221.
Salts of lead, 221.
Salts of platinum, 228.
Salts—(See names of Metals).
Salzede's process for brassing, 222.
Scratch-brush lathe, 215.
Selecting liquids for deposition, 217, 228.
Selection of processes, 217.
Silver and iron with sulphate of copper, 199.
Silver coated by silver, 207.
Silver, cyanide solution of, 225.
Silver-cyanide solution, to test, &c., 236.
Silver-plating solutions, 224.
Silver, platinised, 215.
Silver, recovery of, from solutions, 237, 238.
Silver solutions and salts, 223.
Silver solutions, management of, 235.
Silver, to test the purity of, 236.
Silvering by battery process, 224.
Silvering by wash process, 224.
Single cell batteries, 202, 214.
Sizes of electrodes, liquids, and wires, 212.
Smee's battery, 214.
Solid deposition of silver, 224.
Solid gold deposition, 228.
Solutions for depositing alloys, testing, 217.
Solutions, rules for working, 232.
Solutions—(See names of Metals, &c.)
Solutions, temperature of, 233.
Sources of electricity, 213.
Spread of deposit, 232, 233.
Steele's patent for gilding, 227.
Steele's patent for silvering by immersion, 224.
Steele's patent process for brassing, 222.
Stopping off to prevent deposition, 229.
Stripping solutions, 236.
Sulphate of copper coats brass in contact with zinc, 200.
Sulphate solution for depositing zinc, 228.

Temperature of solution, 210, 233.

Testing cyanide of potassium, 226.
Testing depositing liquids, 217.
Testing purity of silver, 236.
Testing silver, &c., in solutions, 236.
Theory of electro-deposition, 197.
Thermal conditions of deposition, 203, 209.
Tin and iron, electrical relations of, 221.
Tin salts and solutions, 220.
Tuck's patent silvering process, 225.
Two metals in two liquids separated by a porous diaphragm, 199.
Type, to copy in copper, 234.

Vessels, depositing, 215.
Voltaic batteries, 186, *et seq.*, 214.

Washing silvered articles, 236.
Water needed in electro-deposition, 207.
Wires, connecting, 212, 216.
Wiring articles for deposition process, 229.
Wood-cuts, to copy in copper, 233.
Works of art, to copy, 229.

Zinc, amalgamation of, 215.
Zinc and copper batteries, 214.
Zinc for batteries, 215.
Zinc immersed in acids is dissolved, 201.
Zinc salts, 219.
Zinc solutions, 220.

SECTION IV.—MAGNETISM AND ELECTRO-MAGNETISM.

Accidental magnetism, 245.
Alarm-bell, telegraphic, 261.
Allan's deep-sea cables, 272.
Allan's electro-magnetic engine, 252.
Allan's method of telegraphy, 271.
Allan's telegraph alphabet, 273.
Alphabet, telegraphic needle, 261.
Alphabetical telegraphs, 269.
Alphabetical telegraph, Wheatstone's private, 273.
American telegraphic systems, 268.
Apparatus required for electro-magnetic experiments, 247.
Artificial magnets, 243.
Atlantic cable, causes of its failure, 265.
Atlantic, the, cable, 264.
Atmospheric currents and the telegraph, 262.
Atmospheric influence on the needle, 246.
Attraction and repulsion exhibited by a Rhumkorf's coil, 256.
Attraction, magnetic, 243, 244.
Attractive power of electro-magnets, 251.
Aurora borealis imitated by the Rhumkorf spark in *vacuo*, 256.
Aurora borealis, influence of, on the needle, 245.

Bains' electro-chemical printing telegraph, 268.
Bakewell's copying telegraph, 267.
Balloon electric telegraphs, 274.
Barlow's apparatus for explaining the earth's magnetism, 249.
Bar-magnets, 244.
Batteries, voltaic—(See p. 1223).
Bell, the telegraphic alarm, 261.
Birds and telegraph wires, 262.

Cable, Allan's deep-sea, 272.
Cable, Atlantic, 264.
Cable, coatings of a submarine, 263.
Cable, construction, &c., of a submarine, 263.
Cable, insulation of a submarine, 263.
Cable, size and number of wires of a, 263, 264.
Cable, submarine, accidents arising to, 264.
Cable, submersion of a submarine, 264.
Cables, shore ends of, 264.
Cables, submarine, action of intense currents on, 265.
Cables, submarine, statistics of various, 264.
Cables, various submarine (see, also, names of the stations), 264.
Carbon, effects of on iron, in regard to magnetic induction, 249.
Chemical effects of induced currents, 255, 257, 258.
Chemical printing telegraphs, 266.
Clocks, electro-magnetic, 253.
Cobalt, magnetic properties of, 245.
Coil-machine, shock from a, 254.
Coil-machine, the electro-magnetic, 253.
Coil, Rhumkorf's, 255.
Coil, the electro-magnetic, 249.
Coils for telegraphic purposes, 260.
Coils, primary and secondary, 253.
Commercial importance of the telegraph, 263, 270.
Compass, action of the iron and cargo of vessels on the, 246.
Compass, local and accidental disturbances of the, 246.
Compass, the mariner's, 245.
Compass, variation of the, 245, 246.
Compasses, adjustment of ships', 246.
Compound magnets, 244.
Conductor, the earth used as a conductor, 262.
Contact-breakers, 254, 258.
Copper wire as molecularly affected by electric currents, 264.
Copper wire, electrical resistance of, 250.
Copying telegraph, Bakewell's, 267.
Core of iron in the coil-machine, 254.
Currents, intense, peculiar action of, on submarine cables, 265.
Currents of electricity influence the magnetic needle, 247.
Curves, magnetic, 245.

Declination (see Variation), 245.
Deflection of the needle by an electric current, 247, 259.
Dia-magnetics and magnetics, 271.
Dia-magnetism, 270.
Dia-magnetism and gravitation, 271.
Dia-magnetism and motion, 271.
Dia-magnetism of gases, liquids, metals, &c., 271.
Dipping-needle, the, 245.
Diurnal variation of the needle, 245.
Divergence of the magnetic needle by electricity, 247.
Double-needle telegraph, 261.
Dover and Calais cable, 264.
Dover and Ostend cable, 264.

Earth-currents, effect of, on the needle, 262.
Earth, magnetic poles of the, 245.
Earth, magneto-inductive power of the, 245.
Earth, the, used as a conductor, 262.
Earth's magnetism, electro-magnetic theory of the, 249.
Electric and magnetic phenomena, 247.
Electric current, action of, on the magnetic needle, 247.
Electric harmonium, [illegible]
Electric telegraph, the, [illegible]9.
Electric telegraph, various uses of the, 263.
Electric time-balls, 270.
Electricity and magnetism, mutual relation of, 257.
Electricity as a motive power, 251.
Electricity, induction of, by magnetism, 257.
Electrified wire, polarity of an, 248.
Electro-chemical printing telegraphs, Bains', 267, 268.
Electro-magnetic and electric induction analogous, 253.
Electro-magnetic clocks, 253.
Electro-magnetic coil-machine, 254.
Electro-magnetic coil, the, 249.
Electro-magnetic engines, 251.
Electro-magnetic induction, 249.
Electro-magnetic induction, secondary, 253.
Electro-magnetic phenomena, illustrations of, 248.
Electro-magnetic rotation, 249.
Electro-magnetic theory of the earth's magnetism, 249.
Electro-magnetism, 247—274.
Electro-magnets, 249.
Electro-magnets, horse-shoe, 250.
Engines, electro-magnetic, 251.
Equator, the magnetic, 245.

Fires, detection of, by Siemen's electric thermometer, 274.
Fitzroy's storm signals, 269.
Fogs, influence of, on the needle, 246.
Frictional electricity and the induced current of a Rhumkorf's coil, analogies between, 257.
Froment's alphabetical telegraph, 269.
Froment's electro-magnetic engine, 252.

Gassiot's vacuum experiment with Rhumkorf's coil, 256.
Gravitation and dia-magnetism, 271.
Gutta-percha as an insulator for submarine cables, 263.

Heated air extends the length of a spark, 255.
Holmes' magneto-electric light machine, 258.
Horse-shoe electro-magnets, 250.
Horse-shoe magnets, 244.

India-rubber as an insulator for submarine cables, 263.
Induced currents analogous to those of frictional electricity, 257.
Induction, electro-magnetic, 249.
Induction, magneto-electric, 257.
Induction in submarine cables, 265.
Induction, secondary electro-magnetic, 253.
Insulation of land-telegraph wires, 262.
Insulation of submarine cables, 263.
Intense currents, peculiar action of, on submarine cables, 265.
Intensity of magnetic force, 244.
Iron, magnetism of, induced by an electric current, 249.
Iron, soft, cannot be permanently magnetic, 243.

Keepers of magnets, 244.

Laying a submarine cable, 265.
Length and resistance of wires, 250.
Leyden jar, charged, analogous to the state of a submarine cable, 265.
Leyden jar, to charge, by a Rhumkorf's coil, 257.

Light and magnetism, relations of a ray of polarised 271.
Lightning conductors for telegraph poles, 262.
Lightning, its action on the needles of the telegraph, 262.
Loadstone, the, 243.
Longitude and the telegraph, 270.
Luminous effects of induced currents from Rhumkorf's coil, 256.

MACHINES, various forms of magneto-electric, 213, 258.
Magnetic attraction, 244.
Magnetic attraction, theories of, 245.
Magnetic curves, 245.
Magnetic influence of the aurora borealis, 245.
Magnetic needle, divergence of by electricity, 247, 259.
Magnetic needle, variations of the, 245.
Magnetic needle, various uses of the, 243.
Magnetic polarity, 243, 244.
Magnetic poles of the earth, 245.
Magnetic properties of metals, 244.
Magnetic repulsion, 244.
Magnetism, 243—246.
Magnetism, accidental, 245.
Magnetism, action of, on a ray of polarised light, 271.
Magnetism and electricity, mutual relation of, 257.
Magnetism and light, relations of, 271.
Magnetism and soft iron, 243.
Magnetism and steel, 243.
Magnetism a radial force, 244.
Magnetism, familiar instances of its presence, 245.
Magnetism in its relations to iron, steel, &c., 243.
Magnetism, laws of the intensity of, 244.
Magnetism of iron induced by an electric current, 249.
Magnetism of a freely suspended electrified wire, 248.
Magnetism of the earth, 245.
Magnetism, residuary, 249.
Magnet, lines of polar force in a, 271.
Magneto-electric induction, 257.
Magneto-electric-light machine, Holmes', 258.
Magneto-electric machines, 213, 258.
Magneto-electric machine, chemical and other effects of the, 258.
Magneto-electric machine, plating, &c., by the, 213, 258.
Magneto-electric spark, 258.
Magneto-electric telegraph, the, 268.
Magnet, poles of a, 244.
Magnets, artificial, 243.
Magnets, bar, 244.
Magnets, compound, 244.
Magnets, electro, 249.
Magnets, horse-shoe, 244.
Magnets, how to make, 244.
Magnets, keepers of, 244.
Magnets, natural, 243.
Magnets, relay, 268.
Malta and Alexandria cable, 264.
Mariner's compass, the, 245.
Medical uses of the coil-machine, 255.
Mediterranean cable, 264.
Messages, telegraphic, mode of sending, 259, 261.
Meteorology, uses of the telegraph in connection with, 269.
Moisture, its effects on the currents of the telegraphic battery, 262.
Morse's telegraph, 268.
Motion and dis-magnetism, 271.
Motive power of electricity, 251.
Music printed, as composed, by electricity, 266.

NATURAL magnets, 243.
Needle affected by earth-currents, 262.
Needle affected by electric currents, 247.
Needle, dipping, the, 245.
Needle, diurnal variation of the, 245.
Needle, divergence of, by an electric current, 247, 259.
Needle, effects of fog, &c., on the, 246.
Needle, single and double telegraph, 261.
Needle, solar action on the, 245.
Needle telegraphic alphabet, 261.
Needle telegraph, simple form of a, 259.
Needles affected by atmospheric electricity, 262.
Nickel, magnetic properties of, 245.

OERSTED'S discovery of the principle of the electric telegraph, 259.
Oscillation of the magnetic needle, 244.

PERMANENT magnetism of steel, 243.
Photographic registration of magnetic observations, 246.
Physiological effects of induced currents, 254, 257.
Polar force, lines of, in a magnet, 271.
Polarised light in its relations to the magnetic force, 271.
Polarity, magnetic, 243.
Polarity of an electrified wire, 248.
Polarity of needles sometimes reversed by atmospheric electricity, 262.
Poles, magnetic, of the earth, 245.
Poles of a magnet, 244.
Primary and secondary coils, 253.
Printing-telegraphs, 266.
Private telegraph, Wheatstone's, 273.

QUANTITY of electric currents necessary for magnetisation, 250.

RED SEA cable, 264.
Registration, magnetic, by photography, 246.
Relay magnets, 268.
Repulsion and attraction exhibited by a Rhumkorf's coil, 256.
Repulsion, magnetic, 244.
Residuary magnetism, 249.
Resistance of copper wire to the passage of a current, 250.
Resistance thermometer, Siemen's electric, 274.
Rhumkorf's coil, 255.
Rhumkorf's coil, experiments with, 255, *et seq.*
Rottenness of copper wire, 264.

SECONDARY and primary coils, 253.
Secondary electro-magnetic induction, 253.
Secret telegraphy, Allan's method of carrying on, 271.
Ships'-compasses, adjustment of, 246.
Ships'-compasses, errors, &c., of, 246.
Shipwrecks arising from defective compasses, 246.
Shock from Rhumkorf's coil, dangerous nature of a, 255, 257.
Shocks from telegraph wires impossible, 262.
Shocks from the coil-machine, 254.
Shore-ends of cables, 264.
Siemen's electric-resistance thermometer, 274.
Signals, Fitzroy's storm, 270.
Signals, special telegraphic, 261.
Single-needle telegraphs, 261.
Spark, chemical effects, &c., of induced currents, 255.
Spark from Rhumkorf's coil, 255.
Spark from Rhumkorf's coil in a vacuum, 256.
Spark from Rhumkorf's coil in ether, &c., 256.
Speed in transmitting telegraphic messages, 261.
Steam-vessels, compasses of, 246.
Steel and magnetism, 243.
Steel, magnetisation of by an electric current, 249.
Steel, permanent magnetic quality of, 243.
Steel, permanent magnetisation of by electricity, 249.
Submarine cables (see, also, names of each station), 264.
Submarine cables, Allan's, 272.
Submarine cables, construction, &c., of, 263.
Submarine cables, effects of earth-currents on, 266.
Submarine cables, hindrances in working, 265.
Submarine cables, induced currents in, 265.
Submarine cables, resistance and induction in, 265.
Submarine telegraphy, 263.
Submarine telegraphy, difficulties in, 263.
Submersion of a submarine cable, 265.
Sun, action of, on the needle, 245.

TELEGRAPH, Allan's, 271.
Telegraph, alphabetical, 269.
Telegraph and longitude, 270.
Telegraph and meteorology, 269.
Telegraph, Bakewell's copying, 267.
Telegraph, balloon-electric, 274.
Telegraph, double needle, 261.
Telegraph, electric, 259.
Telegraph, Froment's alphabetical, 269.
Telegraph, magneto-electric, 268.
Telegraph, Morse's, 268.
Telegraph, printing, 266.
Telegraph, single needle, 261.
Telegraph, Tyer's train, 273.
Telegraph, Wheatstone's alphabetical, 269.
Telegraph, Wheatstone's private, 273.
Telegraphic alarm-bell, 261.
Telegraphic alphabet, needle, 261.
Telegraphic messages, mode of sending, 261.
Telegraphic messages, speed in transmission of, 261.
Telegraphic systems, American, 268.
Telegraphy, Allan's mode of carrying on secret, 271.
Telegraphy, early methods of, 259.
Telegraphy, submarine, 263.
Time-balls, electric, 270.
Train telegraph, Tyer's, 273.
Tyer's train telegraph, 273.

VACUUM, spark in a, from Rhumkorf's coil, 256.
Variation, diurnal, of the needle, 245.
Variation of the magnetic needle, 245.
Varna and Balaclava cable, 264.
Varna and Constantinople cable, 264.
Vessels, iron, influence of, on the magnetic needle, 246.
Voltaic batteries—(See p. 1223).

WEATHER reports, telegraphic, 269.
Wheatstone's alphabetical telegraphs, 269.
Wheatstone's private, commercial, and general telegraph, 273.
Whitehouse's method of printing music by electricity, 266.
Wires, influence of the quality of, on the passage of electric currents, 250.
Wires, length, area, &c., of, in relation to electric currents, 250.
Wires of submarine cables, 264.
Wires, resistance to the passage of an electric current, 250.
Wires, telegraphic, mode of suspending and insulating, 261.

SECTION V.—ACOUSTICS.

ACOUSTIC effects in buildings, 295.
Acoustic figures, 297.
Acoustics, 275.
Acoustics, practical, 295.
Æolian harp, the, 276.
Air, density of, as affecting vibrations, 276.
Analogy between sound, light, and heat, 275.
Animal sounds, 279.
Animals, voice of, 289, *et seq.*—(See name of each animal).
Apes, voice of, 290.
Ass, bray of the, 290.
Automatic sounds, 288.

BIRDS, larynx of, 292.
Birds of prey, voice of, 293.
Birds, voice of, 291—(See name of each bird).
Buildings, acoustic properties of, 295.

CANAL, oral, the, 287.
Cat, voice of, 290.
Chimpanzee, voice of, 290.
Churches, acoustic construction of, 295.
Cockatoo, voice of, 294.
Concert-rooms, construction of, 296.
Concert, the Telephonic, 277.
Conduction of sound, 276.
Conduction of sound by air, 276.
Conduction of sound by gases, 276.
Conduction of sound by solids, 276.
Conduction of sound, speed of, 276.
Consonants, pronunciation of, 288.
Cords, vocal, 286.
Cornopean, the, 279.
Cricket, chirp of, 294.
Crocodile, voice of, 294.
Cuckoo, voice of, 294.
Curved reflection of sound, 277.
Curved walls in buildings, 297.

DEAF and dumb, education of the, 289.
Deaf-mutes, 289.
Diffusion of sound, 276, 279.
Dove, voice of, 294.
Drum of the ear, the, 297.
Dull sounds, 279.
Dumbness, 289.
Dumb, teaching the, to speak, 289.

EAR, description of the, 297.
Ear, the human, 297.
Echoes, 277.
Echoes in buildings, 297.
Elastic bodies, vibrations of, 275.
Elephant, voice of, 290.
Eustachian tube, the, 282, 297.

FIGURES, acoustic, 297.
Fishes, sounds of, 294.
Flute, the, 279.
Fly, humming of, 295.
Frog, croak of, 294.

GIBBONS, voice of, 290.
Glasses, musical, 275, 276.
Glottis, the, 282.
Gong, sound of a, 276.
Grasshopper, chirp of, 294.

HALLS, acoustic construction of, 295.
Hearing-trumpet, the, 277.
Hog, grunt of the, 290.
Horse, neigh of the, 290.

INSECTS, humming of, 295.
Insects, sound of, 294—(See name of each).
Instruments, musical, 279.
Interference of sound, 296.
Invisible lady, the, 278.

JACKDAW, voice of, 293.
Jay, voice of, 294.

KANGAROO, voice of, 290.

LARYNX, experiments on the, 281.
Larynx, the, 280.
Length of musical strings, ratio of, 279.
Ligaments, vocal, 280.
Light, speed of, 276.
Lion, roar of, 290.
Literal sounds, 288.

MAGPIE, voice of, 294.
Mammals, their organs of voice, 289 *et seq.*
Monkeys, voice of, 290.
Musical boxes, 276.
Musical glasses, 275, 276.
Musical instruments, manufacture of, 279.
Musical sounds, the cause of, 275, 278.

NASAL sounds, 288.
Note, intensity, &c., of a, 286.
Note of a room, 296.
Notes, musical, 278.
Nuthatch, voice of, 294.

OCTAVE, the musical, 278.
Optic nerve, the, 297.
Oral canal, the, 287.
Organs, vocal, of birds, 292.
Organs, vocal, of mammals, 289.
Organs, vocal, of man, 280.

PARROT, voice of, 294.
Percussion produces sound, 275.
Pianoforte-strings, 278.
Pigeon, voice of, 294.
Physiology, comparative, of voice, 289.
Practical acoustics, 295.
Production of sound, 275.
Pronunciation of consonants, 288.
Pronunciation of vowels, 287.
Public speaking, 295.

QUADRUMANA, voice of, 290.

RAVEN, voice of, 293.
Ray of sound, 277.
Reed instruments, 283.
Reflection of sound, the curved, 277.
Reflectors of sound, 277.
Reptiles, voice of, 294—(See also names of each).
Rocks, conducting power of, 277.
Roofs reflecting sounds, 296.
Rooks, voice of, 293.
Room, each has its peculiar note, 296.

SENSORIUM of the brain, 297.
Serpents, hiss of, 294.
Shrill sounds, 279.
Singers, arrangement of, in an orchestra, 296.
Singing, 285.
Singing-birds, voice of, 292.
Song of the blackbird, 293.
Song of the bullfinch, 293.
Song of the canary, 293.
Song of the chaffinch, 293.
Song of the goldfinch, 293.
Song of the linnet, 293.
Song of the nightingale, 293.
Song of the skylark, 292.
Song of the thrush, 293.
Song of the woodlark, 293.
Sound a radial force, 295.
Sound, conduction of, 276.
Sound, diffusion of, 276, 279.
Sound in a vacuum, 277.
Sound, interference of, 296.
Sound, musical, production of, 278.
Sound, production of, 275.
Sound produced by the automaton, 288.
Sound produced by vibration, 275.
Sound, rate of travelling of, 276.
Sound, reflection of, 277.
Sounding-board of stringed instruments, 276, 279.
Sounding-board, use of, 297.
Sounds of telegraph wires, 276.
Speaking, rules for public, 296.
Speaking-trumpet, the, 277.
Speaking-tubes, 278.
Speech, human, 279, 287.
Speech, organs of, 280, 287.
Stammering, 288.
Stammering, cure of, 289.
Stethoscope, the, 276.
Strings, length of, producing notes, 279.

TELEGRAPH wires, sounds of, 276.
Telephonic concert, 277.
Theatres, acoustic construction of, 295.
Tiger, voice of, 290.
Tone, flexibility of, 279.
Treble clef, 279.
Tuning-fork, the, 275.
Turtle-dove, voice of, 294.
Tympanum, the, 297.

UNISON, effect of sounds in, 297.

VACUUM, sound in a, 277.
Ventriloquism, 288.
Vibration of bodies produces sound, 275.
Vibration of steel producing sound, 278.
Vibrations, number of per second, 279.
Vibrations of the atmosphere, 276.
Vibrations producing notes, number of, in strings, 279.
Vibrations, ratio of, 279.
Violin, the, 279.
Vocal cords, tension of, 286.
Vocal ligaments, 280.
Voice, alto, 285.
Voice, baritone, 285.
Voice, bass, 285.
Voice, causes of the human, 280.
Voice, comparative physiology of, 289.
Voice, comparison of male and female, 285.
Voice, compass of, 284, 285.
Voice, contralto, 285.
Voice, effects of climate on, 286.
Voice, falsetto, 286.
Voice, human, 279, *et seq.*
Voice, mezzo-soprano, 285.
Voice of birds, 291, *et seq.*—(See name of each bird: also "Song").
Voice of mammals, 289, *et seq.*
Voice of the horse, 290.
Voice of the mule, 290.
Voice, organs of, 279, *et seq.*
Voice, organs of, in birds, 291.
Voice, pitch of, 284, 286.
Voice, production of, 283.
Voice, soprano, 285.
Voice, tenor, 285.
Vowels, pronunciation of, 287.

WALLS reflecting sound, 296.
Water, conducting power of, 276.
Waves of sound, 277.
Whispering-gallery in St. Paul's Cathedral, 277.
Whistling, 286.
Wind instruments, sound of, 276.
Wind-pipe, the, 280.
Woodpecker, voice of, 294.
Wryneck, voice of, 294.

SECTION VI.—CHEMISTRY.

Acetal, 414.
Acetate of alumina, 414.
Acetate of copper, 376.
Acetate of ethyl, 414.
Acetate of iron, 378, 414.
Acetate of lead, 379, 414.
Acetate of potash, 387.
Acetate of soda, 414.
Acetic acid, 414.
Acetic acid, produced by spongy platina from alcohol, 372.
Acetic acid, the product of the slow combustion of alcohol, 372, 414.
Acetous acid, 414.
Acetyl, 414.
Acid, acetic, 414.
Acid, acetous, 414.
Acid, antimonic, 381.
Acid, antimonious, 381.
Acid, arsenic, 383.
Acid, arsenious, 381.
Acid, auric, 373.
Acid, benzoic, 415.
Acid, boracic, 371.
Acid, bromic, 319.
Acid, butyric, 333.
Acid, camphoric, 419.
Acid, capric, 333.
Acid, carbonic, 325.
Acid, caseic, 333.
Acid, chloric, 318.
Acid, chloro-chromic, 384.
Acid, chlorous, 318.
Acid, cholic, 334.
Acid, chromic, 384.
Acid, citric, 418.
Acid, ferric, 377.
Acid, formic, 415.
Acid, fulminic, 375.
Acid, gallic, 418.
Acid, hippuric, 336, 415, 423.
Acid, hydriodic, 318.
Acid, hydrobromic, 319.
Acid, hydrochloric, 317.
Acid, hydrocyanic, 327.
Acid, hydrofluoric, 319.
Acid, hydrosulphuric, 369.
Acid, hydrosulphuric, reaction of, with alkalies, earths, and metals, 401, 402.
Acid, hypochloric, 318.
Acid, hypochlorous, 318.
Acid, hyposulphurous, 369.
Acid, inosinic, 335.
Acid, iodic, 318.
Acid, kinic, 417.
Acid, lactic, 333.
Acid, malic, 417.
Acid, manganic, 384.
Acid, margaric, 333.
Acid, molybdic, 385.
Acid, mucic, 412.
Acid, nitric, 324.
Acid, nitro-hydrochloric, 318.
Acid, nitro-muriatic, 318.
Acid, nitrous, 324.
Acid, oleic, 333.
Acid, osinic, 335.
Acid, oxalic, 412.
Acid, paratartaric, 417.
Acid, pectic, 347, 349, 412.
Acid, perchloric, 318.
Acid, perchromic, 384.
Acid, phosphoric, 371.
Acid, phosphorous, 371.
Acid, prussic, 327.
Acid, pyrogallic, 418.
Acid, racemic, 417.
Acid, saccharic, 412.
Acid, selenic, 370.
Acid, silicic, 389.
Acid, stannic, 380.
Acid, sudoric, 333.
Acid, sulphuric, 368.
Acid, sulphurous, 368.
Acid, tannic, 418.
Acid, tartaric, 417.
Acid, telluric, 385.
Acid, titanic, 385.
Acid, tungstic, 385.
Acid, uric, 336, 423.
Acid, vanadic, 385.
Acidity of fruit, 348.
Acids, animal, 333.
Acids in vegetable food, 347, 417.
Acids, to detect the presence of, by litmus, &c., 317.
Acids, vegetable, 347, 417.
Aconitine, 417.
Adulteration of beer, 413.
Affinities, relative, 301.
Affinity, chemical, 300.
Affinity, instances of, 301.
Agricultural chemistry, 424.
Air, pure, essential to health, 426.
Air, sources of the impurities of, 427.
Air, the (see Atmosphere), 323.
Albumen, chemical characters of, 422.
Albumen in meat, 341.
Albuminous principles of food, 329.
Alchemy, 299.
Alcohol, 412.
Alcohol, absolute, 412.
Alcohol in French and German wines, 413.
Alcohol in intoxicating liquors, 412.
Alcohol, results of the combustion of, 408.
Alcoholic liquors as food, 352.
Aldehyde, a product of the decomposition of ether, 414.
Ale, brewing of, 413.
Alimentary principles, 328, 339.
Alkalies, earths, metals, &c., tables of tests for, 401, 402.
Alkalies, reaction of the carbonates of, with alkalies, earths, and metals, 401, 402.
Alkalies, the, 385.
Alkaloids, mode of obtaining the, 417.
Alkaloids, nature, properties, sources, &c., of the, 416.
Alkaloids, the active principles of certain plants, 417.
Alkaloids, the, analogous to the alkalies, 417.
Alloys—(See name of each Metal).
Alloys, fusible, of bismuth, 380.
Almond oil, bitter, 415.
Alum, how produced, 389.
Alumina, 388.
Alumina, acetate of, 414.
Alumina, in emeralds, rubies, &c., 388.
Alumina, salts of, 389.
Alumina, sulphate of, 389.
Alumina, used as a mordant in dyeing, 389.
Aluminium, chloride of, 388.
Aluminium in solution, tests for, 394, 401.
Aluminium, low specific gravity of, 388.
Aluminium, nature, properties, source, &c., 388.
Aluminium, numerous uses to which it is applied, 388.
Aluminium, oxide of, 388.
Amalgamation of zinc for voltaic batteries, 375.
Amalgamation, process of, 374.
Amalgams (see also name of each Metal), 374.
Amidogen, 325.
Ammonia, 324.
Ammonia, hydrosulphate, reaction of, with alkalies, earths, and metals, 370, 401, 402.
Ammonia, oxalate of, 412.
Ammonia, reaction of, with alkalies, earths, and metals, 401, 402.
Ammonia, salts of, 325.
Ammonia, salts of, as manures, 325.
Ammonium, 324.
Amygdaline in almonds, &c., 348.
Amyl and its compound, 415.
Analysis, agricultural, how to conduct, 425.
Analysis, apparatus required for, 395.
Analysis, chemical, defined, 301.
Analysis, colours of precipitates to be carefully noted in, 396.
Analysis, crystallisation in, 396.
Analysis, distillation in, 396.
Analysis, effecting fusion in, 395.
Analysis, effecting precipitation in, 395.
Analysis, effecting solutions in, 395.
Analysis, evaporation in, 396.
Analysis, filtration in, 396.
Analysis, inorganic, 394.
Analysis, inorganic, qualitative, general plan of, with tables of tests, &c., 401, 402.
Analysis, objects of, 394.
Analysis of soils, 425.
Analysis, organic, apparatus required in pursuing, 408.
Analysis, organic, how pursued, 410.
Analysis, precautions required in, 394.
Analysis, qualitative, 394, 397.
Analysis, qualitative, general method of conducting, 397—402.
Analysis, quantitative, 394, 403.
Analysis, sublimation in, 396.
Analysis, uses of the blow-pipe in, 396.
Analysis, washing precipitates in, 396.
Aniline, 420, 422.
Aniline-colours (see also Chapter V., Section on *Economic Botany*, Vol. II.), 420.
Animal acids, 333.
Animal chemistry, 327, *et seq*., 422.
Animal oils and fats (see also Index, p. 1220), 423.
Animal proximate elements, 422.
Animal substances contain nitrogen, 325.
Animal sugar, 412.
Antimonic acid, 381.
Antimonious acid, 381.
Antimoniuretted hydrogen, 381.
Antimony, alloys of, 380.
Antimony, butter of, 381.
Antimony, chlorides of, 381.
Antimony, detection of, 381, 393, 402.
Antimony in solution, tests for, 393.
Antimony, nature, properties, source, &c., of, 380.
Antimony, oxide of, 381.
Antimony, property of expanding whilst it cools from fusion belonging to, 380.
Antimony, sulphide of, 380.
Antimony, to distinguish from arsenic when united with hydrogen, 381.
Antimony, used in printing-types, 380.
Antiseptic properties of charcoal, 327.
Apparatus, chemical, 303.
Apparatus required in analysis, 395, 408.
Aqua-regia, 318.
Aragonite, 390.
Argand spirit lamp, 306.
Arithmetic of inorganic analysis, 405.
Arithmetic of organic analysis, 410.
Arrowroot, sago, tapioca, potatoes, &c., chiefly consist of starch, 411.
Arsenic acid, 383.
Arsenic as a pigment, 381.
Arsenic as a poison for vermin, 381.
Arsenic as a sheep-wash, 381.
Arsenic, chloride of, 383.
Arsenic, detection of, after death by poisoning with, 382.

Arsenic, habit of eating, and fattening power of, 381.
Arsenic in candles, 381.
Arsenic in paper-hangings, ladies' dresses, artificial flowers, &c., danger of, 381.
Arsenic, liquid tests for, 382.
Arsenic, Marsh's test for, 382.
Arsenic, nature, properties, sources, &c., of, 381.
Arsenic, oxides of, 381.
Arsenic, precautions to be observed in seeking for, in cases of poisoning, 383.
Arsenic readily volatilised by heat, 381.
Arsenic, Reinsch's test for, 382.
Arsenic, simple means of detecting it, by its odour, &c., 381.
Arsenic, sulphides of, 383.
Arsenic, tests for, 381, 393, 402.
Arsenic, to distinguish from antimony, 381.
Arsenic used as a cosmetic, 381.
Arsenic, white, 381,
Arsenious acid, 381.
Arseniurets of metals, 381.
Arseniuretted hydrogen, 382.
Artificial manures, 426.
Asparagine, 346.
Asphaltum, 421.
Atmosphere, chemical constitution of the, 323.
Atmosphere, height of the, 323.
Atmosphere, pressure of the, 323.
Atmosphere, the, not a chemical compound, 323.
Atomic weights, 302; tables of, 312.
Atropine, 417.
Attraction, chemical, 300.
Attraction, chemical, affected by heat, 300.
Auric acid, 373.
Azote, the old name for nitrogen, 322.

BALANCE, the chemical, 404.
Balloons filled with hydrogen, 320.
Barilla, 387.
Barium, chloride of, 391.
Barium, nature, properties, source, &c., of, 391.
Barium, oxides of, 391.
Baryta, 391.
Baryta in solution, tests for, 391, 394, 401.
Baryta salts, 391.
Beans as food, 346.
Bed-rooms, &c., cause of the "close smell" of, 427.
Beef as food, 341.
Beer, adulterations of, 413.
Beer as food, 352.
Beer, brewing of, 413.
Beet-root sugar, 412.
Bell-metal, 376, 380.
Bell-metal, antimony used in, 380.
Bengal lights, how made, 381.
Benzoic acid, 415.
Benzoyl and its compounds, 415.
Bessemer's process of refining iron, 377.
Bicarbonate of lime, 390.
Bichromate of potash, 384.
Bile, the human, 334.
Binoxalate of potash, 412.
Bismuth, alloys of, 380.
Bismuth, fusible alloys of, 380.
Bismuth in solution, tests for, 393, 402.
Bismuth, nature, properties, sources, &c., 380.
Bismuth, oxides of, 380.
Bismuth salts, 380.
Bisulphide of carbon, 327.
Bitartrate of potash, 386, 417.
Bitumen, 421.
Black dyes, tannic and gallic acids produce, with oxide of iron, 418.
Black-lead constituted of carbon, 325.
Bladders, to prepare, for holding gas, 305.
Bleaching by chloride of lime, 390.
Bleaching by sulphurous acid, 368.
Bleaching-powder, 390.
Bleaching powers of chlorine, 316.
Blende, zinc, 379.
Blood, aëration of the, 335.
Blood, analysis of, 331.
Blood, chemical characters of, 331, 423.
Blood, circulation of the, 335.
Blood, colouring matter of the, 331.
Blood, fibrine in, 331.
Blood, formation and functions of the, 327.
Blood-globules, 331, 423.
Blood, illustrations of the corpuscles of, 423.
Blood manures, 423.
Blood, proportion of water in the, 331.
Blood, serum of, 331.
Bloom of fruit, cause of the, 348.
Blow-pipe, the, 305, 396.
Blow-pipe, the oxy-hydrogen, 320.
Blow-pipe, uses of, in analysis, 396.
Blue colours, vegetable, turned red by acids, 317.
Bone-boiling, &c., and sanitary regulations, 429.
Bones, chemical characters of, 423.
Bones, constitution of, 332, 423.
Bones contain phosphate of lime, 390, 423.
Bones, lime-salts in, 332, 423.
Boracic acid, 371.
Borate of soda (borax), 387.
Borax, 387.
Boron, nature, properties, &c., 371.
Boron with chlorine, fluorine, &c., 371.
Bouquet of wines, 353, 414.
Brass, 379.
Bread as food, 344.
Breathing, a process of slow combustion, 315.
Brewing, process of, 413.
Britannia metal, 380.
Bromic acid, 319.
Bromides (see also names of Metals, &c.), 319.
Bromide of ethyl, 414.
Bromide of potassium, 387.
Bromide of silver, 374.
Bromine, nature, properties, and preparation of, 319.
Bronze, 376, 380.
Brucine, 417.
Building-stone obtained from magnesian limestone, 390.
Butter, 333, 423.
Butter as food, 355.
Butter-milk, 350.
Butyric acid, 333.

CADMIUM, and its compounds, 384.
Cadmium in solution, tests for, 393, 402.
Cæsium, 385, 387.
Caffeine, 417.
Cakes as food, 344.
Calamine, 379.
Calcium, chloride of, 390.
Calcium, chloride of, fused, used in organic analysis, 410.
Calcium, fluoride of, 390, 423.
Calcium, nature, properties, source, &c., of, 389.
Calcium, oxide of, 389.
Calcium, phosphide of, 371.
Calomel, 375.
Camphor, 419.
Camphoric acid, 419.
Cane-sugar, 356, 412.
Caoutchouc, 419.
Capric acid, 333.
Carbolic acid, 420.
Carbolic acid as a disinfectant, 427.
Carbon, 325.
Carbon a constituent of animal and vegetable substances, 327.
Carbon a constituent of coal-gas, 325.
Carbon an essential constituent of vegetable substances, 325, 408.
Carbon and iron, 327.
Carbon and nitrogen, 327.
Carbon, bisulphide of, 370.
Carbon contained in food, 325.
Carbon estimated as carbonic acid in organic analysis, 410.
Carbon, evidences of, in vegetable bodies, 408.
Carbon in gun-cotton and gunpowder, 327.
Carbon in sugar, 326.
Carbon, sulphide of, 327.
Carbonate of baryta, 391.
Carbonate of copper, 376.
Carbonate of ethyl, 414.
Carbonate of iron, 378.
Carbonate of lead, 378.
Carbonate of lime, 390.
Carbonate of magnesia, 390.
Carbonate of manganese, 384.
Carbonates of potash, 386.
Carbonate of silver, 374.
Carbonates of soda, 387.
Carbonate of strontia, 391.
Carbonates of the alkalies, reaction of, as tests, 401, 402.
Carbonic acid, analysis of, 327.
Carbonic acid evolved from the organs of respiration, 336.
Carbonic acid gas, deleterious effects of, in rooms, &c., 427.
Carbonic acid gas in the atmosphere, 323, 325, 427.
Carbonic acid in soda-water, wines, beer, &c., 326.
Carbonic acid in wells, vats, &c., 326.
Carbonic acid liquefied and solidified, 326.
Carbonic acid, preparation, &c., of, 325.
Carbonic acid produced by the combustion of charcoal, coke, coals, candles, &c., also by respiration, 326.
Carbonic acid, tests for, 326.
Carbonic acid the food of plants, 326.
Carbonic acid, weight, poisonous qualities, &c., of, 326, 427.
Carbonic oxide, 325.
Carburetted hydrogen gases, 420.
Carrots, turnips, &c., as food, 347.
Cartilages of the animal body, 332.
Caseic acid, 333.
Caseine, 333.
Caseine, chemical characters of, 423.
Caseine in milk, 350.
Cassius, purple powder of, 373.
Cast-iron, 377.
Celestine, 391.
Cells of starch, 411.
Cellulose, 346.
Cementation of steel, process of, 423.
Cemeteries, influence of, on the purity of water supplied to towns, 322.
Cereals as food, 344.
Cereals, composition of, 424.
Chalk, 390.
Chalk as a manure, 426.
Chalk in water, 321.
Chalk soils, 424.
Charcoal, antiseptic properties of, 327, 427.
Charcoal as a disinfectant, 327, 427.
Charcoal, Dr. Forbes Watson's, experiments on, as a disinfectant, 327, 427.
Charcoal is impure carbon, 325.
Cheese as food, 355.
Cheese, digestibility of, 355.
Chemical action, effects of electricity on, 301.
Chemical action, effects of heat on, 300.
Chemical action, effects of light on, 301.
Chemical action, intensity of, 302.
Chemical action prevented by low temperatures, 301.
Chemical action promoted by minute division, 301.
Chemical affinity, 300.

Chemical analysis defined (see Analysis), 301.
Chemical apparatus, 303.
Chemical attraction or affinity, 300.
Chemical composition, 301.
Chemical compounds, 301.
Chemical decomposition, 301.
Chemical equivalents, 302; table of, 312.
Chemical equivalents, hydrogen the standard of, 303.
Chemical equivalents, how obtained, 303.
Chemical manipulation, 303.
Chemical manufactures, their sanitary relations, 429.
Chemical nomenclature, 308.
Chemical synthesis defined, 301.
Chemistry, 299—430.
Chemistry, agricultural, 424.
Chemistry, animal, 422.
Chemistry easily and cheaply studied, 299.
Chemistry, objects of, 299.
Chemistry of vegetable substances, 407.
Chemistry, organic, 407.
Chemistry, sanitary, 426.
Chicory as food, 351.
Chloral, 414.
Chlorate of potass, 313, 318, 386.
Chloric acid, 318.
Chlorides (see also name of Metals, &c.), 316.
Chloride of aluminium, 388.
Chlorides of antimony, 381.
Chloride of arsenic, 383.
Chloride of barium, 391.
Chloride of calcium, 390.
Chlorides of chromium, 384.
Chloride of cobalt, 384.
Chlorides of copper, 376.
Chlorides of gold, 373.
Chlorides of iron, 377.
Chloride of lead, 379.
Chloride of lime, 316, 390.
Chloride of lime as a disinfectant, 427.
Chloride of magnesium, 390.
Chlorides of mercury, 375.
Chloride of nitrogen, 325.
Chlorides of platina, 372.
Chloride of potassium, 386.
Chloride of silicon, 389.
Chloride of silver, 373, 374.
Chloride of sodium (common salt), 387.
Chloride of strontium, 391.
Chlorides of tin, 380.
Chloride of zinc, 379.
Chlorine a constituent of common salt, 316.
Chlorine a constituent of hydrochloric acid, 316.
Chlorine and the metals, 318.
Chlorine a supporter of combustion, 316.
Chlorine, bleaching powers of, 316.
Chlorine, discovery of, 315.
Chlorine, nature and properties of, 316.
Chlorine, preparation of, 316.
Chloro-chromic acid, 384.
Chloroform, 414.
Chlorous acid, 318.
Chocolate as food, 351.
Cholic acid, 334.
Chondrine, chemical characters of, 423.
Chromate of lead, 379.
Chrome-alum, 384.
Chrome-yellow, 384.
Chromic acid, 384.
Chromium, chlorides of, 384.
Chromium in solution, tests for, 393, 401.
Chromium, nature, properties, sources, &c., of, 384.
Chromate of iron, 384.
Chromate of lead, 384.
Chromate of potash, 384.
Chromium, oxides of, 384.
Chromium, oxides of, used to colour glass, 384.
Chromium, salts of, 384.
Chyle, a result of the digestive process, 330.
Cinchonine, 417.
Cinnabar, 375.
Citrates, 418.
Citric acid, 418.
Clark's process for rendering hard water soft, 321.
Clay, 388.
Clay, burning of, to improve soils, 425.
Clay lands, 424.
Cleanliness, personal, house, &c., 428.
Climate, action of, on soils, 425.
Climate and diet, 358.
Clothing, in respect to health, 428.
Coal and its products (see also Chapter V., Section on *Economic Botany*, Vol. II.), 420.
Coal-gases, 420.
Coal-naphtha, 420.
Cobalt, chloride of, 384.
Cobalt in solution, tests for, 393.
Cobalt, nature, properties, sources, &c., of, 384.
Cobalt, oxides of, 384.
Cobalt salts, 384.
Cobalt used to colour glass, 384.
Cocine, 418.
Codeine, 417.
Cod-liver oil and iodine, 318.
Coffee as food, 351.
Colonial wines, 413.
Colours, vegetable (see also Chapter IV., Section on *Economic Botany*, Vol. II.), 421.
Combining proportions, 302.
Combustion, breathing a process of slow, 315.
Combustion, chlorine a supporter of, 316.
Combustion dependent on oxygen, 315.
Combustion produces carbonic acid, 326.
Combustion-tube used in organic analysis, 409.
Common salt a chloride of sodium, 387.
Composition, chemical, 301.
Compounds, chemical, 301.
Compounds, symbols of, 309.
Condiments to food, 354.
Conine, 417.
Cooking, effects of, on food, 342.
Copper, alloys of, 376.
Copper and ammonia, 376.
Copper and arsenic, 376.
Copperas (sulphate of iron), 377.
Copper, black oxide of, used in organic analysis, 409.
Copper, chlorides of, 376.
Copper, cyanide of, 376.
Copper, detection of, 376.
Copper in pickles, &c., 376.
Copper in solution, tests for, 393, 402.
Copper, nature, properties, sources, &c., 376.
Copper, oxide of, used to colour glass, 376.
Copper, oxides of, 376.
Copper, poisoning by, 376.
Copper-pyrites, 376.
Copper-salts, 376.
Copper, sulphides of, 376.
Copper, tinned vessels of, 376, 380.
Corrosive sublimate, 375.
Corundum contains alumina, 388.
Cosmetic, bismuth pearl-powder as a, 380.
Cream of tartar, 387.
Creosote, 420.
Crops, influence of climate, soils, &c., on the production of, 425.
Crops, rotation of, 425.
Crust of port wine, nature of the, 412.
Cryolite a source of aluminium, 388.
Crystallisation in analysis, 396.
Crystals, how to procure, 396.
Cupellation, 407.
Curdled milk, 350.
Cyanides (see names of Metals), 327.
Cyanide of copper, 376.
Cyanide of ethyl, 414.
Cyanide of gold, 373.
Cyanide of iron, 378.
Cyanide of lead, 379.
Cyanide of mercury, 375.
Cyanide of silver, 374
Cyanogen, 327.
Cyanogen and iron, 378.

DALTON'S discovery of atomic weights, 302.
Dalton's discovery of atomic weights, value of, in organic chemistry, 408.
Davy's, Sir Humphry, discovery of the metallic bases of alkalies and earths, 385.
Decomposition, chemical, 301.
Decomposition, diagrams, illustrating chemical, 309.
Deliquescent crystals, 396.
Derbyshire spar, the source of fluorine, 319.
Deville's, St. Clair, process for obtaining aluminium, 388.
Dextrin, 411.
Diabetic sugar, 412.
Diagrams of decomposition, &c., 309.
Diamond composed of carbon, 325.
Diastase, 412.
Diet and climate, 358.
Diet and the seasons, 366.
Diet for adults, &c., 362.
Diet for childhood, 360.
Diet in its mental and moral aspects, 367.
Diet in respect to health and disease, 367.
Diet, rules for, &c., 358, *et seq.*
Diffusion of gases, 323.
Digestibility of food, tests of the, 340.
Digestion, process of, in animals, 330.
Digestive principles, 339.
Dimorphism, 311.
Disinfectant, chloride of zinc as a, 379.
Disinfectants, 427.
Distillation in analysis, 396.
Distillation of spirituous liquors, 413.
Dobereiner's lamp, 372.
Dolomite, 390.
Drainage, defective, dangers of, 427.
Drainage of land, 425.
Drains, smell of, injurious to health, 427.
Drying-oil, how made, 379.
Drying-tube used in organic analysis, 409.
Dung of cattle as a manure, 426.
Dyeing, 421.
Dye-stuffs (see also Chapter IV., Section on *Economic Botany*, Vol. II.), 421.

EARTHS, 387.
Earths in the animal body, 329.
Earths, &c., tables of tests for, 401, 402.
Efflorescent crystals, 396.
Eggs as food, 341.
Egg-shells contain lime, 390.
Electricity and chemical action, 301.
Electro-gilding and plating (see also Index to "Electro-Metallurgy"), 373, 374.
Elementary bodies and their equivalents, 302; tables of, 312.
Elements, how characterised, 311.
Elements, symbols of the, 308.
Elements, table of the equivalents, symbols, and specific gravity of the, 312.
Emerald, rubies, &c., contain alumina, 388.
Epsom salts, 322, 390.
Equivalents, chemical, 302.
Equivalents, chemical, how obtained, 303.
Equivalents, chemical, oxygen and hydrogen the standard of, 303.
Equivalents of the elements, table of the, 312.
Essential oils, 419.
Etching by hydrofluoric acid, 319.
Ether, 414.
Ether, butyric, 414.
Ether, cholic, 414.
Ether, margaric, 414.

Ether, nitric, 414.
Ether, œnanthic, 414.
Ether, stearic, 414.
Ether, sulphuric, 414.
Ether used in place of chloroform and "laughing gas," 414.
Ether, valerianic, 414.
Ethyl, 414.
Ethyl, compounds of, 414.
Ethyl, oxide of (ether), 414.
Ethyl theory, the, 414.
Euchlorine, 318.
Eupione, 420.
Evaporating dishes, 305.
Evaporation, uses of, in analysis, 300, 396.
Excreting glands, functions of the, 335.
Excretion and food, 337.
Excretions, external, of animals, 336.

Fæces, human, as a manure, 426.
Fallowing of land, objects and advantages of, 425.
Fat in animals, 329.
Fats and oils, animal (see also Index, p. 1220), 423.
Fats as food, 355.
Fatty substances of the body, 333.
Felspar, 388.
Fermentation, acetous, 414.
Fermentation of sugar, 412.
Fermented liquors as food, 353.
Ferric acid, 377.
Ferricyanide of potassium, 378.
Ferrocyanide of potassium, 378.
Ferrocyanogen and iron, 378.
Fibrine, chemical characters of, 423.
Fibrine of the blood, 331.
Filter, simple, for water, 321.
Filters, 305.
Filtration required in analysis, 395.
Fires, open, advantages of, 428.
Fish as food, 344.
Fish as manure, 426.
Flannel as clothing, value of, 428.
Flesh, 423.
Flesh-meat as food, qualities of, 342.
Florence flasks, use of, in chemistry, 304.
Fluoride of calcium, 390.
Fluorine, nature, properties, and preparation of, 319.
Fluor-spar, the source of fluorine, 319, 390.
Food, abstinence from, effects of, 337.
Food, alimentary principles of, 339.
Food, cooking of, 342.
Food, digestibility of, 340.
Food, meat and eggs as, 341.
Food, nutritiveness of, 340.
Food, requirement of, 337.
Food, solid, 341.
Food, various kinds of animal, cereal, vegetable, &c., 341, *et seq.*
Formates, 415.
Formic acid, 415.
French wines, 413.
Fruit as food, 348.
Fulminates, 325.
Fulminating gold, 373.
Fulminating mercury, 375.
Fulminating silver, 374.
Fulminic acid, 375.
Funnels, 305.
Furnace, &c., cause of the rapid combustion of fuel in a, 315.
Furnace, chemical, 306.
Furnace, Faraday's chemical, 306.
Furnace, gas, 306.
Furnace, Griffin's, 306.
Furnace used in organic analysis, 409.
Fusel oil, 415.
Fusible alloys of bismuth, 380.
Fusion favourable to chemical action, 300.
Fusion required in analysis, 395.

Gadolonite, 391.
Galena, 378.
Gallates, 418.
Gallic acid, 418.
Gall-nuts, oak-bark, &c., contain gallic and tannic acids, 418.
Galvanising iron, 377, 379.
Garnets composed of alumina, &c., 388.
Gas-bottles, 305.
Gas, coal, 420.
Gases—(See name of each).
Gases, apparatus for purifying, 305.
Gases, diffusion of, 323.
Gases, specific gravity of, 311.
Gas-furnace, 306.
Gas-holders, 304.
Gas-jars, 304.
Gastric juice, human, 331.
Gelatine, 332, 423.
Gelatine, chemical characters of, 423.
Gelatine in meat, 341.
Gems, artificial, 389.
German silver, 380.
German wines, 413.
Gilding, 373.
Gilding of steel articles, 373.
Gin, 413.
Glacial acetic acid, 414.
Glass, 389.
Glass etched by hydrofluoric acid, 319.
Glass, manganese used in colouring, 384.
Glass tinged ruby-red by oxide of copper, 376.
Glucina, 391.
Glue, 332, 424.
Gluten of wheat, 411.
Goats'-milk sugar, 412.
Gold, alloys of, 373.
Gold, amalgam of, 373.
Gold, chlorides of, 373.
Gold coin, composition of, 373.
Gold, cupellation of, 373, 407.
Gold, cyanide of, 373.
Gold, ductility of, 373.
Gold, fulminate of, 373.
Gold in solution, tests for, 393, 402.
Gold-leaf, thinness of, 373.
Gold, mosaic, 380.
Gold, nature, properties, &c., 372.
Gold, oxides of, 373.
Gold, sources of, 372.
Gold, tests for, 373, 393, 402.
Goulard-water, 380.
Granite, 388.
Grape-sugar, 356, 412.
Grape, the, contains a fermenting principle, 413.
Gravel, 388.
Griffin's furnace, 306.
Guano as a manure, 426.
Guano contains nitrogen, 325, 426.
Guano contains phosphate of lime, 371, 390, 426.
Gums, Arabic, &c., 411.
Gun-cotton, preparation of, 321.
Gun-metal, 376, 380.
Gunpowder, manufacture of, 321, 386.
Gutta-percha, 419.
Gypsum, 390.

Hæmatosine, 423.
Hair-dyes, silver-salts used as, 374.
Heat aids the solution of bodies, 300.
Heat, effects of, on chemical attraction, 300.
Heat, effects of, on fulminating compounds, 300.
Hippuric acid, 336, 415, 423.
Hops, use of, in beer, 413.
Horn, hair, nails, &c., 332, 423.
Horse-flesh as food, 344.
Hunger, effects of, 338.
Hydriodate of potass, 318.
Hydriodates, 318.
Hydriodic acid, 318.
Hydrobromic acid, 319.
Hydrochloric acid, 316, 317.
Hydrocyanic acid, 327.
Hydrofluoric acid, 319.
Hydrofluoric acid, action of, on silica, glass, &c., 389.
Hydrofluoric acid, etching by, 319.
Hydrogen, carbon, and oxygen, the essential constituents of vegetable substances, 408.
Hydrogen estimated as water in organic analysis, 410.
Hydrogen, nature, properties, and preparation of, 319.
Hydrogen, peroxide of, 322.
Hydrogen the lightest body in nature, 319.
Hydrogen the standard of chemical equivalents, 303.
Hydrogen used to fill balloons, 320.
Hydrometer, the, 310.
Hydrosulphate of ammonia, reaction of, with alkalies, earths, metals, &c., 401, 402.
Hydrosulphuric acid, 369.
Hydrosulphuric acid, reaction of, with earths, alkalies, and metals, 401, 402.
Hyoscyamine, 417.
Hypochloric acid, 318.
Hypochlorous acid, 318.
Hyposulphite of sodium, 387.
Hyposulphites, 369.
Hyposulphurous acid, 369.

Iceland-spar, 390.
India-rubber, 419.
Indigo, 422.
Indium, 430.
Ink, how produced, 418.
Inorganic analysis, qualitative and quantitative, 394, *et seq.*
Inorganic elements of the bodies of animals, 328.
Inorganic qualitative analysis, general plan of, with tests, &c., 401, 402.
Inosinic acid, 335.
Intensity of chemical action, 302.
Intoxication, causes and effects of, 353.
Inulin, 411.
Iodates, 318.
Iodic acid, 318.
Iodide of lead, 379.
Iodides of mercury, 375.
Iodide of nitrogen, 325.
Iodide of potassium, 318, 386.
Iodide of silver, 318, 374.
Iodine detected by starch, 318.
Iodine, nature, properties, and source of, 318.
Iodine readily volatilises, 318.
Iodine, tests for, 318.
Iodine, uses of, 318.
Iridium and its compounds, 385.
Iron, acetate of, as a mordant, 414.
Iron and carbon, 377.
Iron and cyanogen-compounds, 378.
Iron and nickel in meteoric stones, 380.
Iron, chlorides of, 377.
Iron, chromate of, 384.
Iron, cyanide of, 378.
Iron, galvanising of, 377.
Iron in blood, 331.
Iron in solution, tests for, 393, 402.
Iron, magnetic properties of, 378.
Iron, nature, properties, sources, &c., of, 376.
Iron, numerous uses of, 377.
Iron, oxides of, 377.
Iron-pyrites, 376.
Iron-salts, 377, 378.
Iron, smelting, refining, &c., of, 377.
Iron, sulphides of, 377.
Isinglass, 424.
Isomerism, 311.
Isomorphism, 311.

Juices of the animal body, 327.

Kakodyl, 415.
Kaligenous metals, 385.
Kaolin, 388.
Kelp, 387.
Kermes mineral, 381.
Kettles, cause of fur in, 390.
Kinic acid, 417.
Kreatine, chemical characters of, &c., 335, 423.
Kreatine in meat, 341.

Lacteals, functions of the, in animals, 330.
Lactic acid, 333.
Lactic acid in milk, 350.
Land, drainage of, 425.
Laughing gas, 323.
Lead, acetate of, 379, 414.
Lead, chloride of, 379.
Lead, chromate of, 379, 384.
Lead, detection of, 378.
Lead in solution, tests for, 393, 402.
Lead, malate of, 417.
Lead, nature, properties, source, &c., of, 378.
Lead, oxides of, 379.
Lead, poisoning in water-cisterns, 378.
Lead-pyrites, 378.
Lead, red, 379.
Lead salts, 378, 379.
Lead, sugar of, 379, 414.
Lead, sulphide of, 378.
Lead, white, 379.
Leather, how produced, 418.
Legumin, a constituent of peas, &c., 346.
Leguminous food, 346.
Lemons, citric acid contained in, 418.
Lentils as food, 346.
Liebig's discoveries in organic chemistry, 407.
Light and chemical action, 301.
Lignin, 411.
Lignin convertible into grape sugar, 411.
Lignite, 420.
Lime, 389.
Lime a constituent of soils, vegetables, and animals, 390.
Lime as a manure, 426.
Lime, bicarbonate of, 390.
Lime, carbonate of, 390.
Lime, chloride of (bleaching-powder), 390.
Lime essential in soils, 425.
Lime, heat produced by, with water, 390.
Lime in bones, 390.
Lime in egg-shells, &c., 390.
Lime in solution, tests for, 389, 394.
Lime manures, 390, 426.
Lime, phosphate of, 390.
Lime, phosphate of, proportion of in bones, 423.
Lime, phosphide of, 390.
Lime salts, 390.
Lime, sulphate of, 390.
Lime, sulphate of, in water, 321.
Lime, superphosphate of, 390, 423, 426.
Lime, uses of, in bleaching, tanning, &c., 390.
Limestone as a manure, 426.
Limestone, magnesian, 390.
Liqueurs, 414.
Liquids, how to pour out from narrow apertures without spilling, 306.
Litharge, 379.
Lithia, 387.
Lithium, nature, compounds, sources, &c., of, 387.
Litmus paper used to detect acids, 317.
Liver, secretions of the, 334.
Loamy soils, 425.
Looking-glasses and mercury, 374.
Lucifer-matches, how made, 371, 386.

Mackintosh's shell for marine warfare, 386.
Magnesia and its salts, 390.
Magnesia in solution, tests for, 390, 394.
Magnesian limestone, 390.
Magnesium, 390.
Magnesium, chloride of, 390.
Magnesium, oxide of, 390.
Magnetic properties of iron, 378.
Malachite, 376.
Malate of potash, 387.
Malates, 417.
Malic acid, 417.
Malt, how produced, 412.
Manganate of potash, 384.
Manganese a test for ozone, 384.
Manganese, binoxide, a source of oxygen, and used to produce chlorine, 384.
Manganese in the lettuce, &c., 347.
Manganese in solution, tests for, 393, 401.
Manganese, nature, properties, sources, &c., of, 384.
Manganese, oxides of, 384.
Manganese, oxides of, used to colour glass, 384.
Manganese salts, 384.
Manganese used in dyeing, writing-inks, &c., 384.
Manganic acid, 384.
Manipulation, chemical, 303.
Mannite, 356, 412.
Manufactures, chemical, sanitary regulations respecting, 428.
Manufactures dangerous to health in certain cases, 429.
Manufactures, special, injurious to health, 429.
Manures, 425.
Manures and ammonia, 325, 426.
Manures, artificial, 426.
Manures containing phosphates, 371, 426.
Maple sugar, 412.
Marble, 390.
Margaric acid, 333.
Margarine, 418.
Marl soils, 424.
Marsh gas, 420.
Marsh's test for arsenic, 382.
Massicot, 379.
Meals, proper food for each, daily, 359.
Meat, alimentary principles of, 341.
Meat as food, 341, 343.
Mercurial salivation, 375.
Mercury, chlorides of, 375.
Mercury, cyanide of, 375.
Mercury, detection of, 375.
Mercury, freezing of, 374.
Mercury, fulminate of, 375.
Mercury in solution, tests for, 393, 402.
Mercury, iodides of, 318, 375.
Mercury, nature, properties, source, &c., of, 374.
Mercury, numerous uses of, 374.
Mercury, oxides of, 374.
Mercury, poisoning and paralysis caused by it, and its salts, 375.
Mercury salts, 375.
Mercury, sulphides of, 375.
Metal, definition of a, 371.
Metals, kaligenous or alkali-producing, 385.
Metals proper, 372.
Metals, properties of the, 371.
Metals, tables of tests for, 393, 394, 401, 402.
Metals, terrigeneous, or earth-producing, 387.
Metals, tests, specially for the (see name of Metals), 391.
Metals, their general characters, 371.
Metamorphosis of organic tissues, 334.
Meteoric stones contain nickel, 380.
Methyl and its compounds, 415.
Methylated spirits, 415.
Milk, acids in, 350.
Milk as food, constitution of, &c., 350.
Milk as diet for children, 361.
Milk, digestibility of, 350.
Milk, inorganic constituents of, 334.
Milk, sugar of, 333, 412.
Mineral waters, 321.
Minute division favourable to chemical action, 301.
Molasses, 412.
Molybdenum and its compounds, 385.
Molybdic acid, 385.
Morphine and its salts, 417.
Mortar, 389.
Mosaic gold, 380.
Moulds made of sulphur, 368.
Mucic acid, 412.
Mucus of the intestines, &c., 334.
Muntz's metal, 376.
Murray's fluid magnesia, 390.
Muscles, human, 423.
Musical sounds from burning hydrogen, 320.

Nails, hair, horns, &c., 423.
Naphtha, coal, 420.
Naphtha, wood, 415.
Narcotine, 417.
Nerves, the chemical characters of the, 423.
Nickel common in meteoric stones, 380.
Nickel in solution, tests for, 393, 401.
Nickel, nature, properties, sources, &c., of, 380.
Nickel, oxide of, 380.
Nickel salts, 380.
Nicotine, 417.
Nitrates (see also name of Metals), 324.
Nitrate of baryta, 391.
Nitrate of bismuth, 380.
Nitrate of cobalt, 384.
Nitrate of copper, 376.
Nitrate of ethyl, 414.
Nitrate of iron, 378.
Nitrate of lead, 379.
Nitrate of magnesia, 390.
Nitrate of mercury, 375.
Nitrate of potash, 386.
Nitrate of silver, 374.
Nitrate of soda, 387.
Nitrate of strontia, 391.
Nitre, 386.
Nitre contains nitrogen, 322.
Nitric acid, 324.
Nitrogen and animal tissues, 325.
Nitrogen and carbon, 327.
Nitrogen, binoxide of, 324.
Nitrogen, chloride of, 325.
Nitrogen does not support combustion, 322.
Nitrogen estimated as ammonia in organic analysis, 410.
Nitrogen, iodide of, 325.
Nitrogen, nature, properties, and preparation of, 322.
Nitrogen, protoxide of, 323.
Nitrogenous constituents of animals, 329.
Nitrous acid, 324.
Nomenclature, chemical, 308.
Norton's inflammable shell for warfare, 370.
Nuisances considered in a sanitary point of view, 429.
Nutritiveness of food, tests of the, 340.
Nux vomica, 417.

Oil of tartar, 386.
Oils, animal (see also Index, p. 1220), 423.
Oils, constitution of vegetable, 418.
Oils, essential, 419.
Oils, fixed (see also Index to "Artificial Illumination," p. 1220, *ante*), 418.
Oils, vegetable, 418.
Oils, vegetable, specific gravity of, 418.
Olefiant gas, 420.
Oleic acid, 333.
Oleine, 418.

Olive oil as food, 355.
Onion tribe, cause of the taste of the, 347.
Ores of metals—(See name of each).
Organic analysis, 408.
Organic analysis, use of oxide of copper in, 376, 409.
Organic chemistry, 407.
Organic impurities of water, 322, 429.
Organic substances of animals (see also Animal Chemistry), 329.
Orpiment, 383.
Osmic acid, 385.
Osmium and its compounds, 385.
Osmium salts, 385.
Ovum and the seminal fluid, human, 333.
Oxalate of ammonia, 412.
Oxalate of ethyl, 414.
Oxalate of nickel, 380.
Oxalate of potash, 387.
Oxalates of the metals, &c., 412.
Oxalic acid, 412.
Oxalic acid producible from sugar, 408.
Oxidation of bodies, 315.
Oxide (see also name of each Metal, &c.), 314.
Oxide of aluminium, 388.
Oxides of antimony, 381.
Oxides of arsenic, 381.
Oxides of barium, 391.
Oxides of bismuth, 380.
Oxide of calcium (lime), 389.
Oxides of chromium, 384.
Oxides of cobalt, 384.
Oxides of copper, 376.
Oxide of ethyl (ether), 414.
Oxides of gold, 373.
Oxides of iron, 377.
Oxides of lead, 379.
Oxide of lithium, 387.
Oxide of magnesium, 390.
Oxides of manganese, 384.
Oxides of mercury, 374.
Oxide of nickel, 380.
Oxides of platina, 372.
Oxides of potassium, 386.
Oxide of silicon, 389.
Oxides of silver, 374.
Oxide of sodium, 387.
Oxide of strontium, 391.
Oxides of tin, 380.
Oxide of zinc, 379.
Oxygen a constituent of acids, 314.
Oxygen an essential constituent of vegetable substances, 408.
Oxygen as a standard of chemical equivalents, 303.
Oxygen, a supporter of combustion, 314.
Oxygen estimated as water in organic analysis, 410.
Oxygen, experiments with, 313, 314.
Oxygen-gas retorts, 305.
Oxygen in the air and water, 313.
Oxygen, its action on metals, 314.
Oxygen, its functions in nature, 315.
Oxygen, preparation of, 313.
Oxygen, properties, &c., of, 313.
Oxygen, universality of its presence, 313.
Oxy-hydrogen blow-pipe, the, 320.
Ozone and animal life, 315.
Ozone and meteorology (see also Section on *Meteorology*), 315.
Ozone detected by salts of manganese, 384.
Ozone, nature and properties of, 315.
Ozone, tests for, and preparation, 315, 384.

PAINT (white lead), 379.
Palladium and its compounds, 385.
Palmitine, 418.
Pancreatic juice, the, 334.
Paraffine (see also Chapter V., Section on *Economic Botany*, Vol. II.), 421.
Paratartaric acid, 417.
Pearlash, potass or potash, 386.
Pearl-powder, 380.
Peas as food, 346.
Pectic acid, 347, 349, 412.
Pectine, 348, 411.
Pectose in fruit, 347, 348.
Perchlorate of potash, 386.
Perchloric acid, 318.
Perchromic acid, 384.
Perfumes, 414, 419.
Permanganate of potash, 384.
Peroxide of barium, 391.
Peroxides—(See Oxides and Metals).
Perspiration, constitution of the, 336.
Peruvian bark, 417.
Petroleum, 420.
Pewter, 380.
Phenyl, 420.
Phosphate of lime, 390, 423, 426.
Phosphate of lime in bones, urine, &c., 370, 423.
Phosphate of lime, proportion of, in bones, 423.
Phosphate of magnesia and ammonia, 390.
Phosphates, animal, 371.
Phosphide of lime, 371, 390.
Phosphides, 371.
Phosphorescence of the sea, &c., 370.
Phosphoric acid, 371.
Phosphorous acid, 371.
Phosphorus, allotropic condition of, 370.
Phosphorus essential as food for the brain, 346.
Phosphorus, its manufacture into lucifer-matches injurious to the workers, 430.
Phosphorus, nature, properties, &c., of, 370.
Phosphorus, solution of, in bisulphide of carbon, highly inflammable, &c., 370.
Phosphorus with chlorine, iodine, &c., 371.
Phosphuretted hydrogen, 371.
Photography, silver-salts used in (see also Index to "Photography," p. 1221), 374.
Pitch, 420.
Plants contain potash, 387.
Plants fed by carbonic acid, 326.
Plaster of Paris, 390.
Platina, catalytic action of spongy, 372.
Platina, chlorides of, 372.
Platina in solution, tests for, 393, 402.
Platina, nature, properties, source, &c., 372.
Platina, oxides of, 372.
Platina, salts of, 372.
Platina, spongy, 372.
Platina stills for sulphuric acid, 372.
Platina, welding property of, 372.
Ploughing, effects of, on land, 425.
Pneumatic trough, uses of the, 304.
Poisoning by arsenic, and detection of the metal, 382.
Poisons, animal and vegetable putrefactive, dangerous nature of, 429.
Porcelain, 388.
Pork as food, 344.
Porter, alcohol in, 412.
Porter, brewing of, 413.
Potash, bichromate of, 384.
Potash, binoxalate of, 412.
Potash, bitartrate of, 386, 417.
Potash, carbonates of, 386.
Potash, caustic, 386.
Potash, chlorate of, 313, 318, 386.
Potash, chromate of, 384.
Potash contained in plants, 387.
Potash, hydriodate of, 318.
Potash, manganate of, 384.
Potash, nitrate of, 386.
Potash, perchlorate of, 386.
Potash, permanganate of, 384.
Potash, potass, or pearlash, 386.
Potash, prussiate of, 378, 387, 423.
Potash, reaction of, 401, 402.
Potash-salts (see names of Acids), 386.
Potash, sulphates of, 386.
Potash-tube used in organic analysis, 409.
Potassiuretted hydrogen, 385.
Potassium, bromide of, 386.
Potassium, chloride of, 317, 386.
Potassium, ferricyanide of, 378.
Potassium, ferrocyanide of, 378.
Potassium, iodide of, 318, 386.
Potassium, nature, source, &c., of, 385.
Potassium, oxides of, 386.
Potassium, peroxide of, 386.
Potassium, sulphide of, 386.
Potatoes as food, 347.
Pottery, 388.
Poultry as food, 344.
Precipitates afforded by the elements, oxides, &c., with hydrosulphuric acid, hydrosulphate of ammonia, potass, ammonia, and the carbonates of the alkalies, 401, 402.
Precipitates, colour of, 396.
Precipitates, washing of, in quantitative analysis, 404.
Precipitation required in analysis, 395.
Proof spirit, 412.
Proportions, combining, 302.
Proteine, chemical characters of, 423.
Prussian blue, 378.
Prussiates of potass, 378, 387, 423.
Prussic acid, 327.
Pyrites, copper, 376.
Pyrites, iron, 376.
Pyrites, lead, 378.
Pyrites of iron, copper, and lead, 370.
Pyrogallic acid, 418.
Pyrophorus, 379.

QUALITATIVE analysis, 394, 397.
Qualitative analysis, general method of conducting, 397—402.
Qualitative analysis, inorganic, general plan of, with tables of tests, &c., 401, 402.
Quantitative analysis, estimation of results, 405.
Quantitative analysis, inorganic, 394, 403.
Quantitative analysis, organic, 408.
Quarts, 388.
Quicksilver (see Mercury), 375.
Quinine, 417.

RACEMIC acid, 417.
Realgar, 383.
Red lead, 379.
Reinsch's test for arsenic, 382.
Resins, 419.
Respiration produces carbonic acid, 326.
Retorts, 303.
Rhodium and its compounds, 385.
Rhubarb contains oxalic acid, 412.
Ring-stands, 304.
Rock-crystal, 389.
Rock-oil, 420.
Rock-salt, 387.
Roots and vegetables compared as to their nutritiveness, &c., 348.
Roots as food, 347.
Rotation of crops, 425.
Rubidium, 385.
Rutile the source of titanium, 385.

SACCHARIC acid, 412.
Sal-ammoniac, 325.
Salicine, 416.
Salicyl, 416.
Saliva, human, 334.
Salivation by mercury, 375.
Salt as a condiment, 354.
Salt, common, a chloride of sodium, 387.
Salt, common table, decomposition of, to afford chlorine and hydrochloric acid, 317.
Saltpetre, 386.

Salts in meat, 341.
Salts in the animal body, 328.
Salts in the blood, 331.
Salts of alkalies—(See Ammonia, Potash, and Soda).
Salts of earths—(See name of each Earth).
Salts of metals—(See name of each).
Salts of sorrel, 412.
Sandy soils, 425.
Sanitary chemistry, 426.
Sanitary regulations in respect to manufactures, 429.
Saurkrout, 346.
Scheele's green, a compound of copper and arsenic, 376, 383.
School-rooms, defective ventilation of, 427.
Sea-water contains silver, 322, 373.
Sea-water, distillation of, on board ships, 429.
Seaweed as a manure, 426.
Seaweed a source of soda, or kelp, 387.
Secretions, animal, constituents of the, 336.
Secretions of the liver, 334.
Seeds, germination of, in soils, 424.
Selenic acid, 370.
Selenium, 370.
Selenium, oxides of, 370.
Seleniuretted hydrogen, 370.
Serum of blood, 331.
Sewage as a manure, 426.
Sewers, deleterious exhalations from, 427.
Shells of eggs contain lime, 390.
Shells of mollusca contain carbonate of lime, 423.
Shells, sea, contain magnesia, 390.
Signal-lights, how made, 381.
Silex, 389.
Silica, 389.
Silica acted on by hydrofluoric acid, 389.
Silica, tests for, 389, 394.
Silicate of soda, 389.
Silicic acid, 389.
Silicon, 389.
Silicon, chloride of, 389.
Silicon, oxide of, 389.
Silver, alloys of, 373.
Silver, amalgam of, 373.
Silver, ammoniuretted oxide of, 374.
Silver, blackening of, by sulphur, 374.
Silver, bromide of, 374.
Silver, chloride of, 373, 374.
Silver coin, 373.
Silver contained in sea-water, 322, 373.
Silver, cupellation of, 373, 407.
Silver, cyanide of, 374.
Silver dissolved in nitric acid, 373.
Silver, ductility of, 373.
Silver, electro-plating by (see also Index to "Electro-Metallurgy," p. 1223), 373.
Silver, fulminate of, 374.
Silver, German, 380.
Silver, how to obtain pure from coin, 373.
Silver in solution, tests for, 393, 402.
Silver, iodide of, 318, 374.
Silver, iodide, sulphide, bromide, &c., of, 374.
Silver, malleability of, 373.
Silver, nitrate of, used to mark linen; as "lunar caustic" in medicine, &c. 374.
Silvering looking-glasses, 374.
Silver-leaf, wire, &c., 373.
Silver, nature, properties, sources, &c., 373.
Silver, oxides of, 374.
Silver-salts, 373.
Silver-salts used for dyeing hair, 374.
Silver-salts used in photography, &c., (see also Index to "Photography," p. 1222), 374.
Size, 424.
Skin, chemical constitution of the, 423.
Skin, excreting power of the, 336.
Skin, excretions of, their effect on personal health, 428.
Skin of animals, 423.
Skins, tanning of, 418, 423.
Smalts, 384.
Smelling-salts constituted of ammonia, 325.
Smoke Act, beneficial sanitary operation of the, 429.
Soap and candles (see also Index, p. 1220), 423.
Soaps, hard, yellow, mottled, &c., 387.
Soaps made with soda, 387.
Soaps, soft, 386.
Soda, 387.
Soda, acetate of, 414.
Soda, biborate of (borax), 387.
Soda, carbonates of, 387.
Soda, nitrate of, 387.
Soda-salts (see also names of the Acids), 387.
Soda, seaweed a source of, 387.
Soda, silicate of, 389.
Soda, sub-carbonate of (the common "washing soda"), 387.
Soda, sulphate of, 387.
Soda, tungstate of, used to render ladies' dresses uninflammable, 385.
Soda used in bleaching, &c., 387.
Sodium, chloride of (common salt), 387.
Sodium, hyposulphite of, 387.
Sodium, inflammability of, 387.
Sodium, nature, properties, source, &c., 387.
Sodium, oxide of (soda), 387.
Sodium, sulphite of, 387.
Soil, absorbing power of the, 425.
Soils, action of climate on, 425.
Soils, action of the atmosphere on, 425.
Soils, amount of water in, 425.
Soils, analysis of, 425.
Soils, chalk, clay, &c. (see also Agricultural Chemistry), 424.
Soils chemically and physically considered, 425.
Soils, clayey, 425.
Soils, clayey, improved by burning, 425.
Soils, composition of, 424.
Soils, drainage of, 425.
Soils, essential constituents of, 426.
Soils, loamy, 425.
Soils, marly, 424.
Soils, pulverisation of, 425.
Soils, qualitative analysis of, 425.
Soils, sandy, 425.
Solder, 380.
Solid food, 341.
Soluble glass used to preserve stone, &c., 389.
Solution aided by heat, 300.
Solution necessary in analysis, 395.
Sorrel contains oxalic acid, 412.
Sorrel, salts of, 412.
Soups as food, 359.
Spanish wines, 413.
Spar, Derbyshire, 319.
Spar, fluor, 319.
Spar, Iceland, 390.
Sparkling wines, 413.
Specific gravity explained, 309.
Specific gravity, low, of hydrogen, 319.
Specific gravity of bodies, how arrived at, 310.
Specific gravity of gases, 311.
Specific gravity of liquids, 310.
Specific gravity of solids, 310.
Specific gravity of the elements, table of the, 312.
Specific gravity of vegetable oils, 418.
Spectrum analysis, uses of, and discoveries made by, in chemical analysis (see also Section on *Light*, pp. 55, 166, *et seq.*), 385.
Specula of telescopes, antimony used in, 380.
Specula of telescopes, tin used in, 380.
Spelter, 379.
Spermaceti, 423.
Spermatine, 333.
Sperm oil, relative value of its light, 421.
Spices as condiments, 357.
Spirit-lamp, 302.
Spirit-lamp, Argand, 306.
Spirit, methylated, 415.
Spirits as stimulants, 353.
Spirits of wine (alcohol), 412.
Spirituous liquors, distillation of, 413.
Spongy platina, 372.
Spongy platina, catalytic action of, 372
Spongy platina converts alcohol into acetic acid, 414.
Sprats as a manure, 426.
Stalactites, 390.
Standard of chemical equivalents, 303.
Standards of specific gravity, 310.
Stannic acid, 380.
Starch, action of diastase on, 412.
Starch a constituent of all plants, 411.
Starch a test for iodine, 318.
Starch-cells, 411.
Starch, gum, and sugar, producing fat in animals, 329.
Starch, iodide of potassium a test for, 318.
Starch, nature, properties, sources, &c., of, 411.
Starch of wheat, 411.
Starch, test for the presence of, 411.
Starvation, death from, 338.
Stearic ether, 414.
Stearine (see Index, p. 1221), 418.
Steel, 377.
Steel articles to gild, 373.
Stimulants, use of, with food, and generally, 365.
Stout, brewing of, 413.
Strontia, 391.
Strontia, nitrate of, 391.
Strontia salts, 391.
Strontia, tests for, 391, 394, 401.
Strontium, chloride of, 391.
Strontium, nature, properties, source, &c., of, 391.
Strontium, oxide of, 391.
Strychnine, 416.
Strychnine, poisoning by, and detection of, 417.
Sublimate, corrosive, 375.
Sublimation in analysis, 396.
Sudoric acid, 333.
Sugar (see also the Section on *Economic Botany*, Vol. II.), 412.
Sugar; alcohol, ether, and acetic acid, producible from, 408.
Sugar as a condiment, 356.
Sugar, detection of carbon in, 326.
Sugar, diabetic, 412.
Sugar, fermentation of, 412.
Sugar from beet-root, 412.
Sugar in the liver of animals, 333.
Sugar, nutritive properties of, 356.
Sugar of lead, 379.
Sugar of milk, 333, 412.
Sugar of the cane, 412.
Sugar of the grape, 412.
Sugar of the grape naturally fermentative, 413.
Sugar of the maple, 412.
Sulphate of alumina, 389.
Sulphate of baryta, 391.
Sulphate of copper, 376.
Sulphate of ethyl, 414.
Sulphate of iron, 377.
Sulphate of lead, 379.
Sulphate of lime, 390.
Sulphate of lime in water, 321.
Sulphate of magnesia, 390.
Sulphate of manganese, 384.
Sulphate of mercury, 375.
Sulphate of nickel, 380.
Sulphates of potash, 386.
Sulphate of silver, 374.

Sulphate of soda, 387.
Sulphate of strontia, 391.
Sulphides of antimony, 380.
Sulphide of arsenic, 383.
Sulphide of bismuth, 380.
Sulphide of carbon, 327.
Sulphide of copper, 376.
Sulphide of ethyl, 414.
Sulphide of iron, 377.
Sulphide of lead, 378.
Sulphides of mercury, 375.
Sulphide of molybdenum, 385.
Sulphide of potassium, 386.
Sulphide of silver, 374.
Sulphide of sodium, 387.
Sulphides of tin, 380.
Sulphide of zinc, 380.
Sulphides, 368, 370.
Sulphites, 368.
Sulpho-cyanic acid, 327.
Sulpho-cyanogen and iron, 378.
Sulphur, bleaching powers of, 368.
Sulphur moulds, 368.
Sulphur, nature, properties, &c., 368.
Sulphurets—(See Sulphides).
Sulphuretted hydrogen, 369.
Sulphuretted hydrogen as a test for metals (see Hydrosulphuric Acid), 370, 393, 401, 402.
Sulphuric acid, 368.
Sulphuric ether, 414.
Sulphurous acid, 368.
"Super-phosphate," 390, 423.
Super-phosphate of lime, 390, 423.
Super-phosphate of lime as a manure, 390, 423, 426.
Supporters of combustion, 315, 316.
Symbols and terms, 308.
Symbols of compounds, 309.
Symbols of the elements, table of the, 312.
Sympathetic ink, 376, 384.
Synthesis, chemical, defined, 301.

TABLES of English and French weights, 430.
Tables of equivalents of the elements, with their specific gravities and symbols, 312.
Tables of precipitates of elements, oxides, &c., produced by hydrosulphuric acid, hydrosulphate of ammonia, potash, ammonia, and the carbonates of the alkalies, 401, 402.
Tables of special tests for metals, 393, 394.
Tables of tests for alkalies, earths, metals, &c., 401, 402.
Tannates, 418.
Tannic acid, 418.
Tanning, 418.
Tar (coal), 420.
Tar-colours (see also Section on *Economic Botany*, Chapter V., Vol. II.), 420.
Tar (wood), 420.
Tartar, cream of, 387, 417.
Tartar-emetic, 381, 417.
Tartar, oil of, 386.
Tartaric acid, 417.
Tartrate of lead, 379.
Tartrate of potass obtained from wines, 413.
Tartrates (see also Alkalies, Metals, &c.), 417.
Taste, influence of, in respect to food, 342.
Tea as food, 351.
Tears, chemical constitution of, 336.
Telluric acid, 385.
Tellurium and its compounds, 385.
Tellurium, oxides of, 385.
Temperature, low, prevents chemical action, 301.
Terchlorides, 318.
Terms and symbols, 308.
Terrigeneous or earth-producing metals, 387.
Test-glasses, 305.
Testing for metals, 391, 392.
Tests for alkalies, 401, 402.
Tests for earths, tables of, 401, 402.
Tests for metals, tables of, 393, 401.
Tests for ozone, 315, 384.
Tests of the digestibility of food, 340.
Test-tubes, 304.
Thallium, 430.
Theine, 417.
Theobromine, 417.
Thermo-electric poles composed of bismuth and antimony, 380.
Thirst, effects of, 339.
Thorina, 391.
Thorite, 391.
Tin, alloys of, 380.
Tin, chlorides of, 380.
Tin, hydrate of the oxide of, 380.
Tin in solution, tests for, 393, 402.
Tin, nature, properties, and sources of, 380.
Tinning copper vessels, 380.
Tin, oxides of, 380.
Tin sulphides of, 380.
Titanic acid, 385.
Titanium and its compounds, 385.
Titanium, oxides of, 385.
Tourmaline, the, contains lithium, 387.
Trough, the pneumatic, 304.
Tungstate of soda used to render ladies' dresses uninflammable, 385.
Tungsten and its compounds, 385.
Tungsten, binoxide of, 385.
Tungstic acid, 385.
Turmeric a test for alkalies, 325.
Turpentine, 419.
Type, antimony used in printer's, 380.

URANIUM, 385.
Uranium and epipolic dispersion of light, 385.
Uranium, oxide of, used to colour glass, 385.
Uranium, oxides of, 385.
Urea, 336, 423.
Urea artificially produced, 423.
Uric acid, 336, 423.
Urine, 336, 423.
Urine, secretion of, stimulated by vegetable food, 347.

VALERIANIC ether, and acid, 414.
Vanadic acid, 385.
Vanadium and its compounds, 385.
Vegetable acids, 417.
Vegetable alkaloid poisons, 416, 417.
Vegetable chemistry, 407.
Vegetable colouring-matter (see also Chapter IV., Section on *Economic Botany*, Vol. II.), 421.
Vegetable oils, 418.
Vegetable putrefactive poisons, 429.
Vegetable substances chiefly composed of hydrogen, oxygen, and carbon, 408.
Vegetable substances, the chemical constitution of, 408.
Vegetable wax, 418.
Vegetables and roots compared as to nutritiveness, &c., 348.
Vegetables as food (see also Section on *Economic Botany*, Vol. II.), 346.
Vegetables, methods of cooking, 346.
Vegetables mostly contain starch, 411.
Venison as food, 344.
Ventilation, defective, of rooms, 427.
Ventilation, necessity and laws of, 428.
Verdigris, 376.
Vermilion, 375.
Vinegar, 414.
Vinegar as a condiment, 356.
Vinegar-plant, 414.
Vinous fermentation, 412.

WASHING of clothes required frequently to remove excreted animal matter, 428.
Washing precipitates in analysis, 396.
Water as a sanitary agent, 429.
Water as food, 349.
Water-baths, 305.
Water, combustion of phosphorus under, 371.
Water, composition of, 320.
Water essential for digestion of food, 349.
Water essential to the human system; and its functions therein, 429.
Water from wells, impurities of, 322.
Water, functions of, in animal and vegetable life, 322.
Water-gilding, 374.
Water, hard, Clark's process for softening, 321.
Water, hard and soft, cause of the difference between, 321.
Water, hardness of, caused by lime, 390.
Water, impurities of, 321.
Water, impurities of, as affecting health, 429.
Water, inorganic impurities of, 322, 429.
Water, mineral, 322.
Water, organic impurities of, 322, 429.
Water poisoned by lead cisterns, 378.
Water produced by the combustion of hydrogen in oxygen, 320.
Water, proportion of, in blood, 331.
Water, simple filter for, 321.
Water, spring, river, &c., 320.
Water-supply of large towns, 321, 429.
Water, tests for hard, 321.
Water the standard of the specific gravity of solids, 310.
Wax, the cause of bloom on fruit, 343.
Wax, vegetable (see also Section on *Economic Botany*, Vol. II.), 418.
Weighing in quantitative analysis, 403.
Weights, atomic, 302.
Weights, table of English, 430.
Weights, table of French, 430.
Weights, troy, avoirdupois, French, &c. 430.
Welding, the property of, confined to platina and iron, 372.
Wells and carbonic acid gas, 326.
Wells, impurity of water from, 322.
Whiskey, 413.
White lead, 379.
Wine as food, 352.
Wine, manufacture of, 413.
Wine, spirits of, 412.
Wines, alcohol in, 412.
Wines, British, 413.
Wines, cause of the *bouquet* of, 414.
Wines, colonial, 413.
Wines, flavour of, due to an ether, 353.
Wines, foreign, 413.
Wines, sparkling, 413.
Wolfram, 385.
Wood-spirit, 415.

YELLOW chrome, 384.
Yellow dyes, 422.
Yttria, 391.

ZINC, alloys of, 379.
Zinc, chloride of, 379.
Zinc, chloride of, as a disinfectant, 427.
Zinc, combustibility of, 379.
Zinc, galvanising iron by, 379.
Zinc in solution, tests for, 393, 401.
Zinc largely used in galvanic batteries, 380.
Zinc, nature, properties, source, &c., of, 379.
Zinc, oxide of, 379.
Zinc salts, 380.
Zinc, sulphate of, 380.
Zinc, sulphide of, 380.
Zinc, use of in water cisterns, 379.
Zirconia, 391.

SECTION VII.—MATHEMATICS.

Abbreviation, arithmetical marks and signs used for, 451.

Addition in algebra, sign of, 451; illustrations of; exercises in, 453, *et seq.*

Addition of compound quantities, 441; of fractions, 444; decimals, 448.

Addition of fractions in algebra, exercises in, 468.

Addition, simple, on the use and application of, 434.

Algebra, addition in, with examples for exercise, 453, *et seq.*

Algebra, arithmetical and symbolical, 512.

Algebra, arithmetical progression in, 477.

Algebra, division in, 462; exponents, roots, and surds, 464; evolution, or extraction of roots, 465; exercises in, 466.

Algebra, extraction inroots—of the square-root of a polynomial, 481; exercises in, 482; of the square-root of a binomial, 482; of the cube-root of a compound quantity, 484; exercises in, 484, *et seq.*

Algebra, fractions, 466; exercises in, 467; reduction of fractions; addition and subtraction of fractions; exercises in; multiplication of fractions, 468: division of fractions; exercises in, 469.

Algebra, general principles of, 451, *et seq.*; signs of; the study of, requires a previous knowledge of arithmetic; definitions and explanations of; exercises in; operations in, 452.

Algebra, geometrical progression, 478; exercises in, 479.

Algebra, homogeneous and symmetrical quadratics, 476.

Algebra, multiplication in, 459; involution, 461.

Algebra, proportion and progression, 479.

Algebra, ratio and proportion, 476.

Algebra, simple equations, 455, *et seq.*

Algebra, solutions to exercises in, 486—511.

Algebra, solution of simple equations, 469; quadratic equations, 472.

Algebra, subtraction in, 454.

Algebra, transposition; clearing fractions, 456: questions for solution and exercise, 457.

"Ambiguities" arising from the use of trigonometrical formulas, 619.

Angle, circular measure of an, 612; definition of, 614.

Angles, formulas for determining the relations of, 616, *et seq.*

Angles of a spherical triangle, sines of the, 657.

Angles, ratios of, 613, *et seq.*; functions of, 615; of a corresponding character, 616; sines and cosines of, 613, 621; the trigonometrical ratios of, 621; to calculate logarithmic sines and cosines of, 635; methods of correcting, 636.

Angles, sines and cosines of, 613; tables of logarithmic sines, &c., of, 666, *et seq.*; Delambre's method for solving, 640.

Apothecaries' weight, 439.

Arcs, circular, lengths of, 540.

Areas, on the mensuration of, 644.

Areas, to find the area of a rectangle; of a triangle; of a parallelogram; of a trapezoid; of a trapezium; of a polygon and of a circle, 644, 645: of the segment of a circle; of an ellipse; of a parabola, 646: of a plane figure bounded by a curve, 647; of a right prism; of a right cylinder; of the curved surface of a right cone; of the frustrum of a cone; of a portion of the surface of a sphere, 648.

Arithmetic, of compound quantities, addition, and subtraction, 441; multiplication and division, 442.

Arithmetic, decimal, 447; addition and subtraction of; multiplication and division of; extraction of the square-root, 448.

Arithmetic, fractional, 443; addition and subtraction of, 444; multiplication and division of, 445; proportion, 445; rule-of-three, 446.

Arithmetic, mental, 450.

Arithmetic, simple addition; subtraction, 434: multiplication, 435; and division, 437.

Arithmetic, tables of money, time, weight, and measures, 439.

Arithmetic, the rule of reduction, 440.

Arithmetic, uses and objects of, 431; the ten figures, numeration table, and the reading of numbers; decimal system of; local value of figures, 433.

Arithmetical algebra, 511.

Arithmetical complement of a logarithm, to find, 522.

Arithmetical progression in algebra, 477.

Arithmetical table of factors, 449.

Arithmetical values of quantities in series, 517.

Avoirdupois weight, 439.

Axioms of Euclid, 543.

Base line, its measurement in surveying, 663.

Binomial equation, roots of a, 631.

Binomial, powers of a, 461; how to extract the square-root of a, 482; multipliers which render binomial surds rational, 483.

Binomial theorem, how to state the, 513; how to prove it, 514, *et seq.*

Briggian logarithms, 519; tables of, 525—539.

Calculable logarithm, every number has a, 519.

Calculations facilitated by logarithms, 518.

Cask, to find the volume of a, 656.

Chords, tables of, 540.

Circle, area of, 645.

Circles, concentric, to find the area between, 646.

Circle, quadrature of the, difficulty of solving the problem, 577.

Circle, sector and segment of, to find, 646.

Circle, to find the radius of an inscribed, 625; to find the area of a quadrilateral inscribed in a, 626.

Circular arcs, tables of, 540.

Circular measures of an angle, 612.

Cloth, measures of, 439.

Coefficient, the multiplier in algebra so called, 452; illustrated, 455; indeterminate, 512.

Coins, gold and silver, 439.

Compasses used in geometry, 600.

Complement, arithmetical, of a logarithm, to find, 522.

Composite numbers, factors of the, 449.

Compound algebraical quantity, cube-root of a, 484.

Compound quantities, addition of; subtraction of; multiplication of; division of, 441, 442.

Concentric circles, area between, 646.

Cone, to find the volume of the frustrum, area, &c., of a, 654.

Conic sections, on the construction of, 608; the ellipse, 608; the parabola, 610; the hyperbola, 611; the cycloid, 611.

Convergent series, meaning of a, 513.

Cosecants, 613.

Cosines, natural, 636; tables of, 665.

Cosines of angles, 613; to obtain the numerical value of, 637; tables of, 666.

Cotangents, 613; calculation of, 637.

Cube-root of a compound quantity, 484.

Cube-root of decimals, exercises for finding the, 485.

Cube-root, tables of, 540.

Cubes, tables of, 539.

Cubic measure, table of, 440.

Cycloid, construction of the, 611.

Cylinder, area of the surface of a, 648.

Decimals, addition and subtraction of; multiplication of; division of, 448.

Decimals, beautiful contrivance of, 433; principles and practice of, 447; reduction of fractions to, 448.

Decimals, exercises for finding the cube-root of, 485.

Definitions of Euclid, 541; of the principles of algebra, 451; of plane trigonometry, 613, *et seq.*; of geometrical planes, 592; of spherical geometry, 596.

Delambre's method of solving logarithmic sines of small angles, 640.

De Moivre's theorem, 628.

Denomination of fractions, 443.

Denominator of fractions, 443, 467.

Development of a binomial, 461.

Distances, the measurement of, 644.

Divergent series, meaning of a, 513.

Dividend, the quantity so called, 462; when a compound quantity, 463; exercises in the working of a, 464.

Division of algebra, the sign of, 451; the dividend, the divisor, and the quotient, 462; operations in, 463.

Division of compound quantities, 442; of fractions, 444; of decimals, 448.

Division of fractions in algebra, exercises in, 466, *et seq.*

Division, simple, on the use and application of; various problems in, 437.

Divisor, the quantity so called, 462; when a compound quantity, 463.

Double rule-of-three, principles and practice of, 447.

Drawing-pens used in geometry, 600.

Dry goods, measures for, 439.

Earthwork, military, to find contents of, 654.

Ellipse, definition and illustration of the, 608; to find the area of, 646.

Equality, algebraical sign of, 452.

Equations, arithmetical and algebraical, 456, *et seq.*; on the solution of, 456; different modes of operating; transposition, and clearing fractions; how to solve a simple equation containing only one unknown quantity, 456: questions for solution and exercises, 457; rules and operations for their solution with unknown quantities, 469, *et seq.*

Equations, quadratic, solutions of, with unknown quantities, 472, *et seq.*

Equivalent forms, permanence of, 511.

Euclid, elements of, and definitions, 541; his postulates, 542; marks of abbreviation, 543.

Euclid, definitions and propositions of Book I., 541; comments on, 551; exercises on, 559.

Euclid, definitions and propositions of Book II., 560; remarks on, 562; exercises on Books I. and II., 563.

Euclid, definitions of Book III., 564; remarks on, 571; exercises on Books I., II., III., 572.
Euclid, definitions of Book IV., 572; remarks on, 576; exercises on the four books of, 577.
Euclid, proportion in place of Book V., 578.
Euclid, Book VI., 584.
Euclid, propositions on planes, Book XI., 592.
Euclid, problems in practical geometry, 600.
Euclid, spherical geometry, 596; definitions and propositions, 596, *et seq.*
Evolution in algebra, 465; exercises, 466.
Exercises in the rules of algebra, 452, *et seq.;* in addition of algebra, 453; in subtraction, 455; in equations, 457, 458; in multiplication of algebra, 459; in involution, 461; in division, 463; in extraction of roots, 466; in fractions, 467; in addition and subtraction of fractions, 468; in multiplication of fractions; in division of fractions, 469: in the solution of simple equations, 471; in quadratic equations, 474; in arithmetical and geometrical progressions, 479; in extracting the square-root of a polynomial, 482; of a binomial, 483; in the cube-root of decimals, 485.
Exercises in the problems and theorems of Euclid, Book I., 559; Books I. and II., 563; Books I., II., and III., 572; on the four first books, 577.
Exercises, solutions to algebraical, 486—511.
Exponentials, to obtain sines, &c., in terms of, 629.
Exponents in algebra, illustrations of, 464.
Expression, meaning of the term in algebra, 452.
Extraction of algebraical roots, 465; rules for; exercises in, 466.
Extraction of the square-root, 448.

Factor, meaning of the term, 435.
Factors of the composite numbers, table of the, 449.
Factors, operations of, when they are simple quantities, 459.
Figures of arithmetic, 433; local value of, 433; use of in arithmetic and algebra, 451.
Formulas of spherical trigonometry, 657, *et seq.*
Formulas, trigonometrical, for determining the relations of different angles, 614, *et seq.;* "ambiguities" arising from the use of, 619; adapted for logarithmic calculation, 624.
Fractions in algebra, addition and subtraction of, 468.
Fractions in algebra, division of; exercises in, 469.
Fractions in algebra, multiplication of, 468; exercises in, 469.
Fractions in algebra, operations of, 466; exercises in, 467; how to reduce them to a common denominator, 467.
Fractions, principles and practice of, 443; addition and subtraction of; multiplication and division of, 444; reduction of to decimals, 448.
Frustrum of a cone, to determine the volume of a, 654.
Functions, trigonometrical, of angles, 615, *et seq.*

Geodetical operations, on the formulas peculiar to, 662, *et seq.*
Geometrical progression in algebra, 478.
Geometry, 541.
Geometry, plane, introduction to; definitions of, 541—(See Euclid).
Geometry, practical, general treatise on, 600, *et seq.;* the instruments in general use, 600; construction of conic sections, 608; the ellipse, 608; the parabola, 610; the hyperbola, 611; the cycloid, 611.
Geometry, spherical, introduction to; definitions of; propositions for solution, 596—599.

Heights, the measurement of, 643.
Homogeneous quadratics, definition and illustration of, 476.
Hyperbola, definition of the, 611.

Impossible expressions, 512.
Indeterminate coefficients, 512.
Indices, theory of, 512.
Infinite series, arithmetical values of, 517.
Instruments used in practical geometry—compasses, ruler, pencil, and drawing-pen, 600.
Involution of simple quantities, 461; exercises in; the powers of a binomial, 462.

Length, tables of, 439.
Letters, use of in algebra, 451.
Lines and ratios, trigonometrical, 613.
Liquids, measures for, 439.
Logarithmic sines, &c., calculation of, 637.
Logarithmic tables of natural numbers, 525—539.
Logarithms, Briggs', 519.
Logarithms, multiplication, division, involution, and evolution by, 523, *et seq.*
Logarithms, Napierian, 517; tables of, 539.
Logarithms of sines, cosines, tangents, &c., 666—688.
Logarithms, on the calculations of, 517; principle on which they may be used to facilitate calculations, 518; every number has a calculable logarithm; numerical values of may be calculated, 519: use of, 521, *et seq.*

Mantissa of a logarithm, 521.
Mathematics, introductory remarks on; different subjects connected with; on the study of, as a science, 431, 432.
Measurement of a base line, 663.
Measures, tables of, 439.
Mensuration, 643, *et seq.;* heights and distances, 643, *et seq.:* the measure of areas, 644; the measure of solids, 649.
Mental arithmetic, 450.
Military earthwork, to find the solid contents of a, 654.
Money, tables of, 439.
Monomial quantity, how to extract the root of a; exercises, 466.
Multiples of angles, sines, &c., of, 619.
Multiplication in algebra, the sign of, 451; the rule of, when the factors are simple quantities, 459; exercises in, 461.
Multiplication of fractions in algebra, 468: exercises in, 469.
Multiplication of compound quantities, 442; of fractions, 444; of decimals, 448.
Multiplication, simple, use and application of; table of, 435; various workings in, 436.
Multiplier, algebraically called the coefficient, 452; in algebra a factor, 452.
Multipliers, which render binomial surds rational, 483.

Napier, logarithms of, 517, 539.
Napierian logarithms, tables of, 539.
Natural sines and cosines, calculation of, 636; tables of, 665.
Negative and positive values in quadratic equations, 475.
Negative angles, 614.
Negative sign, use of, to denote position, 614.
Notation, algebraical, 451.
Notation, arithmetical, 433.
Notation, decimal, 447.
Notation, fractional, 443.
Number, methods of finding the logarithm of a; use of a table of logarithms; method of finding the characteristic, 521, 522.
Numbers, reading of, 433.
Numeration table, 433.
Numerator of fractions, 443, 467.
Numerical solution of right-angled triangles, 641, *et seq.*
Numerical value of logarithms, 522; of sines and cosines of angles, 621.

π, value of, 591, 630.
Parabola, definition of the, 610; area of the, 646; to find the area of a, 646.
Parallelipeds, mensuration of, 650.
Parallelogram, to find the area of a, 645.
Pence table, 439.
Pencils used in geometry, 600.
Pens used in geometry, 600.
Permanence of equivalent forms, 511.
Plane geometry, introduction to, 541.
Plane trigonometry, 612—(See Trigonometry).
Planes, definitions of, 592; propositions in, 592—595.
Polygon inscribed in a circle, area of, 591, 626.
Polygon, to find the area of a, 645.
Polynomial, how to extract the square-root of a, 481.
Positive values in equations, 475.
Postulates of Euclid; problems illustrative of, 542.
Practical geometry, 600.
Prismoid, to find the volume of a, 653.
Prisms, various, measurement of, 648, 651.
Problems—(See Propositions).
Progression, arithmetical, 477; exercises in, 478; geometrical, 479.
Proportion and progression, questions in which they are concerned, 479.
Proportion in algebra, 476.
Proportion, rule of arithmetical, 445.
Proportional parts, use of a table of, 521.
Propositions in geometry of planes, 592.
Propositions in plane trigonometry, 612, *et seq.*
Propositions in spherical geometry, 596.
Propositions in spherical trigonometry, 657.
Propositions of Euclid, 541—595.
Pyramids, mensuration of, 651.

Quadrant, trigonometrical signs of each, of a circle, 616.
Quadratic equations, solutions of, with unknown quantities, 472, *et seq.*, exercises in, 475.
Quadratics, homogeneous and symmetrical, 476.
Quadrature of the circle, problem of the, 577.
Quadrilateral, inscribed in a circle, to find its area, 626.
Quantities in algebra, simple and compound; illustrations of, 452.
Quantities, simple, operation of the factors in, 459.
Quantities, unknown, solution of simple equations with, 469, *et seq.;* of quadratic equations with, 472, *et seq.*
Quantity, marks and symbols of, 452.
Quantity, mixed, reduction of to an improper fraction, 466.
Quotient, the quantity so called, 462.

Radius of an inscribed circle, to find the 625.

Railway-cutting, to find the solid contents of a, 653.
Ratio and proportion in algebra, 476.
Ratios, inverse trigonometrical, explained, 622.
Ratios of angles, 614, *et seq.*
Ratios, trigonometrical, 613, *et seq.*
Rectangle, to find the area of a, 644.
Reduction of fractions, 443, 467.
Reduction, rule of; its rise and application, 440.
Right-angled triangles, solution of, 641.
Roots in algebra, 464; extraction of, 465; rules for; exercises in, 466.
Roots, square and cube, tables of. 540.
Rule-of-three, double, illustrations of, 447.
Rule-of-three, principles and practice of, 446.
Rulers used in geometry, 600.

Sagittas, lengths of, 540.
Secants, 613.
Sections, conic, 608.
Sector and segment of a circle, to find the area of, 646.
Semicircle, ratio of arc of to radius, 630.
Series, 511, *et seq.*; what is meant by a convergent and divergent series, 513.
Series, logarithmic, 517.
Series, trigonometrical, 627, *et seq.*
Sides and angles of triangles, 623.
Sides and area of a triangle, 625.
Signs of operation in algebra; practical illustrations of, 452.
Sines, logarithmic, tables of, 666—688.
Sines, natural, 636; tables of, 665.
Sines of angles, 613; numerical value of, 619; how to calculate the value of, 635.
Sines of small angles, 639.
Solids, mensuration of, 649, *et seq.*
Solution of right-angled triangles, 641.
Solutions to algebraical exercises, 486—511.
Sphere, to find the area of a portion of a, 648; the volume of a portion of a, 654.
Spherical geometry, 596—(See Geometry).
Spherical triangles; sines of the angles proportional, 657; solution of the, 660; Napier's rule for solving, 660.
Spherical trigonometry, 657—(See Trigonometry).
Spheroid, to find the volume of a, 655.
Square measure, tables of, 439.
Square-root, extraction of the, 448, 449, 482.
Square-root of a binomial, 483.
Square-root of a polynomial, 481.
Square-root, tables of, 540.
Square-root, various algebraic exercises for extracting the, 482.
Squares, tables of, 539.
Squaring the circle, problem of, 577.
Subsidiary angles, use of, 623.
Subtraction of algebra, sign of, 451; illustrations of, 454; exercises in, 455.
Subtraction of compound quantities, 441; of fractions, 444; of decimals, 448.
Subtraction of fractions in algebra; exercises in, 468.
Subtraction, simple, use and application of, 434; various workings in, 435.
Surds in algebra, illustrations of, 464, 483.
Surveying a country, operations of, 663, *et seq.*
Symbolical algebra, 512.
Symbols of quantity in algebra, 452.
Symmetrical quadratics, 476.

Tables, logarithmic, of natural numbers, 525—539.
Tables of circular arcs, 540.
Tables of cubes, 539.
Tables of cube-roots, 540.
Tables of logarithmic sines, tangents, &c., 666—688.
Tables of money, time, weights, and measures, 439.
Tables of Napierian logarithms, 539.
Tables of natural sines and cosines, 665.
Tables of sagittas, 540.
Tables of squares, 539.
Tables of square-roots, 540.
Tangents, 613, *et seq.*; the calculation of the numerical value of, 637; tables of, and cotangents, 666—688.
Term, meaning of the word in algebra, 452.
Theorem, binomial—(See Binomial).
Theorem, De Moivre's, 628.
Theorems of Euclid—(See Propositions).
Time, tables of, 439.
Tower, how to determine the height of a, 643.
Trapezium and trapezoid, to find the area of, 645.
Triangle, to find the area of, 645.
Triangles, relations between the sides and the angles of, 623.
Triangles, right-angled, numerical solution of, 641, *et seq.*; spherical, solution of, 660.
Triangles, spherical oblique-angled, solution of, 661.
Trigonometry, calculation of tables, 635.
Trigonometry, Delambre's method for small angles, 640.
Trigonometry, De Moivre's theorem, 628.
Trigonometry, formulas connecting inverse ratios, 622.
Trigonometry, geodetical operations, 662, *et seq.*
Trigonometry, lines and ratios of, 613, *et seq.*
Trigonometry, logarithmic formulas, 624, 637, *et seq.*
Trigonometry, logarithmic sines, 637; tables of, 666.
Trigonometry, method of checking the calculations in, 636.
Trigonometry, method of proving different formulas; principles of proof; the fundamental formulas of; various formulas and expressions, 614, *et seq.*; "ambiguities" arising from their use, 619.
Trigonometry, natural sines and cosines, 637; tables of, 665.
Trigonometry, numerical solution of right-angled triangles, 641, *et seq.*
Trigonometry, plane, treatise on, 612, *et seq.*
Trigonometry, ratio of a semicircle to a radius, 630.
Trigonometry, right-angled spherical triangles, 660; Napier's rule for solution of spherical triangles, 660; oblique-angled triangles, 661.
Trigonometry, roots of a binomial, 631.
Trigonometry, science of defined, 612.
Trigonometry, series, 627, *et seq.*
Trigonometry, sides and angles of triangles, 623.
Trigonometry, spherical, 657, *et seq.*
Trigonometry, spherical, sines and angles, 657.
Trigonometry, subsidiary angles, 623.
Trigonometry, tables of logarithmic sines, cosines, tangents, and cotangents, 666—688.
Trigonometry, tangents, and cotangents, 637; tables of, 666.
Trigonometry, value of the sines, &c. of multiples of angles, 619, *et seq.*
Troy weight, 439.

Versed sines, 613.

Weights, tables of, 439.

SECTIONS VIII. AND IX.—MECHANICAL PHILOSOPHY—APPLIED MECHANICS.

Action and reaction, 693.
Aerodynamics, or Pneumatics, 689.
Aerostatics, 689.
Aerostation, 777.
Agricultural steam-engines described, 880.
Air a source of power, 819.
Air an elastic fluid, 748.
Air, apparatus for exhibiting the flow of, 838.
Air, condensation of, 775.
Air-blast in iron manufactories, 879.
Air-bubbles in cast-iron, 809.
Air has weight, 768.
Air, height of, above the sea-level, 770.
Air is rarer the higher we ascend, 770.
Air, its volume inversely proportional to the pressure, 769.
Air loses heat by rarefaction, 771.
Air, machinery for blowing, 783.
Air, movement of the, 768, 819.
Air, pressure of, 768, 843.
Air-pump, Smeaton's, 776.
Air-pump described, 775.
Air-pump, formula for computing the action of an, 776.
Air-pump in the steam-engine, its action, 872.
Air-pump, Tate's, 776.
Air retards the velocities of falling bodies, 838.
Air, weight of a volume of, 769.
Alcohol rises in vapour at a low temperature, 842.
Altitudes determined by barometer, 771.
Altitudes, formula for computing, 771.
America, ancient architecture of, 778.
Angle-iron for jointing the plates of steam-boilers, 850.
Animal muscular force as a source of power, 780.
Animal muscular power, 817.
Animal products, machinery for treating, 783.
Animals employed as a moving force, 818.
Animals, how they walk, 715.
Apparatus for cutting, piercing, moulding, bending, crushing, &c., 783.
Apparatus, hydraulic, 783.
Arch, none in Egyptian architecture, 778.
Archimedes' problem on specific gravity, 755.
Architectural drawings, what scales are most convenient, 794.
Architecture of antiquity, 778.
Arctic voyagers propelling their sledges by means of kites, 821.
Area of a circle, 908.
Area of an ellipse, 909.
Area of a sector, 909.
Area of a triangle, 908.
Area of a parallelogram, 908.
Area of a trapezoid, 908.

Arms, action of human, 818.
Ash, data for calculating the strength of, 797.
Ash, table of strength of, 797, 810.
Astronomical instruments, machinery for making, 898.
Atmosphere, its density at different heights, 770.
Atmosphere, its weight fluctuates, 769.
Atmosphere, the, as a measure of 15 lbs. weight, 844.
Atmosphere, the, cools as we ascend, 771.
Atmosphere, the height of, 772.
Atmosphere, the most important of elastic fluids, 768.
Atmosphere, total weight of the, 771.
Atmospheric pressure, 768, *et seq.*, 819.
Atmospheric pressure averages 15 lbs. on every square inch, 769.
Atmospheric pressure turned to advantage, 772, *et seq.*
Atmospheric railway, the, 904.
Atmospheric refraction, 772.
Attraction between water and solids, 762.
Attraction, cohesive, 800.
Automata, 783.
Axial lines, important in drawings, 791.
Axis, neutral, 803, 808.
Axis, neutral, in the strain of a beam, 803.
Axle and wheel, 719, 727.
Axles, case-hardened, 902.

BABBAGE's mechanical notation, 784.
Balance, hydrostatic, for ascertaining specific gravities, 756.
Balance of Quintenz, 724.
Balance of Roberval, 725.
Balance-wheels, methods for moving, 895.
Balances, 721, *et seq.*
Ball, motion of a billiard, 746.
Bands for conveying motion in machinery, 886.
Bands to turn wheels, 728, 886.
Barker's mill, 834.
Barker's mill applied to steam, 877.
Barometer determining altitudes, 771.
Barometer determining the height of mountains, 770.
Barometer, its origin, 769.
Bars, data for calculating their cohesive strength, 797.
Bars, malleable iron, section usually employed, 809.
Bars of copper, experiments on their strength, 797.
Bars of wrought iron, experiments on their strength, 797.
Battens, law of deflection in, 807.
Beam-engines, 874.
Beam-engines are generally used in manufactories, 880.
Beams, best form of section in, 805.
Beams, cambered, 807.
Beams, formula for calculating the strength, 805, *et seq.*
Beams loaded at one end, 809.
Beams loaded in the middle, and supported at both ends, 805.
Beams loaded not perpendicularly to their length, 807.
Beams loaded uniformly over their length, 805.
Beams, neutral axis of, 803.
Beams of the balance, 721.
Beams, projecting, 809.
Beams, projecting, distribution of weights on, 803.
Beams, projecting, their strain examined, 803.
Beams, rules for computing the strength of, 811.
Beams, rules for their dimensions, 810, 811.
Beams, strain on, 803.
Beams strengthened by rods or chains, 810.
Beams strongest when fixed, 806.
Beams supported at the ends, 811.
Beams, table of transverse strengths, 810.
Beams, T-shaped, 804.
Beams, their deflection under load, 807.
Beams, their fracture, 806.
Beams, what is the strength product, 811.
Bearing loads, animals employed for, 818.
Bearings for shafts, their arrangement, 885.
Bearings in which shafts revolve, 885.
Bearings used in steam-vessels for screw propellers, 902.
Beauty, its elements in work, 779.
Beauty of machinery, on what it depends, 782.
Beech, data for calculating the strength, 797.
Beech, table of transverse strength, 810.
Bell-crank lever for converting motion, 894.
Bell, diving, 774.
Bellows, hydrostatic, 749.
Bending, effects of transverse strain, 807.
Bending, how to prevent beams from, 808.
Bent-lever balance, 721.
Bevel gearing, 891.
Bevelled wheels, 728, 891.
Billiard-balls, motion of, 746.
Bird's-eye view is horizontal projection, 785.
Birds, how they stand and walk, 715.
Blow-off, a cock in marine boilers, 851.
Board for drawing, 794.
Boards of windmills, 822, 824.
Bodies, specific gravity of, 756.
Boiler, Cornish, 848.
Boiler, effects of internal pressure, 799.
Boiler, its construction, 847, *et seq.*
Boiler, marine, cleaning of a, 851.
Boiler, marine steam-engine, 849.
Boiler, rules as to dimensions, 848.
Boiler, tubular, 850.
Bologna tower, deviation of, 714.
Bones, motions of, 817.
Borda's method of weighing, 723.
Borelli on horses' walk, 715.
Boring machines, methods for moving, 895.
Bourdon's steam-gauge, 854.
Box-wood, data for calculating the strength, 797.
Boyle's law of proportion between the volume and pressure of air, 770.
Bramah hydrostatic press, 750.
Brandy weighs more in winter than in summer, 758.
Brass and brass, table of friction, 902.
Brass and steel, table of friction, 902.
Brass, crushing pressure, 802.
Brass, data for calculating the strength, 797.
Brass, table of torsive strength, 814.
Brass used for bearings, 902.
Brass used to diminish friction, 859.
Brasses, an apparatus in machinery, 885.
Breaks for machinery, &c., 901.
Breast-wheel, 831.
Breast-wheel, combined, 832.
Breast-wheel, comparative power, 831.
Breast-wheel, estimated power, 832.
Breast-wheel, where applicable, 832.
Breeze, velocity and pressure of a, 820.
Brick building, how high one may be safely carried, 801.
Brick-making by steam, 880.
Bricks, effect of compressing, 801.
Bricks, experiments on crushing, 801.
Bricks, machinery for preparing, 783.
Brickwork columns, experiments on, 801.
Bridge (tubular), 805, 809.
Bridges formed of iron plates, 809.
Britannia tubular bridge, 805, 809.
Brunel's tubular bridge, 809.
Buckets, chain of, 830.
Buckets in water-wheels, 828, 830, 835.
Buckets of Persian wheel, 835.
Buckling, how to prevent beams from, 808.
Building materials, experiments on crushing, 801.
Building materials, experiments upon the strength of, 801.
Building materials, influence of pressure on, 801.
Bursting strain, 799.
Bushes, an apparatus in machinery, 884.
Bushes, method of making, 885.
Button-headed rivets in steam-boilers, 850.

CABLES, hempen, experiments on their strength, 796.
Calculating, machinery for, 783.
Calico-printing machinery, 783.
Camber, or amount of arching in beams, 807.
Camel, as a moving force, 818.
Cams, an apparatus to move valves, 862.
Cams, their action, 895.
Canal works, scales employed for plans of, 794.
Canvas of windmills, 823.
Caoutchouc, machinery for preparing, 783.
Caoutchouc, vulcanised, the valves of condenser made of, 872.
Capacity of an irregular vessel, 755.
Capillarity, a manifestation of electric force, 763.
Capillary attraction and repulsion, 762.
Capillary attraction, its action in oiling apparatus, 885.
Capillary attraction opposes that of gravity, 762.
Capstan, 727, 783.
Capstans, the friction of ropes or chains on, 903.
Carding machinery, 783.
Carriage axles case-hardened, 902.
Carriages, methods of arresting, 901.
Carrying loads, elephant employed, 818.
Case-hardening, 902.
Cast-iron, strength of, 798.
Casting metals, machinery for, 783.
Castings of iron contract in cooling from a molten state, 808.
Catgut used for cords to drive machinery, 887.
Catherine-wheel, its principle applied to turbines, 834.
Caulking the rivets in steam-boilers, 850.
Cements, machinery for preparing, 783.
Centigrade scale of temperature, 907.
Central lines in drawings, 791.
Centre of gravity, 711, *et seq.*
Centrifugal force, 740.
Chain as a unit of measurement, 794.
Chain employed to strengthen beams, 810.
Chain, rules for computing the strength, 800.
Chain-pins, the shearing strain on, 815.
Chains, their friction, 903.
Chains used to turn wheels, 728.
Chalk, crushing pressure of, 802.
Change-water apparatus in marine boilers, 851.
Channels for conveying water to mills, 834.
Chariots propelled by means of sails, 822.
Chemical action, a source of mechanical power, 817.
Chemical action a source of power, 781.
Chemistry connected with mechanics, 779.

Chimney of a steam-boiler, 851.
Circular motion, 740.
Circular sections have not so great torsive strength as square, 814.
Circumferences, how to find, 908.
Clay excavating, power developed in, 818.
Clepsydra, or water-clock, 766.
Clipping as a strain, 795, 815.
Clock, astronomical, 692.
Clock machinery, 838.
Clock, magic, 716.
Clock, striking apparatus of a, 838.
Clock, water, 766.
Clock-work, regulation of, 782.
Clocks have the most ingenious devices for regulating power, 782.
Clutch, the friction, 883.
Clutch to couple or uncouple shafts, 896.
Cogs, 727, 887.
Cohesion of a body, what it is, 795.
Cohesive attraction follows a regular law, 800.
Coil of rope, its friction, 903.
Collision of bodies, 745.
Colouring drawings, 790.
Columbus, his poising an egg, 712.
Columns of brickwork, experiments, 801.
Columns of cast-iron, their strength, 801.
Columns of stone, experiments, 801.
Columns of wood, experiments on the strength of, 801.
Combined engines, 876.
Components of force, 693.
Compression, 800.
Compression, effects of, on beams, 806.
Compression, experiments have as yet shown no regular law of, 800.
Compression, influence of height on, 800.
Compression of elastic fluids, 768.
Compression of fibres in beams, 803.
Concave surfaces, fluid pressure on, 752.
Condensation of steam, 845.
Condenser, air, 774.
Condenser in a steam-engine, 871.
Condensing steam-engines—(See Steam-engines).
Cone ascending an inclined plane, 713.
Cone-drawing, 789.
Cone-frustrum, developed in drawing, 789.
Cone, to find its centre of gravity, 718.
Cone-vessel, fluid pressure in a, 753.
Cones, projection of the shadows of, 792.
Conical pulleys, their action, 886.
Conical surfaces developed in drawing, 789.
Connecting-rod of a steam-engine, 860.
Construction, elegance in, 779.
Contraction of cast-iron in cooling, 808.
Copper, alloyed with tin, used to diminish friction in bearings, 859.
Copper bars, experiments on their strength, 797.
Copper (cast), data for calculating the strength, 798.
Copper, crushing pressure, 802.
Copper, table of torsive strength, 814.
Copper (wrought), data for calculating the strength of, 798.
Cordage-making machinery, 783.
Cords, considered as perfectly flexible and inextensible, 693, 719.
Cords used for conveying motion, 887.
Corn-thrashing and winnowing by steam, 880.
Cornish boilers, 848.
Cornish engines, 874, 878.
Cornish granite, 802.
Corrugating adds to the stiffness of plates, 809.
Cost (economy of), the chief study of mechanics, 779.
Cotes's calculation of the weight of the atmosphere, 771.
Cotton, machinery for preparing, 783.
Cotton manufacture, one horse-power sufficient for 100 spindles, 880.
Couples, theory of, 703.
Coupling by friction, 900.
Coupling rods, manner of, 816, 883.
Coupling shafts described, 883.
Crab, a machine, 783.
Crane, a machine for raising weights, 783.
Crane, friction-break of a, 782.
Crane, hydraulic, 840.
Crane, method of stopping the, 899.
Crane, the friction of ropes or chains in a, 903.
Crank for converting motion, 894.
Crank, its action and construction, 858, *et seq.*
Crank-shaft of a steam-engine, conditions of rotation, 814, 859.
Cross-pulleys for reversing motion, 897.
Crowbar, 719.
Crown wheel, 728.
Crushing apparatus, effects of, 783.
Crushing force, table of experiments, 802.
Crushing ore machinery at mines, 878.
Cubes, drawing, 784.
Currents of water, computation of, 826.
Curved surfaces, projection of the shadows, 792.
Curves intersecting, mode of drawing, 789.
Curves, projection of, 787.
Curves, round, the scales for measuring, 795.
Curving timber, machinery for, 783.
Cutting apparatus, 783.
Cylinder, drawing, 785.
Cylinder, floating, its equilibrium, 759.
Cylinder of steam-engine described, 854, *et seq.*
Cylinder, projection of the shadows, 792.
Cylinder represented geometrically shaded, 793.

DAM across valleys, 833.
Dam or reservoir of water, 833.
Dam to check a stream, 833.
Dam, to find the pressure sustained by a, 751.
Day, sidereal, 692.
Day, solar, 692.
Deal, table of strength of, 810.
Deal, white, crushing pressure of, 802.
Decanter, pressure of fluids in a, 753.
Deflection of beams under loads, 807.
Density of bodies, 742.
Desagulier's method for estimating the centre of gravity, 714.
Development, process in drawing, 789.
Direct acting engines, 864.
Direction of forces, 694.
Discharge of fluids—(See Fluids).
Distance and time the elements of velocity, 781.
Distance travelled, an element for measuring power, 781.
Divider, a drawing instrument, 795.
Dividing-machines, 898.
Diving-bell, 774.
Docks, pumping in, 879.
Double-beat valve in steam-engines, 855.
Dragging loads, 818.
Drainage of hills collected in reservoirs, 825.
Drainage performed by windmills, 825.
Draining, form of engine employed, 874.
Draining land by steam, 880.
Draughtsman should draw all details full size, 795.
Drawing a hexagonal prism, 787.
Drawing cubes and cylinders, 785.
Drawing elevations, 785.
Drawing-instruments, 794.
Drawing land surveys, what scales are used, 795.
Drawing, mechanical, its objects, 784.
Drawing-pens, 795.
Drawing sections, 786.
Drawing solids, 791.
Drawing-squares, 794.
Drawing teeth of wheels; rules for, 889.
Drawing the exterior of solid bodies, 785.
Drawing the interior of bodies, 785.
Drawing unfolded surfaces, 789.
Drawings, full size, their object, 795.
Drawings (working), what are, 792.
Drilling machinery, 783.
Driving machinery, 880, 882, *et seq.*
Drum to convey motion, 885.
Drunken thread of a screw, 787.
D-slide in steam-engines, 855.
Duchayla's demonstration of the parallelogram of forces, 695.
Dyeing machinery, 783.
Dynamical and statical mechanics, 779.
Dynamics, 689, 733, *et seq.*
Dynamics, momentum in, 701.
Dynamometers, 691, 900.

EARTH, centrifugal force at the surface of the, 741.
Earth, equatorial diameter of the, 747.
Earth once in a fluid state, 742.
Earth, polar diameter of the, 747.
Eccentric, action of the, 861.
Eccentric for converting motion, 891.
Eccentric link motion, 862.
Eccentric, the throw of the, 861.
Education, general, should embrace practical mechanics, 783.
Egyptian architecture, there is not found an arch in, 778.
Elastic bodies in collision, 745.
Elasticity a source of power, 781.
Elasticity employed for giving motion, 839.
Elasticity exercised in resisting strain, 795.
Elasticity in fluids, 748.
Elasticity, modulus of, 746.
Electricity a source of mechanical power, 842.
Elephants employed for carrying and dragging, 818.
Elevations, drawing, 786, *et seq.*
Ellipse employed for gearing, 898.
Elm, crushing pressure, 802.
Elm, table of strength, 810.
Embankments, how to be constructed, 752.
Emery used in polishing surfaces, 902.
Engine acting by the decomposition of water, 842.
Engines are the products of dynamical mechanics, 779.
Engines (steam)—(See Steam-engines).
Envelopment, process in drawing, 789.
Equator, force of gravity at the, 741, 747.
Equatorial diameter of the earth, 747.
Equilibrium neutral in floating bodies, 758.
Equilibrium of a floating body, 758.
Equilibrium of a material particle, 693.
Equilibrium of a rigid body, 700.
Equilibrium of a rotating fluid, 761.
Equilibrium or rest, 690.
Equilibrium, stable and unstable, 712.
Equilibrium, stable and unstable, in floating bodies, 758.
Escapement in a clock, 839.
Escapement-wheels, methods for moving, 895.
Estuaries, tidal, their mechanical power, 827.
Ether rises in vapour at low temperature, 842.
Excise hydrometer to test spirits, 757.
Exploding strain, 799.
Explosion of gunpowder, &c., as a source of power, 841.
Extension of materials, 808.

Fabrics, textile, machinery, 783.
Face-coupling for shafts, 883.
Falling bodies, their velocity, 838.
Fan for producing air-blast, 879.
Fan, revolving, to regulate the striking of a clock, 839.
Fanners, 783.
Farming machinery, steam, 880.
"Feather," a key for coupling shafts, 883.
Feathering paddle, 881.
Feed-pump, how put in motion, 858.
Feed-pump of a boiler described, 858.
Fibre in bodies, what is, 796.
Fibres (tearing asunder) in beams, 803.
Fibres, their tension and compression in beams, 803.
Field operations by steam, 880.
Fir, data for calculating the strength, 797.
Fire-engine described, 774.
Fire-grate in a steam-engine, 848.
Flange to strengthen beams, 808.
Flanges to strengthen rails, 808.
Flatting iron, 880.
Flaws in cast-iron, 808.
Flax, machinery for preparing, 783.
Float-board, water-pressure on a, 826.
Float for ascertaining the water-level in boilers, 852.
Floating body in equilibrium, 758.
Floating equilibrium, 759.
Floats, their velocity should not exceed one-third that of the stream, 827.
Flood-gates, to find the pressure sustained by, 752.
Flour, machinery for preparing, 783.
Flue-surface in a steam-engine, 848.
Flue-surface in a steam-engine, rules as to size, 848.
Fluid discharge, computation of, 763, *et seq.*
Fluid, how to ascertain the specific gravity of any, 756.
Fluid pressures, 748, *et seq.*
Fluid, rotating, its equilibrium, 761.
Fluids communicating through bent tubes, 760.
Fluids discharged from vessels kept constantly full, 764.
Fluids, elastic or compressible, 768.
Fluids, machinery for moving, 783.
Fluids, resistance of, 766.
Fluids, spouting, 763.
Fluids, their elasticity and pressure, 752, 843.
Fluids, their velocity through orifices, 764.
Fluids, velocity with which they flow from an orifice, 826.
Fluids which do not intermix, their equilibrium in tubes, 761.
Fly-wheel in a steam-engine, its action and uses, 814, 859, 880.
Foot measure, 692.
Force—(See also Power).
Force can be created or annihilated by no machinery, 859.
Force, centrifugal, 740.
Force, its transmission, 689.
Force, its unit, 691.
Force, living, 746.
Force of gravity—(See Gravity).
Force, tangential, 741.
Force, the object of dynamical mechanics, 779.
Force, the sources of, 781.
Forces, accelerating, 734.
Forces are subject to continual variations, 781.
Forces, moment of, 701.
Forces, moving, 742.
Forces, parallel, their centre, 711.
Forces, parallelogram, &c., of, 696.
Forces, polygon of, 696.
Forces, problems on, 696.
Forces, resolution of, 696.
Forces, their geometrical representation, 693.
Forces, triangle of, 696.
Forcing-pump, 774.
Forging machinery, 783.
Fork-end in the connecting-rod, 860.
Fountains, ornamental, hydraulic ram applicable to, 837.
Fourneyron's turbine, 835.
Fracture of beams, 803, *et seq.*
Freestone, crushing force, 802.
Friction, 781.
Friction a very irregular resistance in machinery, 839.
Friction-breaks, 899.
Friction-clutch, 884, 896.
Friction, co-efficient of, 901.
Friction-couplings, 884, 899.
Friction employed as a useful resistance, 782.
Friction employed to stop motion, 899.
Friction losses in steam-engines, 868.
Friction of a coil of rope, 903.
Friction of metals upon each other, 902.
Friction on shafts and pulleys, 903.
Friction stays, 899.
Friction, table of, 902.
Froude's apparatus for regulating rotation, 839.
Froude's apparatus for spring-power, 839.
Fuel, consumption in steam-engines, 848, 852.
Fuel, 1 lb. can convert 10 lbs. of water into steam, 852.
Fulcrum, 701, 719, *et seq.*
Full-size drawings, their object, 795.
Fulling-mills, methods for moving, 895.
Furlong, 692.
Furnace of a steam-boiler, 851.
Furnaces for smelting, the production of air-blast, 879.
Fusee to receive the coils of a watch-spring, 839.

Gale, velocity and pressure of a, 820.
Garisenda, the tower at Bologna, 714.
Gas, its elasticity proportioned to its density, 844.
Gases, elastic fluids, 748.
Gauge-cocks for ascertaining the water-level in boilers, 852.
Gear (striking), its use, 887.
Gearing, bevel, 891.
Gearing, elliptical, 898.
Gearing for the lathe, 897.
Gearing, its action, 887.
Gearing, square, 899.
Gib-heads, keys for coupling shafts, 883.
Girders, best form of section, 805.
Girders, cast-iron, usual section, 808.
Girders formed of plates, 808.
Girders, strength calculated, 805.
Girth, the circumference of cable, 796.
Glass attracts water, 762.
Glass gauge for ascertaining the water-level in boilers, 852.
Glass, machinery for preparing, 783.
Glass the most elastic substance, 745.
Governor for regulating the speed of clock-work, 838.
Governor, steam-engine, 862.
Governor to regulate the velocity of windmills, 823, 824.
Grain weight, 691.
Gramme, a standard weight, 692.
Gramme, French, 692, 747.
Granite, crushing force, 802.
Granite, table of friction, 902.
Gravitation employed for giving motion, 838.
Gravities of two liquids compared, 757.
Gravity a constant power, 780.
Gravity at Spitzbergen, 747.
Gravity at the equator, 747.
Gravity, centre of, 710—717.
Gravity in the latitude of London and Paris, 747.
Gravity opposed by capillary attraction, 762.
Gravity, specific, 755, *et seq.*
Gravity, specific, affected by temperature, 758.
Gravity, specific, balance for ascertaining, 756.
Gravity, specific, examples, 758.
Gravity, specific, of a compound, 755.
Gravity, specific, of a solid found by Nicholson's hydrometer, 757.
Gravity, specific, of fluids, 757.
Grindstone grit, crushing pressure, 802.
Gudgeon, the axis of a pulley, 729.
Gun, its strength, 799.
Gun-metal, table of torsive strength, 814.
Gun-metal used for shaft bearings, 859.
Gun-metal used to diminish friction, 859.
Gutta-percha employed for straps, 887.
Gutta-percha, machinery for preparing, 783.
Gwynne's centrifugal pump, 879.

Hammer, the steam, 877.
Hammers (tilt)—(See Tilt-hammers).
Hand-cart, power of man in dragging a, 819.
Hardness of bodies, 800.
Hatching or section-lining, 790.
Hawksbee's air-pump, 776.
Heat a source of power, 781, 842, *et seq.*
Heat expands liquids, 842.
Heat, latent, 872.
Heat lost by air through rarefaction, 771.
Heating surface in a steam-boiler, 849.
Heavenly bodies, their apparent rest or motion, 690.
Hempen bower-cables, experiments on their strength, 797.
Hempen ropes, rules for computing the strength of, 800.
Hexagon, how to draw it, 794.
Hexagonal prism-drawing, 787.
Hiero, King of Syracuse, proposes a problem to Archimedes, 755.
Hodgkinson's experiments for measuring elasticity, 746.
Hollow key for coupling shafts, 883.
Horology, 782.
Horse, average power of a, 819.
Horse, the, as a moving force, 818.
Horse-power, as a standard, 819.
Horses in motion, 715.
Human body, centre of gravity, 714.
Human power, its various exertions, 818.
Hurricanes, velocity and pressure of, 820
Hydraulic lift and crane, 840.
Hydraulic presses, effects of internal pressure, 799.
Hydraulic ram for raising water, 836.
Hydrodynamics, 763.
Hydrometer for measuring the gravities of solids and fluids, 757.
Hydrometer, the instrument used to test spirits, 757.
Hydrostatic bellows, 749.
Hydrostatic paradox, 749.
Hydrostatic press, Bramah's, 750, 768.
Hydrostatics, 748.
Hyperbola, a curve exhibiting the variation of steam-pressure, 846.
Hyperbola, the surface of a fluid under capillary attraction, 762.
Hyperbolic curve, the outline of the fusee, 839.

Ice-making machine, 777.
Ice, steel, &c., table of friction of, 902.
Impact, of bodies, 745.

Impulse or impact, 745.
Inch-measure, 692.
Inclinations, conveying loads up 818.
Inclined plane, 719, 731, 737, 744.
Inclined plane, a machine, 783.
Indicator, an instrument to ascertain power, 846, 867.
Indicator, a picture of the defects in the steam-engine, 868.
Indicator applied to a condensing engine, 869.
Indicator, formula for finding the power, 868.
Indicator, its action, 867.
Instruments for mechanical drawing, 794.
Involute of the circle, 890.
Iodine rises in vapour at low temperature, 842.
Iron bars, their strength, 796.
Iron, brass, and steel, table of friction, 902.
Iron (cast) columns, their strength, 801.
Iron (cast) contracts in cooling from the molten state, 808.
Iron (cast), data for calculating the strength, 797.
Iron (cast), effects of compressing, 801.
Iron (cast) girders, usual section, 808.
Iron (cast), often deceptive, 799, 802.
Iron, crushing pressure, 802.
Iron, experiments as to compression, 802.
Iron, malleable, rails, best section, 808.
Iron manufactories, 880.
Iron manufacture, steam power for producing blast, 880.
Iron, table of strength, 797, 801, 810.
Iron, table of torsive strength, 814.
Iron, tensive and compressive difference between cast and wrought, 808.
Iron (wrought), data for calculating the strength, 797.
Irrigating by steam, 880.
Irrigation, raising water for 836.
Ivory, its elasticity, 745.

Jack, the, 728.
Jets, computation of their horizontal range, 764.
Joint, universal, for coupling shafts, 884.

Kater's determination of the pendulum standard, 692.
Kepler's hypothesis on the motion of planets, 690.
Keys for coupling shafts, 883.
Keyway, a recess for keys, 883.
King-post fixed to a beam, 810.
Kites propelling vehicles over ice, 822.
Knife, a lever, 719.
Knot in a wooden post an important element of fracture, 801.

Labour as a punishment, 818.
Labour, its economy is the chief study of mechanics, 779.
Labour, manual, important observations for its economy, 818.
Land-surveys, scales used in drawing for, 795.
Lathe and mandril, 897.
Lathe, screw-gearing for the, 897.
Lead (cast), data for calculating the strength, 797.
Lead, crushing pressure, 802.
Lead, effect of compressing, 801.
Lead, table of torsive strength, 814.
Leather employed in straps, 887.
Leather straps, rules for, 903.
Leather, table of friction, 902.
Leaves, the teeth of a pinion, 728.
Leeway, 821.
Length, unit of, 692.
Levelling instruments, 751.
Lever, 719, *et seq.*
Leverage, endless, 727.
Lever, bell-crank, for converting motion, 894.
Lever, its action, 882.
Lever-presses, 783.
Lever represented by the muscles, 780.
Lifting a load, action of man in, 818.
Lifts, hydraulic, 840.
Light, the height of atmosphere deduced from the refraction of, 772.
Lights to complete drawings need no geometrical projection, 792.
Limestone, compact, crushing force, 802.
Lineal measure, 692, 906.
Lines, central, in drawings, 791.
Link motion in marine and locomotive engines, 862.
Links of a chain, their shearing strain, 816.
Liquid measure, 906.
Liquids, different, how to measure their gravities, 757.
Liquids, expansive power of, 842.
Load, power of man in carrying a, 819.
Loads, bearing and dragging, 819.
Lock-up safety-valve, 854.
Locomotive, 880.
Locomotive, boilers employed in, 850.
Locomotive described, 866, 880.
Locomotive for ordinary roads, 880.
Locomotive, friction-break of a, 782.
Locomotive, its essentials, 880.
Locomotives, D-slide, 856.
Locomotives, spring balance of the safety-valve of, 854.
Locomotives, their boiler-pressure ranges as high as 150 lbs., 853.
London, gravity in the latitude of, 747.
London, pendulum, length of, at, 747.
Louvre-boards of windmills, 824.

Machinery cannot create or annihilate force, 857.
Machinery, driving, 879.
Machinery for effecting transit and communication, 783.
Machinery for making ropes, cordage, paper, 783.
Machinery for measuring and calculating, 783.
Machinery for moving fluids, 783.
Machinery for preparing animal and vegetable products, 783.
Machinery for preparing mineral products, 783.
Machinery for preparing timber, 783.
Machinery for raising weights and giving pressure, 783.
Machinery for textile fabrics, 783.
Machinery for working metals, 783.
Machinery, its beauty, on what it depends, 782.
Machinery moved by a weight, 837.
Machinery moved by springs, 838.
Machinery of antiquity, 778.
Machinery, strains to which it may be subjected, 899.
Machinery, varying the speed of, 886.
Machines are the products of dynamical mechanics, 799.
Machines perform their work better than the hand, 819.
Machines, the velocity of any part is proportional to its strain, 883.
Machinist, what is his object, 779.
Magic clock, 716.
Magnetism, as a source of mechanical power, 842.
Magnitude of forces, 694.
Mahogany, data for calculating the strength, 797.
Man, average power of a, 819.
Man, his action when standing and walking, 714.
Man, how much pressure he can exert by his grasp, 819.
Man, how much weight he can bear and lift, 819.
Man's muscular force a source of power, 781.
Mandril of the lathe, 897.
Mangle motion, 896.
Man-hole in boilers, 851.
Manual labour, important observation for its economy, 880.
Manufactories generally employ beam-engines, 879.
Manufactories, power required in, 879.
Marble, crushing pressure, 802.
Marine engines described, 875.
Marine engines introduced into manufactories, 879.
Marine steam-boilers, 849.
Marriotte's law, application of, 846.
Marriotte's law of gases, 843.
Marriotte's law of proportion between the volume and pressure of air, 769.
Mass, explanation of this term, 750.
Mass, unit of a, 750.
Mass, defined, 742.
Material, its economy is the chief study of mechanics, 779.
Material, its disposal to secure strength, 809.
Material particle, 689.
Materials, crude, machinery for preparing, 783.
Mathematical instruments, 783, 795.
Matrix of a punching machine, 815.
Measure of length, 692.
Measures, English and French, 692, 905.
Measuring-machinery, 898.
Mechanical drawing, 784.
Mechanical invention not the result of accident, 779.
Mechanical notation proposed by Babbage, 784.
Mechanical philosophy, 689, *et seq.*
Mechanical powers, 719, *et seq.*
Mechanics, a necessary educational knowledge, 783.
Mechanics, statical and dynamical, 779.
Mechanics, their connection with chemistry, 779.
Men, muscular power of, 818.
Menai Straits bridge, 805.
Mercurial steam-gauge for boilers, 854.
Mercury, as a means of measuring pressure of fluids, 844.
Mercury in the barometer, 769, 844.
Mercury, its capillary repulsion, 763.
Mercury, its density and specific gravity, 750.
Mercury-vapour, proposed engine, 843.
Meridian, 692.
Metacentre in a floating body, 758.
Metacentre, its determination, 759.
Metals as wire become stronger, 800.
Metals, machinery for working, 783.
Metre, 692, 906.
Micrometer screw, 898.
Mile, 692, 906.
Mill-dam, 833.
Mill-shaft, apparatus for shifting, 824.
Mills, channels for conveying water to, 833.
Mills (tide)—(See Tide Mills).
Mills (wind)—(See Windmills).
Mills worked successively by the same water, 833.
Mineral products, machinery for preparing, 783.
Mining, Watt's engines applied in, 878.
Mitre-wheels, 892.
Moment of forces, 701.
Moments, positive and negative, 701.
Momentum, 742, 745.
Momentum in machines, 782.
Momentum of a steam-engine equal to a blow of a 68 lb. cannon-ball, 802.
Momentum of dynamics, 701.

Moon's motion, 690.
Morin's experiments on turbines, 835.
Mortars, their strength, 799.
Motion, circular, 740.
Motion down and up inclined planes, 737.
Motion, eccentric, 861.
Motion in fluids, the resistance to, 766.
Motion in machinery changed transversely, 887.
Motion, its communication, 882, *et seq.*
Motion, laws of Newton, 747.
Motion of heavenly bodies the result of two simple forces, 782.
Motion of projectiles, 738.
Motion of translation, 747.
Motion parallel in steam-engines, 873.
Motion, reciprocating, 894.
Motion, rectilinear, uniform, 734.
Motion, rectilinear, variable, 734.
Motion, reversing, 896.
Motion, rotary, 858, 876, 894.
Motion stopped by friction, 899.
Moulding apparatus, 783.
Moulding metals, 783.
Mountains, the height computed by the barometer, 770.
Moving forces, 742.
Mud-holes in boilers, 851.
Muscles as levers, 720, 780.
Muscles not controlled by the will, 818.
Muscles, their action, 818.
Muscles, their force, 818.
Muscular forces of men and animals a source of power, 781.
Muscular power of men and animals, 818.
Musical-boxes, 839.
Musical instruments, 783.

NEUTRAL axis of beams, 802, 808.
Newcomen, the earliest engine available was his, 871.
Newton's contrivance for measuring elasticity, 745.
Newton's laws of motion, 747.
Newton on the *vena contracta*, 764.
Nicholson's hydrometer, 757.
Non-condensing engines, 864.
Notation, mechanical, proposed by Babbage, 784.
Nutcrackers as levers, 719.

OAK, African, crushing pressure, 802.
Oak, data for calculating the strength 797.
Oak, English, crushing pressure, 802.
Oak, table of strength, 810.
Oar a lever, 719.
Oar, the movement of an, 818.
Oblate spheroid, 910.
Offsets, or scales for measuring, 795.
Oil, machinery for producing, 783.
Oiling apparatus in machinery, 885.
Oiling reduces friction, 902.
Oils, vegetable, machinery for preparing, 783.
Optical instruments, 783.
Ordnance; thickness does not always constitute strength, 799.
Ore-stamping and crushing at mines, 878.
Ores, machinery for preparing, 783.
Orifices, velocity of fluids through, 764.
Ounce weight, 691, 905.
Outlines, drawing, 784.
Overshot water-wheels, 828.
Overshot-wheel, where applicable, 832.
Ox as a moving force, 818.

PACKING-RING of the piston of a steam-engine, 857.
Paddle-feathering, 881.
Paddle-wheel described, 881.
Paddle-wheels, shock from waves, 815.
Paddle-wheels, steam-engine for driving, 875
Palladium used for the construction of balances, 723.
Paper-making machinery, 783.
Parabola, the curve described by fluids issuing from orifices, 764.
Parabola the path of a projectile, 739.
Parabola, the proper longitudinal section of a beam, 809.
Parabola, the surface of rotating fluids, 762.
Paraboloids, 910.
Parallel lines, their use in drawing, 786.
Parallel motion in steam-engines, 873.
Parallelogram of forces, 694.
Parallelogram of velocities, 738.
Paris, gravity in its latitude, 747.
Particle material, 689.
Pascall's experiments on water rising in tubes, 769.
Paving of London represents more labour than the largest pyramid, 779.
Paving, York, crushing pressure, 802.
Pear-tree wood, data for calculating the strength, 797.
Pen, a drawing instrument, 795.
Pencil-compass, 795.
Pendulum as a standard measure of length, 692.
Pendulum beating seconds in London, 747.
Pendulum, conical, to regulate the speed, 838.
Pendulum, conical, to regulate the velocity of engines, 863.
Pendulum of a clock, 838.
Penknives, how three may be balanced on the point of a needle, 713.
Pennyweight, 691, 905.
Perch or pole, 692, 906.
Perpetual screw, 893.
Persian wheel for raising water, 835.
Pet-cocks in steam-engines, 856.
Philosophical instruments, 783.
Pictures, by hand and by photography, 784.
Piercing apparatus, 783.
Pigments, machinery for preparing, 783.
Pile-driving engine, 767.
Pillar, a vein in it an element of fracture, 801.
Pincers as levers, 719.
Pine, American, crushing pressure, 802.
Pine, table of strength, 810.
Pinion and rack, 728, 892.
Pinion form of teeth, 893.
Pinions partly geared, 895.
Pins of a chain, their shearing strain, 816.
Pipe branching out of another, mode of drawing, 790.
Pipe, the velocity of water through a, 764.
Pisa, Leaning Tower of, 714.
Piston, how its reciprocating motion is converted into rotary, 858.
Piston in steam-engines, its construction, 857.
Piston-rod, its action, 856.
Pitch of a screw, 788.
Pitch of a screw, method of cutting, 897.
Pitch of a screw-propeller considered, 881.
Pitch of toothed wheels, 888.
Pitch pine, table of strength, 810.
Pitch-radius of a wheel, 899.
Plan or horizontal projection, 786.
Plane, inclined, 719, 731, 737, 744.
Plane surfaces in drawing, 784.
Plane, what is called so, 719.
Planet and sun-wheel, 899.
Planets, their motion, 690.
Planing iron, 880.
Planing machinery, 783.
Planing-machines, methods for moving, 895, 896.
Planing metals, machinery for, 783.
Plans of railway or canal works, scales employed, 794.
Plates of which boilers are constructed, 850.
Plates, stronger by corrugating, 808.
Platinum used in the construction of scale-pans, 723.
Plug, fusible, for ascertaining the water-level in boilers, 852.
Plumb-line, 710.
Plummer blocks, 884.
Pneumatics, 768, *et seq.*
Poinsot's theory of couples, 707.
Poker, a lever, 719.
Polar diameter of the earth, 747.
Pole or perch, 692, 906.
Polishing by emery, 902.
Portland stone, crushing pressure, 802.
Post, wooden, a knot is an element of fracture, 801.
Pottery-ware, machinery for preparing, 783.
Pounds, troy and avoirdupois, 691, 905.
Power consists of two elements, 815.
Power conveyed by machinery, its conditions, 882.
Power, human, its various exertions, 818.
Power in steam-engines, 879.
Power, its communication, 880.
Power, its sources and application, 781, 817.
Power measured by a dynamometer, 900.
Power, mechanical, defined, 882.
Power, mode of estimating, 780.
Power, muscular, 818.
Power of a horse, 818.
Power of a man, 818.
Power of gravity constant, 780.
Power of the wind, 820.
Power, regulating, 782.
Power required in manufactories, 880.
Power—(See also Force).
Power, standard of, 780.
Power, steam—(See Steam Power).
Power, the means of deriving and communicating it, 780.
Power, the object of dynamical mechanics, 779.
Power wasted by friction, 782.
Power, what is, 780.
Powers, mechanical, 719.
Press, hydrostatic, 749.
Presses, 783.
Presses, hydraulic, effects of internal pressure on, 799.
Pressure and pulleys, 743.
Pressure and tension, 693.
Pressure applied to elastic fluids, 768.
Pressure, atmospheric, 768.
Pressure, centre of, 754.
Pressure, explanation of the term, 750.
Pressure-giving machinery, 783.
Pressure, internal, its effects, 799.
Pressure, its transmission through fluids, 748.
Pressure of different fluids, 752.
Pressure of fluids on concave surfaces, 752.
Pressure without motion, its law, 882.
Pressures, fluid, 751.
Pressures, on triangles and rectangles, 751.
Pressures, resultant of all the, 753.
Priming in boilers, what it is, 851.
Printing-machinery, a peculiar form of screw applied in, 896.
Printing-presses, 783.
Projectiles, motion of, 738.
Projectiles, range and height, 739.
Projection, horizontal, 785.
Projection of curves, 786.
Projection on plane surfaces, 785.
Projections are not representations of the actual appearances, 791.
Propellers, paddle-wheels, 881.

Propellers, screw, 814, 875, 881.
Propulsion of vessels, 875.
Protractor, a drawing instrument, 794
Pulley, 719, 729.
Pulley, a machine, 782.
Pulley, pressure on the axis, 743.
Pulleys, conical, their action, 886.
Pulleys, fast and loose, 885, 887.
Pulleys, friction on, 903.
Pulleys, rules for calculating speeds, 886.
Pulleys, set of, 886.
Pulleys to convey motion, 885.
Pump (air)—(See Air-pump).
Pump (feed)—(See Feed-pump).
Pump for regulating speed, 864.
Pump-forcing described, 774.
Pump, household, 773.
Pumping, action of man in, 818.
Pumping by steam power described, 879.
Pumping-engine, power of a, 781.
Pumping, form of engine employed in, 874.
Pumping in docks, 878.
Pumping in water-works, 878.
Pumps, 783.
Pumps worked by windmills, 825.
Punch, what is a, 815.
Punching a hole in metal, force required, 817.
Punching-machinery, 783.
Punching, the shearing strain in, 815.
Pushing-bearing used for screw-propellers, 902.
Pyramid, centre of gravity of a, 718.
Pyramids, a labour that might have been better applied, 779.

QUADRANT, the, 907.
Quadrupeds, centre of gravity of, when walking, 715.
Quintenz's balance, 724.

RACK and pinion, 892.
Rack first proposed for railroads, 881.
Racks and partly-geared pinions, 895.
Racks, machines for cutting, 898.
Rails, question of deflection in, 808.
Rails, the best section of, 808.
Railways, scales employed for plans, 795.
Railway trains, method of arresting, 901.
Ram, hydraulic, for raising water, 836.
Ramsden's balance, 723.
Ratchet-wheel for vibrating motions, 895.
Rays of light considered in drawing, 786.
Razor-grinder's machine, 720.
Reaction, 693.
Reciprocating movement, 894.
Rectangles, pressures on, 751.
Refraction, atmospheric, 772.
Regulating-powers in machinery moved by weight, 838.
Regulators for water-wheels, 833.
Relief valves in steam-engines, 856.
Rennie's experiments on friction, 902.
Reservoirs, 833.
Resistance to motion in fluids, 766.
Rest or equilibrium, 690.
Resultant of force, 693—695.
Reversing by cross straps, 896.
Reversing by toothed gearing, 896.
Reversing motion, 896.
Rhine tidal mills, 828.
Ribs to strengthen rails, 808.
Rigid body, 699.
Rigid body in equilibrium, 700.
Rivers, estimated speed of, 827.
Riveting-machinery, 783.
Rivets used in constructing boilers, 850.
Roberval's balance, 725.
Rods, a manner of coupling, 816.
Rods to strengthen beams, 810.
Rolling iron, 880.
Rolling metals, machinery for, 783.
Roman steelyard, 723.
Roofs, ancient forms of, 778.
Rope-dancers, 715.
Rope, friction of coils, 903.
Rope-making machinery, 783.
Ropes, rules for computing the strength, 800.
Ropes, their tension calculated, 796.
Rotary engines, 876.
Rotary motion converted into reciprocating, 894.
Rotary motion conveyed through machinery, 883.
Rotary movement, how produced by the motion of the piston-rod, 858.
Rotating fluid, its equilibrium, 761.
Rotation, 690, 741, 747.
Rotation, how to reverse the direction, 886.
Rotation, rapid, in shafts, decreases the strain, 815.
Rotation, uniform, Froud's apparatus, 839.
Rowing, an operation in which man exerts the greatest power, 818.
Rowing, power of man in, 818.
Rudder of a ship, to find its maximum effect, 767.
Rules and examples for measuring a circle, 908.
Rules and examples for comparing scales of temperature, 907.
Rules and examples for measuring time, 907.
Rules for finding the area of a circle, 908.
Rules for finding the area of a parallelogram, 908.
Rules for finding the area of a sector, 909.
Rules for finding the area of a trapezoid, 908.
Rules for finding the area of a triangle, 908.
Rules for finding the area of an ellipse, 909.
Rules for finding the circumference, 908.
Rules for finding the cubic contents of a sphere, 910.
Rules for finding the mensuration of the superficies, 908.
Rules for finding the solid contents of a prism, 910.
Rules for finding the surface of a cylinder, 908.
Rules for finding the weight of boilers, 910.
Rules for measuring a cone, 910.
Rules for measuring a curved figure, 909.
Rules for measuring a sphere, 910.
Rundle of a pulley, 729.

SAFETY-VALVE in steam-boilers, 852, *et seq*.
Sail, first rude notion of a, 819.
Sail of a ship, its action, 820.
Sailor's art, 819.
Sails, computation of the angle at which should be set, 824.
Sails of windmills, 822.
Sails of windmills, their angle and dimensions, 822.
Sails propelling chariots, 821.
Sandstone, table of friction, 902.
Savery's engine, 871.
Sawing-machinery, 783.
Sawing-machines, methods for moving, 895.
Scale, a drawing instrument, 795.
Scale-drawings, their object, 795.
Scales—(See Balances).
Scales, circular-drawing, 795.
Scales most convenient for architectural drawings, 795.
Scales most convenient for mechanical drawings, 795.
Scales used in drawings of land-surveys, 795.
Scissors are levers, 719.
Screens that right themselves after being pressed down, 713.
Screw, 719, 731, 732.
Screw, a machine, 783.
Screw-curves, drawing, 788.
Screw-cutting machines, method of motion in, 897.
Screw-drawing, 788.
Screw-gearing for the lathe, 897.
Screw micrometer, 898.
Screw, peculiar form applied to printing machinery, 896.
Screw, perpetual, 893.
Screw-presses, 783.
Screw-propeller, 881.
Screw-propeller, pitch of screw, 881.
Screw-propellers, form of bearing used, 902.
Screw-propellers, steam-engine for driving, 875.
Screw-threads, their forms generally agreed, 889.
Sea currents, 742.
Section-lining or hatching, 790.
Sections, drawing, 786.
Seed-crushers, methods for moving, 895.
Seine tidal mills, 828.
Set-square, a drawing instrument, 794.
Shades to complete drawings need no geometrical projections, 793.
Shading drawings, 792.
Shading, how may be effected, 792.
Shadowing, circular, 791.
Shadowing drawings, 791.
Shaft, a part of machinery, considered, 883.
Shaft, mill—(See Mill-shaft).
Shafts, deflection an important element of weakness, 815.
Shafts, friction on, 902.
Shafts, hollow or tubular, their advantage, 814.
Shafts of paddle-wheels, the shocks from waves on the, 814.
Shafts, prime movers should be stronger than second movers, 815.
Shafts, rapid rotation decreases the strain, 815.
Shafts, rules for finding the proper dimension, 815.
Shafts, table of torsive strengths, 814.
Shafts, their bearings case-hardened, 902.
Shafts, their torsion, 813.
Shafts, the number of revolutions an element of calculation, 814.
Shafts, the power communicated, reckoned in horse-power, 814.
Shafts, the resistance to torsion is as the cube of the radius, 813.
Shaping metal, machinery for, 783.
Sheaf of a pulley, 729.
Shearing, as a strain, 795.
Shearing iron, 880.
Shearing machinery, 783.
Shearing-strain, 815.
Shears are levers, 719.
Sheave, the eccentric disc in steam-engine fittings, 861.
Ship in motion, the action of the wind on, 821.
Ships, caution in constructing and loading, 759.
Shiver of a pulley, 729.
Shrouding in water-wheels, 829.
Shut-off valve in steam-engines, 857.
Silk, machinery for preparing, 783.
Skeleton, human, 818.
Skid for arresting carriages, 901.
Sledges over ice propelled by means of kites, 821.
Slide, cylindrical, 856.

Slide, D, how its motion is produced by rotary movement, 861.
Slide-jacket, 856.
Slides, adjustment of, 867.
Slides in steam-engines, 855.
Slips, launching, 783.
Slotting machine, methods of moving, 898.
Sluices for opening and closing water-channels, 833.
Smeaton's air-pump, 776.
Smeaton's angles of the sails of a wind-mill, 823.
Smeaton's pulley, 730.
Smelting furnaces, the production of air-blast for, 879.
Smoke-consuming apparatus, 851.
Sole of a bucket in water-wheels, 829.
Solid body, how to delineate, 786.
Solid measure, 692, 906.
Solids immersed in two fluids, 756.
Solids in general attract water, 762.
Solids, to find their specific gravity by Nicholson's hydrometer, 757.
Solway Firth, the tidal current of, 833.
Space passed through by a falling body, 837.
Space passed through by a moving body, 735, *et seq.*
Spade a lever, 719.
Specific gravity, 750, 755.
Speed is distance and time, 781.
Speed of pulleys, rules for calculating, 886.
Sphere filled with fluid, to determine the pressure of a, 752.
Sphere, floating its equilibrium, 759.
Sphere, to find its diameter when the weight is given, 756.
Spheres, projection of the shadows, 793.
Spindles, rules to calculate strain on, 814.
Spinning machinery, 783.
Spirits, instrument to ascertain their strength, 757.
Spirits of wine and capillary attraction, 763.
Spitzbergen, force of gravity at, 747.
Spokes of a wheel are levers, 727.
Sponginess in cast-iron, 799.
Spouting fluids, 764.
Spouts, computation of their range and velocity, 765.
Spring, air acting as a, 879.
Spring-balance in locomotives, 854.
Springs employed as a force, 839.
Springs, governing power of, 839.
Springs, intermitting, 773.
Springs, their motion not regular, 839.
Spur-wheel, 728.
Square sections resist tension better than circular sections, 814.
Square wheel-work, 899.
Squirt is a miniature forcing-pump, 774.
Staff-riveting used in constructing boilers, 850.
Staircase, power of man in carrying loads up a, 818.
Stamper, methods for moving a, 895.
Stamping ore at mines, 692.
Standards of measure, 692.
Stars, their motion, 690.
Statical and dynamical mechanics, 689.
Statics, 689.
Statuaries represent horse's walk erroneously, 715.
Stays for fixing the plates of steam-boilers, 850.
Steam-boiler, apparatus for ascertaining the water-level in a, 852.
Steam-boiler, apparatus for supplying water to a, 852.
Steam-boiler, effects of internal pressure on the plates of a, 799.
Steam-boiler explosion, 852.
Steam-boiler, quantity of water required to supply a, 852.
Steam-boiler safety-valve, 853.
Steam-boilers, risk of explosion of, 853.
Steam-condensation, 845.
Steam-driving machinery, 879.
Steam-engine, 842, *et seq.*
Steam-engines combined, 876.
Steam-engines compared, 871.
Steam-engines, condensing, 872.
Steam-engines, condensing, power determined, 876.
Steam-engines, Cornish, reports of, 878.
Steam-engines, double-acting, described, 874.
Steam-engines, estimating the power of, 866, 869.
Steam-engines for driving paddle-wheels, described, 875.
Steam-engines for driving screw-propellers, 875.
Steam-engines, formula for calculating the power, 845.
Steam-engines, governor, 862.
Steam-engines, high-pressure and low-pressure, 846.
Steam-engines, influence on the arts, 781.
Steam-engines, marine, 875.
Steam-engines, momentum equal to a blow of a 68 lb. cannon-ball, 802.
Steam-engines, Newcomen's, 871.
Steam-engines, non-condensing, where convenient, 880.
Steam-engines, portable, 880.
Steam-engines, power of, for pumping reckoned, 878.
Steam-engines, power measured by the dynamometer, 900.
Steam-engines, ratio between ca lculted and real power, 868.
Steam-engines, rotary, 876.
Steam-engines, Savery's, 871.
Steam-engines, single acting, 874.
Steam-engines, single acting were the earliest, 878.
Steam-engines the most advantageous of all motive apparatus, 842.
Steam-engines, Watt's improvements, 871.
Steam entering a cold cylinder becomes condensed, 856.
Steam, estimated volume of, 845.
Steam-gauges, 854.
Steam-hammer, 904.
Steam in boilers, how much space there should be for, 851.
Steam, indication of its power, 846.
Steam, in what consists the great secret of its power, 845.
Steam, its elasticity is proportional to its temperature, 844.
Steam, its power by expansion, 846.
Steam, 1 lb. of fuel can turn 10 lbs. of water into, 852.
Steam passages, their size, 870.
Steam-pipe conveying the steam to the cylinder, 854.
Steam power, applications of, 878.
Steam power, direct application of, 904.
Steam power, formula for calculating, 845.
Steam pressure and temperature table, 845.
Steam pressure measured in inches of mercury, 844.
Steam pressure, what is the average actual force of, 867.
Steam-riveting machine, 904.
Steam, superheated, 877.
Steam table-engine described, 866.
Steam, the volume multiplied by the pressure is constant, 846.
Steam traction-engines, 866.
Steam-vessels, form of bearing used in, 902.
Steam-vessel, shock on paddle-wheels, 813.
Steam-vessel, the power required for a, 881.
Steam, waste between boiler and engine, 866.
Steel and brass, table of friction, 902.
Steel and ice, table of friction, 902.
Steel, data for calculating the strength, 797.
Steel, table of torsive strength of, 813.
Steelyard, Roman, Danish, Quintenz, 724; Roberval's, 725.
Stick, pointed, how it may be balanced on the tip of the finger, 713.
Stiffness obtained by corrugating, 808.
Stirrat and Whitelaw's turbines, 835.
Stone columns, experiments on, 801.
Stone, Portland, crushing pressure, 801.
Stones, effect of compressing, 801.
Stones, experiments on crushing, 801.
Stones, machinery for preparing, 783.
Stop-cock in steam-engines, 857.
Stop-valve in steam-engines, 857.
Storms, velocity and pressure of, 820.
Strain, clipping or shearing, 815.
Strain, compressive—(See Compression).
Strain decreases by rapid rotation, 815.
Strain in machinery, rules for estimating, 882.
Strain, torsive—(See Torsion).
Strain, transverse, 802.
Strains of materials, 795.
Strap, crossed, 886.
Strap-eye in the connecting-rod, 859.
Straps for conveying motion, 885.
Straps, friction, 899.
Straps, rules for finding dimensions, 902.
Straps, shifting mechanism for, 887.
Straps to turn wheels, 728.
Streams, calculation of their force, 826.
Streams, computed power of, 834.
Streams, deep and shallow, comparative velocity of, 834.
Streams, estimated speed of, 826.
Strength, how to secure the greatest, 810.
Strength of bars of any material, 797.
Strength of materials, 795.
Strength of materials a necessary knowledge, 779.
Strength of materials, a subject in an unsatisfactory state, 817.
Strength of materials, rules for calculating, 797.
Strength-product in beams, 811.
Strength secured by a proper disposal of material, 809.
Strength, transverse, of beams, table of the, 810.
Strength, transverse, of materials, mode of computing, 804.
Striking gear, its use, 887.
Strings, tension of, 743, 744.
Strut fixed to a beam, 810.
Stuffing-box of a piston, 857.
Sucker, a proof of atmospheric pressure, 768.
Suction-pump, 773.
Sugar-cane mills in the West Indian islands, 825.
Sugar, machinery for preparing, 783.
Sulphide of carbon, proposed engine, 843.
Sun and planet-wheel, 899.
Sun, motion of the, 690.
Superficial measure, 692, 906.
Surfaces, plane, in drawing, 784.
Surfaces, unfolded, drawing, 789.
Surveys, scales used in drawing, 795.
Syphon described, 772.
Syphon, Wurtemberg, 773.
Syringe, 774.

TABLE of cohesive strengtn of cylindrical copper bars, 797.
Table of cohesive strength of hempen bower cables, 797.

Table of the cohesive strength of various materials, 797.
Table of the cohesive strength of wrought-iron bars, 797.
Table-engine described, 866.
Table of angles of the sails of a windmill, 823.
Table of friction, 902.
Table of pressures and temperatures of steam, 845.
Table of screw-gearing for the lathe, 897.
Table of the resisting power of materials to crushing force, 802.
Table of torsive strength of cylindrical shafts, 814.
Table of velocity for water-power, 826.
Tables and rules for calculating quantities, 905.
Tables of transverse strengths, 810.
Tables of weights, &c., 905.
Tacking, an important part of the sailor's art, 821.
Tackle, 783.
Tail-water, precaution for a free flow, 830.
Tail water, what it is, 828.
Tallow, machinery for preparing, 783.
Tangential force, 742.
Tate's air-pump, 776.
Teak, data for calculating the strength, 797.
Teak, table of strength of, 810.
Tearing asunder iron bars, force required, 816.
Tearing asunder of fibres in beams, 803.
Teeth-cutting machines, 898.
Teeth of wheels, engineers do not agree as to forms, 889.
Teeth of wheels, rules for setting out, 889.
Teeth of wheels, their theory, 887.
Telegraph, electric, its importance, 842.
Temperature affects the volume of bodies, 758.
Temperature of steam, 844.
Tempest, to find the pressure of a, 820.
Tenacity impaired by long strain, 797.
Tender of a locomotive, 881.
Tendon, its action, 817.
Tension, 693, 796.
Tension, effect of, 806.
Tension of fibres in beams, 804.
Tension of materials, 796.
Tension of strings, 744.
Tension, the resistance of square bars greater than that of circular, 814.
Tensive strain of beams, how met, 809.
Textile fabrics, machinery for, 783.
Textile fabrics, methods of gearing employed in manufacturing, 899.
Thames river, its velocity, 828.
Thickness of materials is not always strength, 799.
Thrashing by steam power, 880.
Thread, drawing the, of a screw, 788.
Throttle-valve, water, 838.
Throttle-valve, how put in action, 857.
Throttle-valve in steam-engines, 857.
Throw of the crank, 861.
Throw of the eccentric, 861.
Tidal currents, their velocities, 833.
Tide-mills, 828.
Tides, when first converted into mechanical force, 828.
Tile-making by steam, 880.
Tilt-hammers used in iron manufactures, 893.
Timber, data for calculating the strength, 797.
Timber, machinery for preparing, 783.
Time, an element for measuring power, 781.
Time and distance the elements of velocity, 781.
Time, apparatus for measuring, 782.
Time as a measure of mechanical work, 781.
Time, unit of, 692.
Tin alloyed with copper used to diminish friction, 859, 902.
Tin (cast) data for calculating the strength, 797.
Tin, crushing pressure, 802.
Tin employed in bearings, 859, 902.
Tin, table of friction, 902.
Tin, table of torsive strength, 814.
Tin, used for shaft-bearings, 902.
Tinting a drawing, 793.
Tongs are levers, 719.
Tools are the products of dynamical mechanics, 779.
Tooth-wheel, 719, 728, 888.
Tooth-wheels, drawing, 787.
Toothed gearing, reversing by, 896.
Toothed wheels described, 888.
Torricelli's experiment on atmospheric pressure, 769.
Torricelli the first recogniser of atmospheric pressure, 769.
Torsion, 812.
Torsion, table of strengths, 814.
Torsion, the resistance of a cylindrical shaft to, 812.
Towers at Pisa and Bologna, 714.
Toys, on the principle of unstable equilibrium, 715.
Traction-engines, steam, for common roads, 866.
Trains, railway, breaks for, 901.
Translation in space, 747.
Transverse strength, 802, 810.
Travellers and tackle, a machine, 783.
Treadmill, how it is a penal labour of severe character, 818.
Trees, the force which sustains their sap, 750.
Triangles, fluid pressures on, 751.
Troy-weight, 905.
T-shaped girders, 804.
Tube, capillary, its diameter, 763.
Tube-girders, 809.
Tubes, equilibrium of fluids in, 760.
Tubes, fixing in steam-boilers, 851.
Tubular boilers—(See Boilers).
Tubular bridge, Britannia, 805—809.
Tubular shafts, their advantage, 814.
Turbine applied to steam power, 877.
Turbine-wheel, 834.
Turbine-wheel, estimated power of, 835.
Turbine-wheel described, 835.
Turning iron, 880.
Turning-lathe, treadle of the, 720.
Turning-machines, methods for moving, 895.
Turning-machinery, 783.
Twisting (see also Torsion), 795.
Twisting-force, 812.

UNDERSHOT water-wheels, 825.
Undershot wheels with vertical floats, 827.
Unit of force, length, time, &c., 691, 692.
Universal joint for coupling shafts, 884.

VACUUM valve in boilers, 854.
Valve, double-beat, 855.
Valve, relief, 856.
Valve, safety, 852.
Valve, shut-off, 857.
Valve, slide, 855.
Valve, stop, 857.
Valve, vacuum, 854.
Valves for opening and closing water-channels, 833.
Valves of the condenser, 872.
Valves, self-acting, in the steam-engine, 854.
Vanes or boards of windmills, 822.
Vapour generated from liquids by heat, 843.
Vapours, their latent heat, 872.
Vegetable products, machinery for preparing, 783.
Vehicles for transport, 783.
Vehicles propelled by kites over ice, 821.
Vein in a marble pillar, an element of fracture, 821.
Velocities, parallelogram of, 738.
Velocity, 735.
Velocity and weight are convertible, 781.
Velocity is distance and time, 781.
Velocity of falling bodies, 837.
Velocity of projectiles, 738, 841.
Velocity of the wind, tables of, 820.
Velocity of toothed wheels, rules, 888.
Velocity of water-power, 826.
Vena contracta in fluids flowing through orifices, 764.
Vena contracta, observation by Newton, 764.
Vertical lines, what are so called, 751.
Vessel, irregular, how to ascertain its capacity, 755.
Vessels for water-carriage, 783.
Vessels, steam, propulsion of, 881.
Vessels, their form, 821.
Vessels, their motion in fluid, 821.
Vis viva, 746.
Volume, 742.
Volume affected by temperature, 758.
Volume determined from specific gravity, 755.

WALK of man and animals, 714, 715.
Walking, the action of, 714, 715.
Washing-machines, methods for moving, 895.
Watch-spring, its action described, 839.
Water a source of mechanical force, 817.
Water a source of power, 781, 825.
Water attracted in general by solids, 762.
Water, channels for conveying it to mills, 833.
Water-clock, 766.
Water, computation of the flow of currents of, 826.
Water, computed power of streams, 834.
Water, contrivances for raising, 835.
Water converted into steam, occupies 1,600 times its bulk, 845.
Water conveyed by pipes from a reservoir, 761.
Water, distilled, its gravity, 750.
Water, engine acting by the decomposition of, 842.
Water-engines, high-pressure, 904.
Watt's improvements were first applied to single-acting engines, 878.
Water an inelastic fluid, 748.
Water, its velocity through a pipe, 763.
Water, 10 lbs. can be converted into steam by 1 lb. of fuel, 852.
Water lifted, becomes a reservoir of power, 840.
Water, movement of, 825.
Water power, 825.
Water power, adaptation for, 833.
Water, velocity of, 826.
Water pressure in the hydraulic crane, 840.
Water pressure on a float-board, 827.
Water-pumping in docks, 879.
Water, quantity discharged by a pump, 774.
Water, raising from mines, 878.
Water reservoirs, 833.
Water rises about thirty-two feet through tubes exhausted of air, 769.
Water-streams, comparative velocity, 834.
Water, the force of vapour raised from, 843.
Water, the object of hydrodynamics, 763.
Water, troy-weight of a cubic inch, 755.
Water, weight of a cubic foot of, 826.
Water-wheel (breast), 831.

Water-wheel, breast and undershot combined, 832.
Water-wheel (breast), comparative power, 831.
Water-wheel (breast), estimated power, 832.
Water-wheel (breast), where applicable, 833.
Water-wheel, overshot, 828.
Water-wheel, overshot, its best construction, 830.
Water-wheel, overshot, its most advantageous velocity, 830.
Water-wheel, overshot, rules for calculating velocity, 829.
Water-wheel, overshot, where applicable, 833.
Water-wheel turbine, 834.
Water-wheel turbine described, 834.
Water-wheel turbine, estimated power, 835.
Water-wheel, undershot, 825.
Water-wheel, undershot, the greatest possible effect, 767.
Water-wheels are of three kinds, 825.
Water-wheels, regulators for, 833.
Water-wheels, undershot; their velocity should not exceed one-third that of the stream, 827.
Water-works for supplying towns, 879.
Watt began a new era in the mechanical arts, 778.
Watt's governor for steam-engines, 862.
Watt's improvements in the steam-engine, 871.
Watt's parallel motion, 873.
Watt's sun and planet wheels, 899.
Weaving-machinery, 783.
Wedge, 719, 731.
Wedge, a machine, 783.
Weighing-machines, 725.
Weight, 691.
Weight a source of mechanical force, 817.
Weight a source of power, 781, 837.
Weight an element for measuring power, 781.
Weight and velocity are convertible, 781.
Weight as a measure of mechanical work, 883.
Weight, explanation of this term, 750.
Weight multiplied by the velocity represents horse-power, 781.
Weight of a body, 691.
Weight of a body, how it may be readily determined, 755.
Weight of bodies as a moving power, 837.
Weight true or absolute is the weight in a vacuum, 756.
Weight without motion, its law, 882.
Weights and measures, 905.
Weights in French and English, how to reduce, 905.
Weights preferable to springs for regular motion, 839.
Weights raising machinery, 783.
Weir to check a stream, 833.
Wheel, a machine, 783.
Wheel and axle, 719, 727.
Wheel and worm, 892.
Wheel-barrow, the action of man by, 818.
Wheel, bevelled, 728, 891.
Wheel, catherine, its principle applied to turbines, 834.
Wheel, elliptical, 898.
Wheel, Persian, for raising water, 836.
Wheel, sun and planet, 899.
Wheel, toothed, 719, 728, 887.
Wheel, undershot, to find the greatest possible effect, 767, 827.
Wheel-work, 887.
Whitelaw's turbines, 835.
White's pulley, 730.
Winch, 727.
Winch, manual labour at the, 819.
Wind, computation of its power, 820.
Wind, its pressure proportional to the square of the velocity, 820.
Wind-power, 820.
Wind, table of velocity of, 820.
Wind, when first converted into mechanical force, 819.
Windlass, 727, 783.
Windlass, the friction of ropes or chains, 903.
Windmills, advantages of, 825.
Windmills, apparatus for regulating, 823, 824.
Windmills for giving motion to machinery, 822.
Windmills, horizontal, not so effective as vertical, 822.
Windmills partially surrounded by a casing, 822.
Windmills, power of, 825.
Windmills, self-regulating, 824.
Windmills, their construction, 822, *et seq.*
Windmills, velocity of, 825.
Wine-taster described, 775.
Winnowing corn by steam power, 880.
Wire-drawing machinery, 783.
Wire, the strength computed, 800.
Wood columns, experiments on, 801.
Wood, data for calculating the strength, 797.
Wood, experiments as to compression, 800.
Wood, how sections in drawing are hatched, 790.
Wood on wood, table of friction, 902.
Wood-working machinery, 880.
Wool, machinery for preparing, 783.
Woollen cloth, table of friction, 902.
Work defined, 781.
Work, mechanical, defined, 882.
Working-drawings, what are, 790.
Worm and wheel, 892.
Wrenching force, 812.
Wrinkling adds to the stiffness of plates, 808.
Wurtemberg syphon, 773.

YARD, a measure of length, 692.
York paving, crushing pressure, 802.

SECTION X.—ASTRONOMY.

ABERRATION of light, 931.
Acceleration, daily, defined, 918.
Aldebaran, 959.
Algol, 959.
Altair, 960.
Altitude and azimuth instrument, 998.
Andromeda, 959.
Andromeda, nebula of, 956.
Annual equation of the moon, 937.
Annular nebulæ, 957.
Annular solar eclipses, 982.
Aphelion defined, 918.
Apogee defined, 918.
Apparent magnitude of the stars, 950.
Apsides, line of, 923.
Apsides of the moon, 936.
Aquila, 960.
Arc of meridian, determining the length of an, 921.
Arcturus, 959, 960.
Artificial day, 919.
Ascension, right, defined, 917.
Asteroids, 946.
Asteroids, discovery of the, 947.
Asteroids, distance of the, 947.
Asteroids, telescopic appearance of the, 947.
Astronomical day, 919.
Astronomical instruments, 989, *et seq.*
Astronomical telescopes (see also Index, p. 1219), 991.
Astronomy, cometary, 960.
Astronomy, history and definitions of, 913.
Astronomy, planetary, 940.
Astronomy, practical, 989.
Astronomy, stellar, 950.
Atmosphere of Jupiter, 947.
Atmosphere of Mars, 946.
Atmosphere of Venus, 946.
Atmosphere of the earth, 924.
Atmosphere, solar, 934.
Atmosphere, tides of the, 989.
Axis of the earth defined, 916.
Axis of the earth, inclination of the, 923.
Axis of the earth, nutation of the, 933.
Azimuth and altitude instrument, 998.
Azimuthal errors, determination of, 1005.

BAILY's beads seen during a solar eclipse, 984.
Bear, great, constellation of the, 959.
Bellatrix, 959.
Belts of Jupiter, 947.
Betelgeux, 959.
Biela's comet, 962.
Boötes, 959.
Brorsen's comet, 963.

CANIS major, 959.
Canis minor, 959.
Cassiopeia, 959.
Castor and Pollux, 959.
Catalogues of stars, 951.
Centrifugal force of the rotation of the earth, 988.
Ceres (see Asteroids), 946.
Circle, the repeating, 994.
Circles in astronomy, 916.
Circumference, equatorial, of the earth, 922.
Clock-errors, 1016.
Clock-errors of observers, 1001.
Cluster of Hercules, 955.
Collimation, errors of, formulæ for, 1005.
Collimation, errors in observance of, 1002.
Collimation, formula for determining, 1013.
Collimation, tables illustrating, observed and corrected, 1003.
Colure, equinoctial, defined, 923.
Colure, solstitial, defined, 923.
Colures defined, 917.
Cometary nebulæ, 957.
Comet, Gambart's or Biela's, 963.
Comet, Halley's, 961.
Comets, elements of, 961.
Comets, history and notes on various, 962—972.
Comets, light, &c., of, 962.
Comets, low gravity of, 988.
Comets, nature of, 963.
Comets, notes on all observed since 371 B.C., 964—972.
Comets, periodicity of, 961.
Comets, physical appearance of, 961.
Comets, recent, 972.
Comets, tables of the orbits, elements of, observed during the last two thousand years, 1031—1034.

Comets, their orbits, tails, &c., 960.
Conjunction, planetary, defined, 918.
Constellations (see Folio Plates, illustrating the northern and southern systems, 960.
Constellations and fixed stars, 958.
Constellations, northern, 959.
Constellations of the zodiac, 958.
Constellations, southern, 959.
Copernican system, 942.
Corona Borealis, 960.
Craters of the moon, 939.
Culmination defined, 918.
Cygnus, 960.

D'ARREST's comet, 963.
Day, solar and sidereal, length of, 922.
Day, solar, sidereal, astronomical, and artificial, defined, 919.
Declination defined, 917.
Definitions of terms in astronomy, 916.
Degree, length, and measurement of a, 920.
Degree, length of, at various places, 922.
Degrees of latitude and longitude, length of, at various places, 922.
Density of the earth, 924.
Disc of a planet defined, 918.
Disc of the sun, 927.
Distance, zenith, to measure the, 996.
Distances of the planets (see Note at foot of page), 926.
Donati's comet, 972.
Double stars, 952.

EARTH an oblate spheroid, 920.
Earth, atmosphere of the, 924.
Earth, axis of, defined, 914.
Earth, density of the, 924.
Earth, distance of from the sun, 926.
Earth, equatorial circumference of the, 922.
Earth, figure of the, 919.
Earth, force of gravity of the, 924.
Earth, inclination of the axis of the, 923.
Earth, polar and equatorial diameter of the, 921.
Earth, proofs of the rotundity of the, 919.
Earth, rate of the motion of in space, 923, 926.
Earth, revolution of the, 923.
Earth, rotation of the, 922.
Earth, sun, and planets, comparative volumes, &c., of the, 926, 927.
Earth's axis, rotation round the, 933.
Eclipse, calculation of an, 975.
Eclipse, corona observed during a solar, 983.
Eclipse, darkness during a solar, 983.
Eclipse, effects of the earth's atmosphere during an, 974.
Eclipse, graphical construction of a lunar, 976.
Eclipses, how occasioned, 972.
Eclipse, lunar, prediction, duration, &c., of, 975.
Eclipse of the sun, prediction, calculation, &c., of an, 979.
Eclipse, partial, of the moon, 973.
Eclipse, phenomena observed during a solar, 983.
Eclipse, solar, calculation of, 979, *et seq.*
Eclipse, solar, magnitude of, 978.
Eclipse, solar, red flame seen during one, 984.
Eclipses and occultations, 972.
Eclipses and photography, 164, 984.
Eclipses, dimension of the shadow in, 973.
Eclipses, lunar, 972.
Eclipses of Jupiter's satellites, 948.
Eclipses, solar, annular, &c., 982.
Ecliptic defined, 916.
Ecliptic, obliquity of the, 923.
Elliptic system of planetary motion, 987.
Ellipticity of the earth's figure, 921.
Elongation of a planet, 943.
Encke's comet, 971.
Epicycle theory of the ancients, 940.
Equator defined, 916.
Equatorial diameter of the earth, 921.
Equatorial, the, 999.
Equinoctial colure defined, 923.
Equinoctial defined, 916.
Equinoxes, precession of the, 931.
"Establishment of the port," a term applied to the determination of the high water at a port, 989.
Evection of the moon, 937.

FACULÆ on the sun's disc, 927.
Faye's comet, 963.
Figure of the earth, 919.
Fixed stars and constellations, 958.

GALVANISM and astronomical registration, 1001.
Gambart's comet, 962.
Geocentric latitude, 1029.
Geocentric zenith, the, 1029.
Gravitation, and the planetary orbits, motions, &c., 985.
Gravitation, laws of, 985.
Gravitation, nature of, 985.
Gravity, force of, on the surface of the earth, 924.

HALLEY's comet, 961.
Harvest moon, 937.
Hercules, cluster of, 955.
Herschel's telescope, 994.
High-water, what causes, 989.
History of astronomy, 913.
Horizon defined, 917.
Horizontal parallax, 1028.
Hyades, cluster of, 955.

ILLUMINATION, defective, of the moon, corrections for, in observations, 1030.
Inclination of an orbit defined, 918.
Instruments, astronomical, uses, precautions in using, &c. (see name of each), 989, *et seq.*

JUNO (see Asteroids), 946.
Jupiter, atmosphere of, 947.
Jupiter, belts of, 947.
Jupiter, disc of, 947.
Jupiter, eclipses of the satellites of, 948.
Jupiter, ellipticity of, 947.
Jupiter, rotation of, 947.
Jupiter, satellites of, 948.
Jupiter, telescopic appearance of, 947.

KEPLER's laws, 944.
Kepler's laws and gravitation, 986.

LATITUDE defined, 917.
Latitude, geocentric, 1029.
Laws of Kepler, 944.
Lenses for astronomical instruments, 990.
Lenses, principles of (see also Index, p. 1219), 990.
Level, corrections of, formulæ for, 1005.
Level of instruments, error, and correction of the, 1004.
Level, use of the, 996, 997.
Libration of the moon, 935.
Light, aberration of, 931.
Light, zodiacal, the, 930.
Longitude defined, 917.
Longitude, determination of terrestrial, 1019.
Longitude determined by the eclipses of Jupiter's satellites, 948.
Longitude determined by lunar occultations, 984.
Longitude determined by transits of the moon, and moon culminating stars, 1019.
Longitudes, examples illustrating the method of finding, 1021.
Lunar eclipses, 972.
Lunar horizontal parallax, 1028.
Lunar nutation, 933.
Lyra, 960.

MACULÆ on the sun's disc, 927.
Magellanic clouds, 955.
Magnitude, degrees of, in respect to the stars, 950.
Mars, apparent diameter of, 946.
Mars, atmosphere of, 946.
Mars, density of, 946.
Mars, diameter of, 946.
Mars, ellipticity of, 946.
Mars, rotation of, 946.
Mars, seasons of, 946.
Mars, snow, &c., observed on, 946.
Mars, telescopic appearance of, 946.
Mars, volume of, 946.
Masses of the planets, 926, 988.
Mercury, 941, 945.
Mercury, phases of, 945.
Meridian, methods of determining the length of an arc of, 921.
Meridian, or Mural Circle, 1023.
Meridians defined, 917.
Micrometer, microscopic indication of, converted into the arc of a circle, 1027.
Micrometer-observation, errors in, 1001.
Micrometer, the, 998.
Milky Way, the, 951.
Moon, annual equation of the, 937.
Moon, apsides of the, 936.
Moon, craters of the, 939.
Moon, defective illumination of, corrections for, in observations, 1030.
Moon, earth-light illuminating the, 932.
Moon, eclipses of the, 972.
Moon, evection of the, 937.
Moon, harvest, 937.
Moon, height of the mountains of the, 939.
Moon, libration of the, 935.
Moon, mountains of the, 938.
Moon, occultation of stars by the, 935, 984.
Moon, opacity of the, 935.
Moon, orbit of the, 936.
Moon, parallax of the, 936.
Moon, partial eclipse of the, 973.
Moon, path of, in the heavens, 936.
Moon, phases of the, 935.
Moon, physical constitution of the, 938.
Moon, rotation of, on her axis, 935.
Moon, telescopic appearance of the, 938.
Moon, variation of the, 937.
Moon, volcanoes of the, 938.
Moon's motion in space, 937.
Motion of the sun in its orbit, 924.
Motion of the sun, irregularities of the, 924.
Mountains of the moon, height, &c., of the, 939.
Mural Circle, how to take observations by the, 1025.
Mural Circle, the, 1023.

NEBULÆ, 955.
Nebulæ, annular and cometary, 957.
Nebulæ, double, 957.
Nebulæ, ellipticity of, 957.
Nebulæ, globular, 957.
Nebulæ, nature of, 957.
Nebulæ, resolution of, 957.
Nebulæ, theories of, 957.
Nebulæ, various, 956.
Neptune discovered inductively, in accordance with the laws of gravitation and planetary perturbation, 988.
Neptune, satellite, &c., of, 949.
Nodes of an orbit defined, 918.
Nutation, lunar, 933.
Nutation of the earth's axis, 933.
Nutation, solar, 933.

Obliquity of the ecliptic, 923.
Observations, errors incidental in, and corrections for, 1001, *et seq.*
Occultations of stars by the moon, 935, 984.
Opposition, planetary, defined, 918.
Orbit of a planet defined, 918.
Orbit of the moon, 936.
Orbit of the sun, 924.
Orbits of comets, 960.
Orbits of comets, tables of, observed for the last two thousand years, 1031—1034.
Orbits of planets elliptical, whilst those of comets are parabolic, &c., 960.
Orion, constellation of, 959.
Orion, nebula of, 956.

Pallas (see Asteroids), 946.
Parabolic orbits of comets, 960.
Parallax, horizontal, 1028.
Parallax, nature of the, 926.
Parallax of the heavenly bodies, how obtained, 926.
Parallax of the moon, 936.
Parallax of the sun, recent discoveries respecting the (see Editorial Note at foot of the page), 926.
Partial eclipse of the moon, 973.
Pegasus, 959.
Pendulum, vibration of, at the equator and poles, 924.
Pendulum, vibration of, in a day, 923.
Penumbra in eclipses, 973.
Perigee defined, 918.
Perihelion defined, 918.
Perseus, 959.
Perseus, cluster of, 955.
Personal equation of observers, 1001.
Perturbations of the planetary motions, 988.
Phases of Mercury, 941, 945.
Phases of the moon, 935.
Phases of the superior planets, 943.
Phases of Venus, 941, 945.
Plane of an orbit defined, 918.
Planet, elongation of a, 943.
Planetary astronomy, 940.
Planetary motion and gravitation, 985.
Planetary motion, and the laws of Kepler, 986.
Planets, 940.
Planets, distance of, from the sun, as affected by the new value of solar parallax (see Note at foot of the page), 926.
Planets, masses of the (see also Note at page 926), 988.
Planets, motion of the, 940.
Planets, mutual effect of their masses in producing perturbations, 988.
Planets, perturbations of the, 988.
Planets, phases of the superior, 943.
Planets, retrograde motion of, 941, 943.
Planets, telescopic appearance of the, 945.
Pleiades, cluster of, 955.
Polar diameter of the earth, 921.
Pole-star, the, 959.
Pollux and Castor, 959.
Practical astronomy, 989.
Præsepe, cluster of, 955.
Precession of the equinoxes, 931.
Prediction, duration, &c., of a lunar eclipse, 975.
Procyon, 959.
Ptolemaic system, 942.

Repeating circle, the, 994.
Retrograde motion of some planets, 941, 943.
Revolution of the earth, 923.
Rigel, 959.
Right ascension calculated by transits, illustrated, 1017.
Right ascension defined, 917.
Right ascension, determination of, by the transit instrument, 1015.
Rings of Saturn, 948.
Rising and setting, 919.
Rosse's, Lord, telescope, 957.
Rotation of Jupiter, 947.
Rotation of Mars, 946.
Rotation of Saturn, 948.
Rotation of the earth, 922.
Rotation of the earth generates a centrifugal force, 988.
Rotation of the earth, proofs of the, 922.
Rotation of the earth, rate of at the equator, &c., 923.
Rotation of the earth, time occupied in the, 922
Rotation of the moon on her axis, 935.
Rotation of Venus, 945.
Rotation, stellar, defined, 918.

Satellites of Jupiter, 948.
Satellites of Saturn, 949.
Satellites, &c., of Uranus, 949.
Saturn, rings of, 948.
Saturn, satellites of, 949.
Seasons, cause of the, 930.
Seasons, unequal length of the, 926.
Setting and rising, 919.
Shadow of eclipses, 973.
Sidereal day, 919.
Sidereal day, length of a, 922.
Sidereal year, length of the, 923.
Signs of the zodiac defined, 916.
Sirius, 959.
Solar atmosphere, the existence of a, 934.
Solar day, apparent, 919.
Solar day, length of a, 922.
Solar day, mean, 919.
Solar eclipses, 978.
Solar nutation, 933.
Solar spot of July, 1862, 934.
Solar spots, 927.
Solar spots, nature and cause of, 928.
Solstices defined, 923.
Solstitial colure defined, 923.
Spectrum analysis revealing the physical constitution of the sun, 934.
Spica Virginis, 960.
Spots on the sun's disc, nature and cause of, 927, 928.
Stars, binary systems of, 953.
Stars, brilliancy and magnitude of, 950.
Stars, catalogue and number of, 951.
Stars, clusters of (see also Nebulæ), 955.
Stars, colour of, 953.
Stars, double, 952.
Stars, fixed, number and magnitude of, 958.
Stars, luminosity of, 952.
Stars, motion of the, 952.
Stars, nature and species of, 952.
Stars, periodic and variable, 954.
Stars, temporary, 954.
Stars, variable, 953.
Stellar astronomy, 950.
Sun, the, 924.
Sun, and distances of the planets (see Note at foot of the page), 926.
Sun, bulk of the, 926.
Sun, diameter of the, 926.
Sun, disc of the, 927.
Sun, distance of the, 926.
Sun, eclipses of the, 978.
Sun, luminous envelope of the, 929.
Sun, motion of the, in its orbit, 924.
Sun, physical constitution of the, 929.
Sun, physical constitution of the, as discovered by the spectrum analysis, 934.
Sun, solid mass of the, 927.
Sun, spots on the disc of the, 927.
Sun, telescopic appearance of the, 927.
Sun, the surface of, in a state of incandescence, 934.
Sun, volume of the, 926.

Tables of elements of the comets, observed for the last two thousand years, 1031—1034.
Tables of observed and corrected collimation, 1003.
Tables of the length of a degree of latitude and longitude, radius vector, angle of vertical, &c., 922.
Telescope zenith, the, 1030.
Telescopes, astronomical (see also Index, p. 1219), 991.
Telescopes, reflecting (see also Index, p. 1219), 992.
Telescopes, refracting and achromatic (see also Index, p. 1219), 991, 992.
Theodolite, the, 996.
Tidal-wave, height of the, 989.
Tides, atmospheric, 989.
Tides, cause of the, 988.
Time, method of finding the, 1013.
Transit-clock, 1001.
Transit-clock errors, 1016.
Transit instrument, the, 1000.
Transit, method of observing a, 1001.
Transit micrometer, corrections for errors in using the, 1006.
Transit observation, tables illustrating the correction, &c., of, 1007, *et seq.*
Transit observations, method of recording at Greenwich, 1018.
Transit of Venus and the solar parallax, 926.
Transits, observations of, illustrated, 1017.
Tropical year, length of the, 923.
Tropics defined, 917.
Tycho Brahe's planetary system, 942.

Uranus, satellites, &c., of, 949.
Ursa Major, constellation of, 959.
Ursa Minor, constellation of, 959.

Variable stars, 953.
Variation of the moon, 937.
Vega, 960.
Venus, apparent diameter of, 946.
Venus, density of, 946.
Venus, diameter of, 946.
Venus, distance from the earth of, 941.
Venus, irregular apparent motion of, 940.
Venus, phases of, 941, 945.
Venus, rotation of, on its axis, 945.
Venus supposed to possess an atmosphere, 946.
Venus, transit of, affords a means of discovering the solar parallax, 926.
Venus, volume of, 946.
Vesta (see Asteroids), 946.
Volcanoes, extinct, of the moon, 938.
Voltaic electricity, and astronomical registration, 1001.

Waves, tidal, of the sea and atmosphere, 989.
Weather prediction, falsity of, in connection with lunar phases, 989.
Weight of bodies, ratio of, at the equator and poles, 924.

Year, sidereal, defined, 919.
Year, solar, defined, 919.
Year, tropical, defined, 919.
Years, sidereal and tropical, length of the, 923.

Zenith distance, instances of determination of the, by the Transit Circle, 1027.
Zenith distance, to measure the, 996.
Zenith, geocentric, the, 1029.
Zenith-telescope, the, 1030.
Zodiac, constellations of the, 958.
Zodiac, signs of, defined, 916.
Zodiacal light, the, 930.
Zones defined, 917.

SECTION XI.—NAVIGATION AND NAUTICAL ASTRONOMY.

Account by latitude and longitude defined, 1051.
Altitude, apparent and observed, 1076.
Altitude, meridian, of the sun, 1086.
Altitude, observed and corrected, 1977.
Altitude of a celestial body, 1074.
Altitude of a celestial object, to determine with least error (for longitude), the, 1093.
Altitudes at sea, examples of corrections for, 1078.
Altitudes, double, problem of, 1086.
Altitudes, equal, equation of, 1096.
Altitudes, to compute, 1103.
Amplitude, 1074.
Amplitude, rising, 1074.
Amplitude, setting, 1074.
Angular distances of heavenly bodies, 1073.
Apparent time, 1075.
Artificial horizon, the, 1086.
Ascension, right, 1075.
Astronomical instrument-making, refinements of, 1112.
Astronomical phenomena and navigation, 1073.
Astronomical time, 1075.
Astronomy, Nautical, 1070.
Astronomy, nautical, definition of terms in, 1073.
Axis of the earth, 1049.
Axis of the heavens, 1074.
Azimuth, 1074.

Celestial latitude, 1075.
Celestial longitude, 1074.
Celestial meridians, 1074.
Charts, plane, and Mercator's, 1115.
Chronometer, error of a, 1097.
Chronometer, examples of obtaining the longitude by a, 1098.
Chronometer, mean daily rate of a, 1097.
Chronometer, to find the longitude by a, 1097.
Chronometer, to find the rate of a, 1097.
Chronometers, correction for, 1097.
Chronometers, history and construction of, 1092.
Chronometers, management of, 1097.
Circles of declination, 1074.
Compass, deviation of the, 1090.
Compass, points of the, 1051.
Compass, the mariner's, 1050.
Compass, to find the variation of the, by an amplitude, 1090.
Compass, to find the variation of the, by an azimuth, 1091.
Compass, variation of the, 1050, 1090.
Compasses, derangement of, through inductive action of iron vessels, 1119.
Compound courses, or traverse-sailing, 1055.
Corrections for altitudes of celestial bodies, 1076.
Corrections for parallax, 1077.
Corrections for refraction, 1076.
Corrections, instrumental, 1097.
Counter-currents in the Mediterranean, 1067.
Courses, definition of a ship's, 1050.
Current, drift of a, 1066.
Current, learning the set and drift of a, 1066.
Current-sailing, examples in, 1066.
Current, set of a, 1066.
Current, velocity of a, 1066.
Currents, sub-marine or under, 1066.

Day, lunar and solar, &c., 1075.
Day's work, meaning of the term, 1051, 1115.
Dead-reckoning, 1051, 1115.
Declination, 1074.
Definitions in navigation, 1049.
Departure, definition of the term, 1052.
Deviation of the compass, 1090.
Difference of latitude and departure, tables of, 1068, 1069.
Difference of latitude in plane sailing, 1052.
Dip of the horizon, 1076.
Distance in plane sailing, 1052.
Distances, lunar, 1093.
Division by logarithms, 1037.
Double altitudes, problem of, 1086.
Drift of a current, 1066.

Earth, figure of the, 1049.
Earth, Foucault's illustration of the rotation of the, 1070.
Earth, proofs of the rotation of the, 1070.
Earth, rotation of, on an axis, 1049.
Earth, rotundity of the, 1070.
Ecliptic, the, 1074.
Equation of equal altitudes, 1096.
Equation of time, 1075.
Equator of the earth, 1049.
Equinoctial points, 1074.
Equinoctial, the, 1074.
Equinox, autumnal, 1074.
Equinox, vernal, 1074.
Error, the index, of the sextant, 1077, 1112, 1114.
Evolution by logarithms, 1037.
Extraction of roots by logarithms, 1037.

Falling bodies, and the pendulum experiment, 1073.
Figure of the earth, 1048.
Foucault's pendulum experiment, illustrating the rotation of the earth, 1070.

Gravitation, the law of, 1070.
Great circle-sailing, principles of, 1067.
Greenwich mean time, to obtain at sea, 1105.
Gunter's scale, 1054.

Horizon, artificial, the, 1086.
Horizon, dip of the, 1076.
Horizon, nature of the, 1050.
Horizon, the rational, 1050.
Horizon, the sensible, 1050.
Hour-angle, 1075.

Index-error of the sextant, 1077, 1112, 1114.
Index of a logarithm, 1037.
Instruments, difficulties in the construction of, 1112.
Instruments, nautical, 1111.
Invention of the sextant, 1115.
Involution of powers by logarithms, 1037.
Iron vessels, magnetism of, 1118.

Journal, ship or sea, how to keep the, 1115.
Journal, specimen page of a ship's, 1116.
Jupiter's satellites, occultations and eclipses of, used in obtaining the longitude, 1111.

Knot, definition of the term, 1050.

Latitude and departure, tables of difference of, 1068, 1069.
Latitude at sea, from the sun above the pole, 1079.
Latitude at sea, obtained from a meridian altitude, 1078.
Latitude, celestial, 1075.
Latitude, definition of, 1049.
Latitude from a star above the pole, 1080.
Latitude from a star, above the pole, rules and examples of obtaining the, 1081.
Latitude from a star, below the pole, 1083.
Latitude from an altitude near the meridian, the declination, hour-angle, and latitude by account, 1085.
Latitude from the altitude of two fixed stars, observed at the same time, 1089.
Latitude from the declination, altitude, and hour-angle, 1084.
Latitude from the moon, above the pole, 1081.
Latitude from the moon, above the pole, examples of obtaining the, 1082.
Latitude from the moon, below the pole, 1083.
Latitude from the sun, above the pole, examples of obtaining the, 1079.
Latitude from the sun, below the pole, 1083.
Latitude from two altitudes of the sun, and the time between the observations, 1086.
Leeway, meaning of the term, 1050.
Local time, to find, 1093.
Logarithmic differences for lunar distances, 1100.
Logarithmic tables, construction of, 1036.
Logarithmic tables, method of using, 1036.
Logarithmic trigonometrical tables (for the tables themselves, see page 666, *et seq.*), 1038.
Logarithms, explanation of the nature of, 1036.
Logarithms, proportional and lunar distances, 1105.
Log-board, use of the, 1051.
Log-book, use of the, 1051.
Log, use of the, 1050.
Longitude at sea, to find the, 1092.
Longitude at sea, to find the, by lunar observations, 1098.
Longitude, celestial, 1074.
Longitude, celestial, measured from Aries, 1074.
Longitude, celestial, measured on the ecliptic, 1074.
Longitude, celestial, reckoned to 360°, 1074.
Longitude, definition of, 1049.
Longitude, effect on, by error in the lunar distance, 1104.
Longitude from lunar observations, examples of different methods of finding the, 1106—1111.
Longitude from lunar observations, to find the, 1104.
Longitude obtained by the distances of the planets, &c., 1111.
Longitude obtained by the eclipses, &c., of Jupiter's satellites, 1111.
Longitude, to find the, by a chronometer, 1097.
Loxodromic curve, nature of the, 1064.
Lunar distance, formula for clearing the, 1099.
Lunar distance, rule for clearing the, 1100.
Lunar distances, 1093.
Lunar distances, examples of clearing, 1103.
Lunar distances, how to observe by a sextant, 1114.
Lunar distances, logarithmic differences for, 1100.
Lunar distances, precautions to be taken in making, 1104.

Lunar distances, various methods of clearing, 1101.
Lunar observations, 1093.
Lunar observations, examples of obtaining the longitude at sea by, 1106, *et seq.*
Lunar observations, how to make, 1101.
Lunar observations, to find the longitude at sea by, 1098.

MAGNETIC amplitude and azimuth, 1090.
Magnetism induced in iron vessels, 1118.
Magnetism of iron vessels, 1118.
Magnetism, retentive, Scoresby's definition of, 1119.
Mantissa of a logarithm, 1037.
Maury's wind and current charts, 1068.
Mean time, 1075.
Mean time at Greenwich, to obtain at sea the, 1105.
Mediterranean, counter-currents of the, 1067.
Mercator's method, discovery of, 1062.
Mercator's sailing, 1060.
Mercator's sailing, examples in, 1062.
Mercator's sailing, theory of, 1061.
Meridian altitude of the sun, 1086.
Meridians, 1074.
Meridians of longitude, 1049.
Meridional difference of latitude, 1061.
Meridional parts, construction of tables of, 1064.
Meridional parts, definitions of, 1061.
Meridional parts, table of, 1062.
Middle latitude, construction of table for correcting, 1063.
Middle latitude sailing, 1057.
Middle latitude sailing, examples in, 1058.
Middle latitude sailing, rules for, 1058.
Middle latitude sailing, theory of, 1058.
Middle latitude, Workman's table of corrections for, 1060.
Moon's transit, table of times of the, and daily variation, 1081.
Multiplication by logarithms, 1037.

NADIR and zenith, 1074.
NAUTICAL ASTRONOMY, 1070.
Nautical instruments, 1111.
Nautical mile, length of the, 1050.
NAVIGATION, 1048.
Navigation, uses of the art of, 1035.

OBLIQUE-ANGLED triangles, solution of, 1043.
Oblique sailing, taking departures in, 1067.
Obliquity of the ecliptic, 1074.
Observations by the quadrant or sextant, how to make, 1113.
Observations, lunar, 1093.

PARALLAX, 1077.
Parallax, horizontal and in altitude, 1077.
Parallel sailing, 1056.
Parallel sailing, examples in, 1057.
Parallels of declination, 1074.
Parallels of latitude, 1049.
Passages shortened by Great Circle sailing, 1067.
Pendulum experiment, and falling bodies, 1073.
Pendulum experiment, Foucault's, 1072.
Pendulum experiment, mathematical principles of Foucault's, 1072.
Pendulum, the, and the earth's rotation, 1071.
Plane sailing, examples in, 1052.
Plane sailing, principles of, 1051.
Plane sailing, proportions in, 1052.
Points, equinoctial, 1074.
Points of the compass, 1051.
Poles of the earth, 1049.
Prime vertical, the, 1074.
Proportional logarithms and lunar distances, 1105.
Proportions in plane sailing, 1052.

QUADRANT, the, 1111.
Quadrant, use of the, 1113.

RATE of sailing, 1050.
Ratios, trigonometrical, 1038.
Reckoning, civil and astronomical, 1075.
Refraction of the heavenly bodies, 1076.
Rhumb-line, definition of the term, 1035, 1051.
Rhumb-line, the continued, 1064.
Right-angled triangles, solution of, 1039.
Right ascension, 1075.
Rotation of the earth, Foucault's experiment on the, 1071.
Rotation of the earth on an axis, 1049.
Rotation of the earth, proofs of the, 1070.
Rotation of the earth, time required for a, 1049.
Rotundity of the earth, how proved, 1070.

SAILING in currents, 1066.
Sailing, rate of, 1050.
Scoresby on the magnetism of iron vessels, 1118.
Secants, cosecants, &c., 1037.
Secondary circles to the horizon, equinoctial, and ecliptic, 1075.
Semi-diameter of the sun, moon, &c., 1076.
Set of a current, 1066.
Sextant, 1111.
Sextant, invention of the, 1115.
Sextant, use of the, 1113.
Ship's journal, how to keep the, 1115.
Sidereal time, 1075.
Signs of the zodiac, 1075.
Sines, cosines, &c., 1037.
Single courses, examples in, 1054.
Solar day, the, 1075.
Solution of oblique-angled triangles, 1043.
Solution of plane triangles, 1039.
Solution of right-angled triangles, 1039.

TABLE for correcting middle latitude, to construct a, 1063.
Table of difference of latitude and departure, 1068, 1069.
Table of meridional parts, construction of a, 1064.
Tables of sines, cosines, &c. (for the tables themselves, see p. 666, *et seq.*), 1038.
Tangents, cotangents, &c., 1037.
Tayleur, loss of the ship, owing to the derangement of her compasses, 1119.
Time, apparent, mean, sidereal, &c., 1075.
Time at sea, deduced from a single altitude, 1094.
Time at sea, examples of obtaining the, 1096.
Time at sea, to find, 1093.
Time deduced from a star, 1095.
Time deduced from equal altitudes, 1096.
Time deduced from the sun, 1094.
Time, local, to find, 1093.
Transit of the moon, table of, 1081.
Traverses by mid-latitude and Mercator, 1064.
Traverse-sailing, examples in, 1056.
Traverse-sailing, mid-latitude and Mercator, examples in, 1065.
Traverse-sailing, or compound courses, 1055.
Traverse-sailing tables, specimens of, 1117.
Traverse-table (see also pages 1068 and 1069), 1053.
Traverse, working or resolving a, 1055.
Triangle, solution of plane, 1039.
Triangles, examples in solving plane, 1047.
Triangles, oblique-angled, solution of, 1043.
Triangles, ratio of the sides and angles of plane, 1038.
Triangles, right-angled, solution of, 1039.
Trigonometrical ratios, 1038.
Trigonometrical terms explained, 1037.
Trigonometry, plane, use of in navigation, 1035.

USE of trigonometrical tables, 1038.

VARIATION of the compass, 1050, 1090.
Velocity of a current, 1066.
Vernier on the sextant, &c., how to use the, 1114.
Vernier, principles of the Vernier, 1114.
Vertical circles, 1074.
Vertical, the prime, 1074.

WORKMAN'S table for corrections of middle latitude sailing, 1060.

ZENITH and Nadir, 1074.
Zenith distance, 1074.
Zodiac, the, 1075.

SECTION XII.—METEOROLOGY.

ABSORPTION and radiation, gaseous, 1191.
Actinic force, Glaisher's observations on the, 1184.
Actinometer, the, 1164.
Aërolites, 1153.
Africans, their climate, habits, &c., 1204.
Agriculture and meteorology, 1186.
Ague, cause of, 1186.
Air, blue colour of moist, 1178.
Air, clearness of, at great elevations, 1184.
Air, mean pressure of dry, 1169.
Air, specific gravity of, 1129.
Air, weighing of, 1129.
Air, weight of a cubic foot of, 1169.
Air, weight of vapour in a cubic foot of, 1168.
Alps, elevation of the snow-line on the, 1193.
Altitude influences the climatic zone, 1199.
Altitudes, tables of, for the barometer, 1189.
Andes, elevation of the snow-line on the, 1193.
Anemometers, 1170.
Anemometers, various, 1164.
Aneroid and mercurial barometers, comparative readings of, during a balloon ascent, 1214.
Aneroid barometers, 1126.
Animals, acclimatisation of, 1201.
Animals and plants, their distribution in respect to climate, 1199.
Aqueous vapour, power of, in absorbing heat, 1192.
Aqueous vapour, specific gravity of, 1129.
Aqueous vapour, suspended in the air, 1183.
Ararat, elevation of the snow-line on Mount, 1193.
Ascents by Glaisher in the balloon, 1180, *et seq.*
Atmosphere, absorbing power of the, 1192.

Atmosphere, chemical constitution of the, 1120.
Atmosphere, density of, decreases with elevation, 1124.
Atmosphere, elasticity of the, 1128.
Atmosphere, height of the, 1123.
Atmosphere, limits of the, 1127.
Atmosphere over towns, 1183.
Atmosphere, weight of the, 1123.
Atmospheric currents, reverse, 1135.
Atmospheric disturbances, Fitzroy's views of, 1174.
Atmospheric moisture, 1138, 1198, 1210.
Atmospheric moisture, determination of, 1145.
Atmospheric moisture, diurnal variation of, 1147.
Atmospheric moisture, monthly variation of, 1147.
Atmospheric phenomena, 1134.
Atmospheric pressure, 1123.
Atmospheric refraction, 1147.
Aurora Borealis, cause and nature of the, 1150, 1185.
Aurora Borealis in Scotland, 1185.
Auroræ, height of, 1151, 1185.

BALLOON ascent, tables of the decrease of temperature during a, 1182, 1215.
Balloon ascent, table of the height of the barometer, height above the sea, temperature, and dew-point, during a, 1216.
Balloon ascents, Glaisher's, 1179, *et seq.*
Balloon ascents, results of Glaisher's, 1182, *et seq.*
Balloon ascents, value of, 1181.
Barometer affected by certain winds, 1174.
Barometer, difference-table of, for successive elevations, 1189.
Barometer, government standard, 1190.
Barometer, mean height of the, 1138.
Barometer, periodical variations of the, 1138.
Barometer, principles of the, 1123.
Barometer, table of the height of, during a balloon ascent, 1216.
Barometer, testing at Kew, 1190.
Barometer, variations of the, 1138.
Barometers, aneroid and mercurial, comparative readings of, during a balloon ascent, 1214.
Barometers, errors of, incorrect, 1159.
Barometers, manufacture of, 1125.
Barometers, marine, 1190.
Barometers, various forms of, 1124.
Barometers, Vernier scale for, 1125.
Barometric changes depending on certain winds, 1174.
Barometric column, causes of the variation of the, 1174.
Barometric column, surfaces of the, 1125.
Barometric corrections for altitudes, 1167.
Barometric corrections for capillarity, 1166.
Barometric corrections for diurnal range, 1166.
Barometric corrections for temperature, 1165.
Barometric determination of heights, precautions to be observed in making, 1188.
Barometric disturbauce, causes of, 1174.
Barometric observations, 1166.
Barometric reductions of readings, 1166.
Birds, their distribution, 1202.
Breezes, causes of land and sea, 1135.

CAPILLARITY, correction for, 1126.
Capillarity of glass tubes, 1125.
Capillarity, table of, for barometers, 1126.
Caribs, and their climate, 1204.
Carpathians, elevation of the snow-line on the, 1193.
Central heat of the earth, 1155.
Charts for weather-registration, 1189.
Chemistry of the atmosphere, 1120.
Chinese and their climate, habits, &c., 1203.
Cholera in connection with climate, &c., 1205.
Climate and scrofulous diseases, 1206.
Climate and the distribution of birds, 1202.
Climate as affecting the health of the navy, 1206.
Climate, influence of, controlled by other causes, 1204.
Climate, influence of, in respect to the distribution of plants and animals, 1199.
Climate, influence of, in respect to ethnology, 1202.
Climate influenced by islands, 1197.
Climate influenced by lakes, 1197.
Climate in relation to typhus and typhoid fevers, 1206.
Climate of America (North), 1196.
Climate of America (South), 1196.
Climate of Asia (Central), 1195.
Climate of Australia (South), 1195.
Climate of Borneo, 1197.
Climate of Brazil, 1196.
Climate of California, 1196.
Climate of Canada, 1196.
Climate of Ceylon, 1197.
Climate of China, 1195.
Climate of India, 1195.
Climate of Madagascar, 1197.
Climate of Mexico, 1196.
Climate of New Zealand, 1195.
Climate of Shanghae, 1195.
Climate of Sicily, 1197.
Climate of Sydney, 1195.
Climate of the Canaries, 1197.
Climate of the Crimea, 1193.
Climate of the Sahara, 1195.
Climate, rainfalls, mean temperature, &c., tables of, 1210—1214.
Climates, excessive, 1193.
Climatic effects of suspended moisture, 1192.
Climatic influences, 1155.
Climatic zones of altitude and latitude, 1199.
Cloud, estimate of the amount of, 1169.
Clouds and the weather, 1142.
Clouds, appearance of, as indicating weather, 1177.
Clouds, appearance of, described by Glaisher, 1182.
Clouds, classification of, 1169.
Clouds, composition, height, position, &c., of, 1142.
Clouds, names of the different kinds of, 1141.
Clouds, shape of, 1141.
Cold, effects of, 1158.
Cold winds, 1137.
Compressibility of gases, 1122.
Consumption and meteorology, 1206.
Corrections, barometric, 1165, 1166.
Corrections for temperature, 1165.
Crystals, shape of snow and frost, 1158.
Currents of air, polar and tropical, 1174.
Currents of the ocean, &c., 1157.
Cyanometer, the, 1165.
Cyclones, definition and direction of, 1136, 1175.
Cyclones, general causes of, 1175.
Cyclones, generation of, 1174.

DANIELL'S hygrometer, 1146.
Decrease of temperature during a balloon ascent, table of the, 1182, 1215.
Decrement of temperature at great elevations, 1182, *et seq.*
Dew, amount of, 1140.
Dew, conditions required to produce, 1139.
Dew dependent on radiation, 1139.
Dew, deposition of, 1139.
Dew, honey, 1140.
Dew, maximum fall of, in various countries, 1140.
Dew-point at great elevations, 1183.
Dew-point hygrometers, 1146.
Dew-point, mean temperature of the, 1168.
Dew-point, nature of the, 1146.
Dew-point, reduction of, from temperature, 1170.
Dew-point, table of, during a balloon ascent, 1216.
Dew, production of, 1138.
Dew, time of deposition of, 1140.
Differential thermometer, the, 1130.
Diffusion of gases, 1120.
Diseases and climate, 1154, 1205.
Diseases, epidemic and endemic, influenced by climate, 1205.
Diseases of seamen in respect to climate, 1206.
Distance-measurer, the, 1161.
Distribution of plants and animals in relation to climate, 1199.
Drainage improves climate, 1186.
Drainage, meteorological influence of, 1185.
Dysentery in the navy, 1207.

ELECTRIC phenomena, 1178.
Electric phenomena on the Jungfrau, 1178.
Electrical origin of lightning, 1152.
Electricity, atmospheric, nature of, 1173.
Electricity, free, causes and amount of, in the air, 1179.
Electricity, free, instances of, 1178.
Electricity, prevalence of free, 1179.
Electricity, to collect free, 1179.
Electricity, to detect free atmospheric, 1179.
Electro-magnetic thermometers, 1133.
Electrometers, 1163.
Elevation and temperature, 1182, *et seq.*
Elevation, differential tables of, for the barometer, 1189.
Endemic diseases and meteorology, 1205.
Epidemic diseases and meteorology, 1205.
Equator, elevation of the snow-line at the, 1193.
Esquimaux, and their climate, habits, &c., 1202.
Ethnology and meteorology, 1202.
Evaporation, to find mean daily amount of, 1170.
Evaporators, 1162.
Excessive ranges of temperature, 1193.
Expansion by heat, 1126.

FATA-MORGANA, cause of the, 1148.
Fire-balls, &c., origin of, 1154.
Fish, their distribution in respect to climate, 1200.
Fitzroy's forecasts of weather, 1172.
Fitzroy's opinions on aërial currents, 1174.
Fogs, 1140.
Fogs, dry, 1141.
Fogs, local, 1186.
Fogs, prevalence of, in certain countries, 1141.
Föhn, the (a kind of hot wind), 1137.
Forecasts, general principles of weather, 1173.
Forecasts of the weather, bases of, 1175, 1176.
Forecasts, useful charts for making, 1190.

GASEOUS radiation and absorption, 1191.
Gases, amount of the expansion by heat, 1127.
Gases, condensation of, 1122.
Gases, definition of the term, 1122.
Gases, diffusion of, 1120.

Gases expanded by heat, 1127.
Gases, expansion and compression of, 1122.
Gases, law as to the volume of, 1122.
Gases, Marriotte's law respecting, 1122.
Gases, physical properties of, 1122.
Gimbal vane, the, 1163.
Glaisher's balloon ascents, 1179, *et seq.*
Glaisher's winter ascent in January, 1861, 1209.
Gulf-stream, influence on climate of the, 1156, 1198.
Gulf-stream, limits of the, 1157.
Gulf-stream, temperature of the, 1157.
Gulf-stream, the, 1156.

Hail, production, fall, &c., of, 1145.
Hail-stones, fall of extraordinary, 1145.
Halo, causes of the, 1149.
Health affected by changes of weather, 1177.
Heat absorbed by aqueous vapour, 1192.
Heat, and the volume of bodies, 1126.
Heat, and the volume of gases, 1127.
Heat, conduction of, 1134.
Heat, convection of, 1134.
Heat, expansion by, 1126.
Heat, radiation of, 1134.
Heat, terrestrial, distribution of, 1194.
Heights, barometric determination of, 1188.
Heights, measurement of, by the barometer, 1124.
Heights, normal correction for determining by the barometer, 1188.
Heights, Plantamour's observations on the barometric determinations of, 1188.
Himalayas, snow-line on the, 1192.
Hoar-frost, cause of, 1140.
Honey-dew, 1140.
Hospitals, Dr. F. Watson's method of purifying the air admitted into, for India, 1208.
Hottentots, their climate, habits, &c., 1204.
Hot winds, 1136.
Humidity, to calculate the degree of, 1168.
Hurricanes, 1136.
Hygrometers, use and corrections of, 1164.
Hygrometers, various, 1146.
Hygrometric observations, reduction of, 1168.
Hygroscopes, 1146.

India, sanitary measures in relation to the climate of, 1207, 1208.
Indian Ocean, currents of the, 1157.
Instincts, animal, as foreboding weather, 1177.
Instrument-stands, 1160.
Islands, influence of, on climate, 1197.
Isothermal lines, 1194.
Isothermal lines, direction of, 1194.

Japanese, their climate, habits, &c., 1203.

Lakes, influence of, on climate, 1197.
Land-surfaces, effects of, on weather, 1177.
Laplanders and their climate, habits, &c., 1202.
Latitude influences the climatic zone, 1199.
Lightning, cause of, 1151.
Lightning-conductors, 1152.
Lightning-conductors, precautions respecting, 1153.
Local fogs, haze, &c., 1186.
Loricata, their distribution in respect to climate, 1200.
Luminous meteors, 1184.
Luminous meteors, height of, 1185.
Lunar rainbows, 1149.

Malaria, dangerous effects of, 1205.
Mammalia, their distribution in respect to climate, 1200.
Man, influence of a change of climate on the general character of, 1203.
Man, influence of climate on the varieties of, 1202.
Marine barometers, 1190.
Marriotte's law respecting gases, 1122.
Marshes, &c., meteorological influence of, 1185.
Maximum and minimum thermometers, 1162.
Mean temperature of the dew-point, 1168.
Mean temperature, reduction of the, 1167.
Mediterranean, currents of the, 1157.
Mercurial and aneroid barometers, comparative readings of, during a balloon ascent, 1214.
Meteoric stones, 1153.
Meteorological deductions, Fitzroy's, 1174.
Meteorological instruments, 1171.
Meteorological observations, 1159.
Meteorological phenomena to be observed, 1165.
Meteorology and agriculture, 1186.
Meteorology and endemic diseases, 1205.
Meteorology and epidemic diseases, 1205.
Meteorology and ethnology, 1202.
Meteorology, definition, &c., of, 1120.
Meteorology in its connection with other branches of science, 1209.
Meteorology, practical, 1159.
Mexicans, ancient, and their climate, 1204.
Mirage, cause of the, 1147.
Moisture, atmospheric, 1138.
Moisture, atmospheric, determination of, 1145.
Moisture, common effects of, in daily life, 1175.
Moisture, comparative, of various places, tables of, 1210—1214.
Moisture of air at great elevations, 1182, *et seq.*
Mollusca, their distribution in respect to climate, 1200.

Natural meteorological indications, 1171.
Negretti's thermometer, 1162.
Newfoundland fogs, cause of the, 1187.
North Cape, elevation of the snow-line at the, 1193.
Norway, elevation of the snow-line in, 1193.

Obliquity of the solar rays, 1191.
Observations, charts for meteorological, 1190.
Observations, general results of meteorological, 1191.
Observations, how to make meteorological, 1160.
Observations, precautions required for making, 1170.
Odessa, climate of, 1193.
Organic influence of climate, 1159.
Ozone, amount of, at great elevations, 1184.
Ozone, amount of free, 1187.
Ozone and epidemic diseases, 1187.
Ozone, detection of, 1122.
Ozone, effects of, on the health, 1187.
Ozone, extraordinary production of free, 1187.
Ozone, physiological effects of, 1122.
Ozone, preparation of, 1121.
Ozone, properties of, 1122.
Ozone, purifying powers of, 1122.
Ozone, smell and detection of free, 1188.
Ozone test-papers, 1122.
Ozone test-papers, to make, 1164.
Ozone, tests for the presence of, 1122.
Ozonometer, the, 1164.

Paraselenæ, cause of, 1150.
Parhelia, cause of, 1150.
Patagonians and their climate, 1204.
Petersburg, St., climate of, 1193.
Photographs taken at great elevations, 1184.
Phthisis, meteorological conditions favourable to, 1206.
Plants, acclimatisation of, 1201.
Plants and animals, their distribution in respect to climate, 1199.
Practical meteorology, 1159.
Predicting weather, rules for, 1176.
Pressure of the atmosphere, 1123.
Productions, natural, limits of, 1191.
Psychrometer, the, 1146.

Radiation and absorption, gaseous, 1191.
Radiation, solar, Glaisher's observations on, 1184.
Radiation, solar, to find amount of the, 1169.
Radiation, terrestrial, to find amount of the, 1169.
Rain-angle, the, 1164.
Rainbow, nature and cause of the, 1149.
Rain, cause and annual fall of, 1142.
Rain, distribution of, 1143.
Rain, to find the mean daily amount of, 1170.
Rain, with fall of fish, stones, &c., 1144.
Rainfall in Africa, 1194.
Rainfall in America (North), 1195.
Rainfall in America (South), 1194.
Rainfall in Asia, 1195.
Rainfall in Australia, 1195.
Rainfall in Europe, 1143, 1195.
Rainfall throughout the world, tables of the annual, 1210—1214.
Rain-gauges, 1143, 1163.
Rainless regions of the earth, 1143.
Rains, periodic, 1143.
Rain-water, contents of, 1144.
Rainy days, number of, in various places, 1143.
Recorder, the atmospheric, 1164.
Red Sea, currents of the, 1157.
Reduction of barometric readings, 1166.
Reduction of hygrometric observations, 1168.
Reduction of mean temperature, 1167.
Reduction of thermometric readings, 1167.
Reduction tables, hygrometric, 1165.
Refraction, atmospheric, 1147.
Registration of weather, charts for the, 1189.
Reptilia, their distribution in respect to climate, 1200.
Russia, climate of, 1193.

Scrofula and climate, 1206.
Shooting-stars, 1153, 1184.
Simoom, the, 1136.
Sirocco, the, 1137.
Snow, causes, crystals, &c., of, 1144.
Snow, coloured, 1145.
Snow-gauges, 1171.
Snow-level or line, 1192.
Snow-line, altitude in various places of the, 1192.
Snow-line, elevation of the, 1144, 1192.
Snow-line, tables of, for various places, 1193.
Snow, times and places of its fall, 1144.
Solano, the, 1137.
Solar eclipses, 1165.
Solar heat, absorption of, 1191.
Solar radiation at different levels, 1192.
Solar radiation, Glaisher's observations on, 1184.

Solar radiation, to find amount of the, 1169.
Spectrum at great elevations, 1184.
Spitzbergen, snow-line at, 1193.
Standard barometers, 1190.
Stands for instruments, 1160.
Storms, causes of, 1136.
Sun's rays, obliquity of the, 1191.
Suspended moisture, climatic effects of, 1192.

Tables of altitudes for the barometer, 1189.
Tables of the annual rainfall, mean annual temperature, extreme, and range of temperature, comparative moisture, latitude and longitude of the chief places throughout the world, with temperatures of the ocean, &c., 1210—1214.
Tables of the decrease of the temperature during a balloon ascent, 1215.
Tables of the elevation of the snow-line, 1193.
Tables of the height of the barometer, height above the sea, temperature, and dew-point during a balloon ascent, 1216.
Telegraph, use of, in meteorology, 1175.
Temperature at great elevations, law of, 1182, *et seq.*
Temperature, excessive ranges of, 1193.
Temperature, extraordinary low in England (in 1860), 1194.
Temperature, mean annual, range and extreme, tables of, throughout the world, 1210—1214.
Temperature, mean daily range of, 1169.
Temperature, monthly range of, 1169.
Temperature of the wet bulb, to find the, 1169.
Temperature, table of, during a balloon ascent, 1216.
Temperature, table of the decrease of, during a balloon ascent, 1215.
Temperatures, table of mean monthly, 1172.
Terrestrial heat, 1155.
Terrestrial radiation, to find amount of the, 1169.
Testing barometers, method adopted at Kew for, 1190.
Thermo-electric measurement of heat, 1133.
Thermometer, 1129.
Thermometer, air, 1130.
Thermometer, Breguet's, 1132.
Thermometer, centigrade, 1132.
Thermometer, electro-magnetic, 1133.
Thermometer, Fahrenheit's, 1132.
Thermometer, Reaumur's, 1132.
Thermometer-stands, 1161.
Thermometers, conversion of the scales of various, 1132.
Thermometers, discrepancies of, 1134.
Thermometers, graduation of, 1132.
Thermometers, manufacture of, 1131.
Thermometers, registering, 1132.
Thermometers, spirit, 1130.
Thermometers, various, 1130, 1162.
Thermometric observations, how to make, 1161.
Thermometric reductions, 1167.
Thermometric scales, 1130.
Thermoscope, Nobili's, 1132.
Thibet, elevation of the snow-line in, 1193.
Thibet, great elevation of, 1193.
Thunder-storms, prevalence of, 1153.
Tornadoes, 1136.
Trade-winds, causes of the, 1135.
Trade-winds, direction of the, 1135.
Trees, effects of, on suspended moisture, 1186.
Trees, their distribution in respect to climate, 1199.
Travadoes, 1136.
Tyndall's researches on gaseous radiation and absorption, 1191.
Typhoons, 1136.
Typhus fever and climate, 1206.

Vapour, weight of, in a cubic foot of air, 1168.
Vegetable productions, and climates, 1191.
Vernier-scale for barometers, 1125.
Volume increased by heat 1126.
Volumes of gases, 1122.

Water, maximum density of, 1158.
Water-spouts, 1137.
Weather, changes of, indicated by animals, 1177, 1178.
Weather, effects of, on the human system, 1177.
Weather-forecasts, rules for making, 1176.
Weather-glass, the barometer a, 1124.
Weather-registration, charts for, 1189.
Weight of the atmosphere, 1123.
Whirlwinds, 1137.
Will-o'-the-wisp, 1154.
Wind, effects of, on the barometer, 1174.
Wind influences the barometric column, 1138.
Wind, to estimate the force of, 1170.
Wind-vane, the, 1164.
Wind, velocity of, affects the barometer, 1174.
Winds, cold, 1137.
Winds, effects of various, on weather, 1176.
Winds, hot, 1136.
Winds, the prevalence of various, 1136.
Winds, the trade, 1134.
Winter balloon ascent, Glaisher's, 1209.

Yellow fever in the navy, 1207.

Zones, climatic, of altitude and latitude, 1199.
Zones, position of climatic zones, 1199.
